This literature, however, is far from complete, even at the adult level. Reliance on small sample sizes, failure to use noncriminal control groups, and use of a wide variety of types of offenders precludes the drawing of any firm conclusions. The very tentative suggestion is that the results of neuroimaging studies are consistent with results from performance tests of neuropsychological function. However, the two literatures are not integrated, and much future research is needed to explore these issues more fully.

Although it is difficult to demonstrate causality unequivocally in most areas of human behavior, studies of the relation between neuropsychological health and antisocial behavior suggest that neuropsychological deficits can be one cause of serious antisocial behavior. The evidence reviewed suggests that poorer neuropsychological health is associated with more severe antisocial behavior, with moderate effect sizes that survive frequent, conservative controls for other variables. Additionally, several observational studies suggest that poor neuropsychological health is present before the onset of serious antisocial behavior (e.g., Denno, 1989), although there is one published exception. Aguilar, Sroufe, Egeland, and Carlson (2000) found differences between childhood-onset and adolescent-onset offenders in late childhood but not early childhood; methodological problems including the small, nonrepresentative sample and psychometrically weak instruments may account for this

anomaly. Natural experiments in which individuals have sustained severe head injury also suggest that changes in neuropsychological status are associated with changes in antisocial status, with the case of Phineas Gage being the best known. Finally, several studies have tested and ruled out viable third variable explanations of the relation (e.g., Lynam et al., 1993).

### **Biological Factors**

To the degree that temperament, personality, and neuropsychological health are based in biology, the evidence reviewed above demonstrates that biological variables are consistently related to antisocial behavior. In the sections that follow, we examine the relations between more direct indicators of biological function and antisocial behavior. Specifically, we review evidence that links antisocial behavior to pre- and perinatal complications, early exposure to nicotine, neurotransmitter activity, sex hormones, and autonomic reactivity. As we show, each of these factors has been linked to antisocial behavior. Perhaps most interesting, across many studies, the effects of many of these biological variables are strongest under adverse environmental circumstances.

### ***Prenatal and Perinatal Complications***

Moffitt's (1993) theory of LCP antisocial behavior posits that prenatal and perinatal complications contribute to the neuropsychological problems that underlie this type of offending. These complications have been examined as predictors of antisocial behavior in multiple studies. At least 6 studies have found associations between minor physical anomalies (MPAs), presumed to be markers for fetal maldevelopment, and antisocial behavior in children (see Raine, 2002, for a review). Arsenault, Tremblay, Boulerice, Seguin, and Saucier (2000) found that MPAs assessed in a sample of 170 males at age 14 predicted violent delinquency at age 17. In several studies, MPAs have been found to interact with social factors to predict antisocial behavior. For example, Brennan, Mednick, and Raine (1997) found that men with both MPAs and high family adversity had the highest rates of adult offending in a sample of male offspring of psychiatrically ill parents. Pine, Coplan, et al. (1997) found that the presence of MPAs interacted with environmental disadvantage to predict CD at age 17.

There have also been a number of studies from large, longitudinal studies in multiple countries examining the

relation between birth complications and antisocial behavior. Almost all have found that the relations between birth complications and antisocial behavior are stronger when other psychosocial risk factors are present. In one of the most impressive demonstrations, Raine, Brennan, and Mednick (1994) found that birth complications and maternal rejection at age 1 interacted to predict violent offending at age 18 in a sample of over 4,200 men from Copenhagen. In the follow-up at age 34, the interaction between biological and social risk predicted early onset, serious violent behavior. These findings from Denmark have been replicated in 4 other countries. Piquero and Tibbett (1999), in the Philadelphia Collaborative Perinatal Project, found that the combination of prenatal/perinatal complications and family disadvantage was linked with adult violent offending. Similar results have been obtained in large samples from Sweden (Hodgins, Kratzer, & McNeil, 2001), Finland (Kempainen, Jokelainen, Jaervelin, Isohanni, & Raesaenen, 2001), and Canada (Arseneault, Tremblay, Boulerice, & Saucier, 2002).

#### *In Utero Exposure to Nicotine*

Several large, longitudinal studies in various countries have shown that maternal smoking during pregnancy places the offspring at increased risk for later antisocial behavior. For example, in the Christchurch Health and Development Study, a large, longitudinal study based in Christchurch, New Zealand, Fergusson, Woodward, and Horwood (1998) found that smoking during pregnancy almost doubled the risk for conduct problems in boys, even after controlling for antenatal and postnatal risk factors (see also, Wakschlag et al., 1997; Weissman, Warner, Wickramaratne, & Kandel, 1999). Relations between smoking during pregnancy and later adult offending have also been observed. Brennan, Grekin, and Mednick (1999) found a twofold increase in adult violent offending in the offspring of mothers who smoked in a birth cohort of over 4,000 men. Several studies have found that these relations hold even after controlling many potentially confounding variables, including socioeconomic status, maternal education, mother's age at first birth, family size, parenting behaviors, parental psychopathology, birth weight, and perinatal complications. One study found that the relation between heavy maternal smoking and CP at age 7 persisted even in the face of multiple, well-measured controls; using data from the E-risk study, Maughan, Taylor, Caspi, and

Moffitt (2004) found that after controlling for genetic influences, parental antisocial behavior and depression, and family disadvantage the effect of heavy maternal smoking on CP at age 7, but not age 5, remained significant. The models estimated by Maughan et al. are consistent with heavy maternal smoking playing a mediating role between the more distal risk factors and the outcome.

As with other biological variables, there is evidence that smoking during pregnancy interacts with social risks to increase the likelihood of antisocial behavior. Rasanen et al. (1999), using data from a large Finnish birth cohort, found an almost 12-fold increase in recidivistic violent offending through age 26 in offspring whose mothers smoked and who were born into single-parent families.

#### *Autonomic Nervous System Activity*

There is extensive evidence for the relation between low resting heart rate and antisocial behavior. In fact, Raine (2002) calls low resting heart rate "the best-replicated biological correlate of antisocial behavior in child and adolescent samples" (p. 418). The relation is present in cross-sectional studies (e.g., Rogeness, Cepeda, Macedo, Fischer, & Harris, 1990) and prospective studies (e.g., Farrington, 1997). Raine, Venables, and Mednick (1997) examined the relation between low resting heart rate at age 3 and antisocial behavior at age 11 in a sample of 1,795 male and female children from Mauritius. These authors found that early low resting heart rate predicted later aggressive behavior. Moreover, these results were the same across gender and ethnicity and held despite controls for various biological, psychological, and psychiatric mediators and confounds. Similar findings have been obtained in other large, prospective studies from England (Farrington, 1997), New Zealand (Moffitt & Caspi, 2001), and Canada (Kindlon et al., 1995). These findings hold after controlling for other variables including physique, exercise, socioeconomic status, motor activity, substance use, and psychosocial adversity. Farrington (1997), in the Cambridge Study in Delinquent Development, found that low resting heart rate and poor concentration were the only two risk factors, out of 48 examined, that were independently predictive of violence. Low resting heart rate does not appear to interact with social adversity to increase offending. To the contrary, a single study reports that low resting heart rate is related to antisocial behavior only in

children with nonadverse circumstances (Raine, Brennan, & Farrington, 1997).

### *Sex Hormones*

Theoretically, testosterone is a likely candidate as an important biological factor in antisocial behavior. The distribution of testosterone across the population and across development parallels what is known about the distribution of antisocial behavior. Testosterone and antisocial behavior are more concentrated in men than women, and its level increases dramatically across adolescence. In nonhuman animals, the relation between testosterone and aggression has been unequivocally demonstrated through correlational and experimental studies (Turner, 1994). Despite the theoretical appeal, the evidence suggests that testosterone has, at best, a relatively weak correlation with antisocial behavior in humans.

Archer (1991) conducted three meta-analyses, including only 5 to 6 studies each, and found a weak, positive correlation between testosterone and aggression. A more recent, larger, meta-analysis by Book, Starzyk, and Quinsey (2001) confirms Archer's initial results. These authors analyzed 45 independent studies that yielded 54 independent effect sizes. Their correlations ranged from  $-.28$  to  $.71$  with a weighted mean correlation of  $.14$ . In contrast to several qualitative reviews, these authors reported that the relation between testosterone and aggression was actually somewhat larger in younger, compared to older samples; this effect of age, however, held for males but not females. Book et al. reported weighted mean correlations of  $.21$ ,  $.18$ , and  $.10$  for participants aged 13 to 20, 21 to 35, and over 35, respectively. Interestingly, there was no difference in the effect size for testosterone across genders.

Not only is the relation between testosterone and aggression relatively weak, the direction of effect is not entirely clear. On one hand, a study by Finkelstein et al. (1997) in hypogonadal adolescents showed that changes in testosterone may instigate changes in aggression. These authors administered depo-testosterone to 35 adolescents in 3-month blocks alternating with placebo at 3 dose levels approximating early, middle, and late pubertal amounts. Results demonstrated significant hormonal effects on physically aggressive behaviors and impulses. On the other hand, there is evidence that dominance may increase testosterone. Archer (1988) reviewed animal studies relating to this question and concluded that dominance or success in conflict often

increases testosterone levels. Observational and experimental research in humans supports this conclusion as well. Schaal, Tremblay, Soussignan, and Susman (1996) examined the relations among testosterone, aggression, and social status in 13-year-old boys whose aggressive behavior and peer status had been assessed continuously for the previous 7 years. They found that testosterone was more closely linked to social dominance than to aggression. Those boys rated by newly acquainted peers as both tough and social leaders had the highest testosterone levels, even though they were not rated by everyday peers and teachers as being high on physical aggression. Boys rated as tough, but not leaders, had testosterone levels no greater than the nontough boys, even though the tough nonleaders were rated highest in physical aggression by peers and teachers. Boys who had been highly aggressive from ages 6 through 12 had lower testosterone levels at age 13 than boys who were consistently low on fighting in elementary school. Salvador, Simon, Suay, and Llorens (1987) studied male judo competitors and found that testosterone levels were positively related to success in competition. Gladue, Boechler, and McCaul (1989) found that winners in a reaction-time competition had elevated testosterone levels after the competition, but losers maintained their original levels. Similar results were obtained even when the contest simply involved coin-tossing (McCaul, Gladue, & Joppa, 1992).

One study has examined the interaction between testosterone and environmental context. Rowe, Maughan, Worthman, Costello, and Angold (2004) examined the relations among testosterone, peer deviance, antisocial behavior, and social dominance in a large sample of boys from the Great Smoky Mountains Study. These authors found that levels of testosterone were related to nonaggressive conduct problems, primarily among boys with deviant peers. Among boys with nondeviant peers, levels of testosterone were related to social dominance but not CP.

### *Neurotransmitters*

The most widely studied of the neurotransmitters in relation to aggression and antisocial behavior is serotonin. There is an extensive research literature, including both human and animal studies, indicating that the central serotonergic system is involved in the regulation of impulsive aggressive behavior (Herbert & Martinez, 2001). Decreased serotonergic functioning has been found

among adults with past histories of aggressive acts including violent offenses and suicide (see Asberg, 1994). Specifically, lower concentrations of cerebrospinal fluid (CSF) 5-HIAA, the major metabolite of serotonin, have been found among individuals with past histories of suicide attempts, in violent offenders, in individuals with personality disorders characterized by aggression, and in violent alcoholics (e.g., Tuinier, Verhoeven, & van Praag, 1995; Virkkunen, Eggert, Rawlings, & Linnoila, 1996). Other researchers have indexed platelet levels of monoamine oxidase (MAO), which is responsible for metabolizing both serotonin and dopamine. Although MAO activity is an indirect measure, results from studies using it are consistent with studies that have examined serotonin more directly. Low MAO activity in platelets has been shown to be associated with impulsivity, violent crime, and persistent criminality (e.g., Alm et al., 1994; Belfrage, Lidberg, & Orelund, 1992). In another noninvasive approach, Coccaro (1989) has shown that a blunted prolactin response to fenfluramine challenge, taken as an index of diminished serotonergic response, is associated with impulsive aggression. Some experimental research is also consistent with the idea that levels of serotonin are related to levels of aggression. Cleare and Bond (1995) depleted levels of tryptophan, a serotonin precursor, in a sample of normal male participants. These authors found that among those participants with preexisting aggressive traits, tryptophan depletion increased both subjective feelings and objective ratings of aggression.

In studies of children, however, results are more mixed. Kruesi, Swedo, Leonard, and Rubinow (1990) found, in a sample of children with disruptive behavior disorders, that lower levels of CSF 5-HIAA were related to higher ratings of aggressive behavior. Moreover, Kruesi et al. (1992) found that lower 5-HIAA levels were predictive of aggressive behaviors at a follow-up 2 years later. Other studies have found opposite results. Castellanos et al. (1994) found that CSF 5-HIAA was positively correlated with aggression in 29 boys with attention-deficit hyperactivity disorder (ADHD). Halperin et al. (1994) and Pine et al. (1997) both found that increased prolactin response to fenfluramine challenge, indicating increased serotonergic activity, was related to increased aggression.

One study examined the interaction between neurotransmitters and environments. Moffitt, Caspi, and Fawcett (1997) found that serotonergic activity interacted

with a history of family conflict to predict violence at age 21 in the males of the Dunedin study. The nature of the interaction was such that men with high levels of whole blood serotonin, and therefore low levels of serotonin in the brain, and history of psychosocial adversity were the most violent by both official and self-report.

### **Ecological Factors and Social Stressors**

As compelling as constitutional and biological factors are in leading to aggressive behavior, ecological factors play just as strong a role, and an even stronger role for certain indicators of aggression. The 600% increase in juvenile murder arrests between 1965 and 1994 (Blumstein, 2000) and wide variations across countries cannot be accounted for by enduring characteristics such as genes and traits. Ecological contexts surely play a major role in predicting individual differences in aggressive behavior as well.

### ***Culture, Laws, and Policies***

Cultural norms and public policies have enormous influence over community-wide rates of aggressive behaviors such as gun violence. Firearm homicide rates, including rates for children, are 12 to 16 times higher in the United States than in the average of 25 other industrialized countries, including Canada, simply because of differences in laws that allow gun ownership (U.S. Department of Health and Human Services, 1997). In the United States, children in the 5 states with the highest levels of gun ownership are 3 times more likely to die from firearm homicide as are children from the 5 states with the lowest levels of gun ownership (M. Miller, Azrael, & Hemenway, 2002). Gun ownership is a product of laws and cultural norms, but surely these factors cannot be dismissed as by-products of genetic or biological variations across states in this country (Wintemute, 2000). Nisbett and Cohen (1996) compiled population-level and laboratory evidence to argue that a "culture of honor" is responsible for consistently higher rates of violence in the American South than in other geographic regions.

### ***Community Factors***

The crowded inner city has long been highlighted as a setting for high rates of violence (Hammond & Yung, 1991). In a classic work, C. Shaw and McKay (1942) argued that the three community structural variables of

poverty, ethnic heterogeneity, and high residential mobility are associated with high violent crime rates that persist across time, even after the entire population in a community changes. Sampson, Raudenbush, and Earls (1997) used multilevel analyses of adolescents to find large variations in violent behaviors that are associated with structural characteristics across neighborhoods in Chicago. Census tract data document that neighborhood-level scores for the proportions of families characterized by poverty, unemployment, low education, single-parent households, high residential mobility, and low income represent significant risk factors for individual-level conduct problems (Beyers, Bates, Pettit, & Dodge, 2003).

A problem in interpretation of neighborhood and community effects concerns the likelihood of self-migration into neighborhoods by families of varying background characteristics. As Jencks and Mayer (1990) noted, "the most fundamental problem confronting anyone who wants to estimate neighborhoods' effects on children is distinguishing between neighborhood effects and family effects" (p. 119), known as the omitted variable bias or social selection. The problem of self-selection has been partially solved by quasi-experiments in housing afforded by government-assisted housing programs that assign families somewhat randomly into different neighborhoods. Votruba and Kling (2004) analyzed data from the Gautreaux Program in Chicago and found that mortality of African American male youth (mainly by violence) varied as a function of neighborhood characteristics related to human capital and work, such as unemployment rates and levels of education among the adults in the neighborhood.

Neighborhood effects go well beyond structural characteristics to social factors such as disorganization and control. These latter factors have been called collective efficacy by Sampson et al. (1997) and are indexed by levels of trust among neighbors, supportive social networks, and the degree to which neighbors "look out for one another." These factors partially mediate the effects of structural factors but also operate independently (Ingoldsby & Shaw, 2002).

#### ***Within-Family Ecological Factors***

Neighborhood factors influence a child's development at least partly through their effects on the family unit (McLoyd, 1990; Wilson, 1987), and the family social context exerts its own independent effect on antisocial development. The most important of these factors is low

socioeconomic status. Controlling for other community variables, poverty in the family is associated with higher rates of peer-directed aggressive behavior by children (Bradley & Corwyn, 2002), adolescents (Spencer, Dobbs, & Phillips, 1988), and adults (Sampson & Laub, 1994). The potential problem of selection bias into poverty limits confidence in the causal role that family poverty plays in child conduct problems. A recent study by Costello, Compton, Keeler, and Angold (2003) capitalized on the natural experiment afforded by a government policy enabling Native American families in western North Carolina to reap the financial benefits of a new casino in their community. Of the previously poor families, those that were suddenly thrust out of poverty (21.3% of all poor families) had children whose behavioral problem symptoms declined by 40%, whereas never-poor children in the same community displayed no change in symptoms across the same period. This finding might suggest a causal role of family wealth in alleviating these symptoms, although even this natural experiment has a caveat: not all families who received financial benefits were brought out of poverty. Almost 79% of poor families remained below the poverty level even after the casino brought them financial gains (either they squandered the resources or the resources were insufficient to have an enduring impact); their children's symptoms increased by 21% across the same time period. The full effect (combining ex-poor and always-poor families) of the introduction of the casino on child behavior problem symptoms was actually negligible.

McLoyd (1990) has examined the family mechanisms through which poverty might exert its impact. She found that poverty increases single African American parents' psychological distress and impairs their social support systems, which, in turn, diminishes their effectiveness and increases their coerciveness toward their children. These effects, in turn, may lead to child aggression. Consistent with this formulation, Guerra, Huesmann, Tolan, Van Acker, and Eron (1995) found that, among urban Chicagoans, poverty is correlated with stressful life events and a lack of parental involvement in religious support systems and that these two factors, in turn, account for the effect of poverty on peer-nominated aggression. Sampson and Laub (1994) reanalyzed the Glueck and Glueck (1950) longitudinal data set involving 1,000 Depression-era White families and found that the structural variable of family poverty influenced family processes of harsh discipline, low su-

pervision, and poor parent-child attachment, which, in turn, influenced juvenile delinquency. Family process accounted for two-thirds of the effect of poverty on delinquency. Likewise, Dodge, Pettit, and Bates (1994) found that harsh physical discipline by parents accounted for about half of the effect of low socioeconomic status on children's aggressive behavior.

A second major family context factor is marital conflict. Cummings and Davies (2002) accumulated laboratory and naturalistic evidence to determine that ambient conflict increases child aggression. Cummings, Goeke-Morey, and Papp (in press) used daily home diary reports to find that everyday marital conflicts increase children's aggressive behavior. Fergusson and Horwood (1998) found robust correlations between observing domestic violence and later antisocial behavior. The stress of child conduct problems can increase marital conflict, and so the issue of temporal ordering is crucial in understanding the role of this context factor in child behavior. Recent advances in multilevel modeling of developmental trajectories afford the opportunity to evaluate within-individual changes in a child's behavior as a function of an environmental event, reducing the likelihood that the environmental effects can be explained away as being due to correlation with static traits or to reverse causal processes. Malone et al. (2004) followed 356 boys and girls across 10 years, as some of their families experienced divorce, and found that for boys (especially younger boys) the experience of parental divorce increased their externalizing problems in the year of the divorce. Furthermore, these problems continued for several years following divorce. Finally, Jaffee, Moffitt, Caspi, Taylor, and Arseneault (2002) employed a twin research design to find that adult domestic violence accounted for 5% of the variance in child antisocial behavior, even when genetic factors are controlled.

Other early environmental conditions also increase children's aggression, including being born to a teenage (Morash & Rucker, 1989) or single (Blum, Boyle, & Offord, 1988) parent, being raised in a large family (Rutter, Tizard, & Whitmore, 1970), and being parented by convicted felons (Farrington, 1992). These factors are intercorrelated and likely share a common pathway through effects on parenting quality, although they may have more direct effects or may be linked to child aggression through common genes. Furthermore, these risk factors are apparently not merely redundant in their impact on the developing child; rather, their effects are cumulative (Rutter & Garmezy, 1983).

Alternatively, analyses by Bolger, Patterson, Thompson, and Kupersmidt (1995) indicate that the effects of economic hardship are more dramatic among children in the racial majority than among those who are already stressed by the circumstances of racial minority status. Being Black brings numerous social hardships in American society (Ogbu, 1990) and, with these hardships, relative risk for aggressive behavior. The effects of economic hardship, above and beyond the hardships already imposed by racial stratification, are muted for African American children (Bolger et al., 1995).

### *Non-Family Child Care*

The experience of early out-of-home group child care has been posited as a cause of child aggressive behavior (Belsky, 2001). However, families self-select into group child care for a variety of reasons, including attitudes about day care, availability, and ability to pay for other kinds of care (including a parent staying at home). The National Institute of Child Health and Human Development (NICHD) Early Child Care Research Network (2004) study of child care in the United States offers the most comprehensive opportunity to study these effects. Analyses of the 1,081 children in this sample, controlled for many potentially confounding variables, yielded a positive effect size of about one-fourth standard deviation of day care experience on aggressive behavior at age 4.5 years and kindergarten as rated by mothers, caregivers, and teachers. Borge, Rutter, Cote, and Tremblay (2004) analyzed data from the 15,579 families of the Canadian National Longitudinal Survey of Children and Youth to find that once selection factors were taken into account, children reared in homes by their mothers were actually *more* physically aggressive than children reared in group day care. Further analyses of the NICHD study sample by Love et al. (2003) and Votruba-Drzal, Coley, and Chase-Lansdale (2004) indicate that the effect of group day care depends on the quality of that care. Furthermore, the effect of group care must be interpreted in light of the alternative type of care that is available to a child—the quality of available home-rearing may differ across families such that group day care might offer a better *or* worse experience for a child than available alternatives.

### *A Case of Pervasive Environmental Influence: The Effects of Media Violence*

Perhaps no greater cultural influence on children's aggressive development can be found than the effects of

viewing violence on television. Meta-analyses (Wood, Wong, & Chachere, 1991) indicate that television violence-viewing accounts for about 10% of the variance in child aggression, which approximately equals the magnitude of effect of cigarette smoking on lung cancer.

Laboratory experiments demonstrate that viewing televised aggressive models results in aggressive behavior toward “Bobo” dolls (Bandura, Ross, & Ross, 1963) and peers (Björkqvist, 1985). Field studies repeatedly demonstrate significant correlations between television-violence viewing and aggressiveness, even when self-selection factors, such as parental supervision and socioeconomic status, are controlled. Eron, Huesmann, Lefkowitz, and Walder (1972) found that boys’ television-violence preferences at age 8 predicted aggressiveness at age 18. Follow-ups to age 30 showed that age 8 television violence predicted self-reported aggression and seriousness of criminal arrests, even when social class, intelligence, parenting, age 8 aggression, and age 30 TV violence viewing all were controlled statistically (Huesmann, 1986). Huesmann and Eron (1986) replicated these findings in urban Israel, Poland, and the United States but not in Australia and an Israeli kibbutz. More recently, Huesmann, Moise-Titus, Podolski, and Eron (2003) followed 450 6- to 10-year-old Chicagoan boys and girls for 15 years and found that childhood exposure to television violence predicted a composite adult aggression score that included self-ratings, ratings by others, and crime records, even when early parenting, parent aggression, and socioeconomic status were controlled.

A major moderator of this effect is age of the viewer: the effects hold more strongly for children than for adults (Huesmann & Miller, 1994), perhaps because the effects act more strongly on the individual’s development of a repertoire than on the accessing of responses already in one’s repertoire. Also, the effects of viewing television violence are greater if the child believes that the violence is real, perhaps because perceived reality increases salience and the encoding of scripts, and if the child identifies with the violent TV character—believes that the character is like the self (Huesmann, Lagerpetz, & Eron, 1984). The family context in which TV violence is viewed is another qualifier, in that children who watch violence without parental supervision and in home contexts in which harsh discipline is utilized are subject to greater influence by TV violence (Singer & Singer, 1981).

Perhaps even more threatening than passive viewing of television violence is the active experience of playing violent video games. C. Anderson (2004) has reviewed the growing laboratory and longitudinal evidence to conclude that chronic experience playing video games that require and reward the shooting of victims on a computer screen increases children’s future aggressive behavior, through many of the same psychological mechanisms that hold for viewing television violence.

### **Processes in Early Family Socialization**

There is ample evidence of differences in discipline and parenting practices between families of aggressive children and nonproblem children. Much of the early research on this point was cross-sectional, however, and there has long been recognition of the difficulty in separating cause and effect in these relations (Bell & Harper, 1977). K. Anderson, Lytton, and Romney (1986) demonstrated that parents of normal children will resort to more punitive discipline practices when confronted with conduct-disordered boys than when they manage their own sons. Despite these problems of interpretation, longitudinal, behavior-genetic, and intervention studies show convincingly the causal role of early family socialization.

### ***Mother-Infant Attachment Relationships***

The results of longitudinal studies on infant attachment and conduct problems in childhood are mixed. Bates et al. (1991) failed to establish insecure attachment as a predictor of externalizing problems in a predominantly middle-class, two-parent sample followed from infancy into elementary school. The same held for a similar study by Fagot and Kavanagh (1990) and a longitudinal investigation by Lewis, Feiring, McGuffog, and Jaskir (1984). Alternatively, Renken, Egeland, Marvinney, Mangelsdorf, and Sroufe (1989) have repeatedly found insecure attachments to predict childhood behavior problems in a sample from low-income and predominantly single-parent households. Lyons-Ruth found that disorganized attachment status predicted hostile behavior to peers at age 5 (Lyons-Ruth, Alpern, & Repacholi, 1993) and teacher-rated externalizing problems at age 7 (Lyons-Ruth, Easterbrooks, & Davidson, 1995). Finally, D. Shaw et al. (1995) found that insecure attachment, particularly disorganized attachment, predicted CBCL aggression

scores at age 5. This latter sample was predominantly lower income, having been recruited from a federally funded nutritional support program for mothers, infants, and children. Greenberg, Spelz, and Deklyen (1993) have argued that secure attachment is a protective factor for infants of low-income, highly stressed mothers but is less crucial to antisocial development in middle-class families. Dishion and Bullock (2002) proposed a general "nurturance hypothesis," whereby parents' positive attention, emotional investment, and behavioral management combine in ways that protect otherwise high-risk children from becoming aggressive.

Support for the interaction between parent-infant warmth and a biological factor comes from Raine, Brennan, and Mednick (1997), who found that Danish males with a history of birth complications and early rejection by the mother (unwanted pregnancy, attempt to abort fetus, and public institutional care of the infant) were at high risk for violent crime by age 19. Of children who had both risk factors, 47% became violent, compared to 20% of those who had just one factor. Thus, the strength of the mother-child bond protected children from later violence, but only for high biological-risk children.

### *Parental Warmth and Proactive Teaching*

Closely related to the attachment construct is the concept of maternal warmth. Bates and Bayles (1988) found maternal affection to be negatively related to externalizing problems in both boys and girls at ages 5 and 6, and Booth, Rose-Krasnor, McKinnon, and Rubin (1994) found maternal warmth at age 4 negatively related to externalizing problems at age 8. As with many other parenting factors, the problem of selection bias and alternate causal paths calls into question whether parental lack of warmth causes child conduct problems or the reverse. Caspi et al. (2004) used a monozygotic twin study that controls for genetic differences to find that maternal expressed emotion (i.e., verbal statements of negative affect about a child) predicted children's antisocial behavior problems. Deater-Deckard (2000) used identical and fraternal twin pairs to reach the same conclusion.

One social-learning explanation for the role of parental warmth is that for a parent to be effective in socializing a child to parental behavior standards, the parent must be seen by the child as a potential source of reward, which occurs through the exchange of warmth. Eisenberg (Eisenberg, Cumberland, et al., 2001; Eisen-

berg, Pidada, & Liew, 2001) found support for a second possible mechanism, that parental negative emotion expression directly interferes with the child's normal development of self-regulation and regulation of emotion, which, in turn, mediate the child's development of externalizing problems (Eisenberg et al., 2003). Cole, Teti, and Zahn-Waxler (2003) found that maternal negative expressed emotion directly observed in laboratory tasks operates through dyadic exchanges with their preschool boys, leading to conduct problems. Zhou et al. (2002) found support for yet another pathway, that parental warmth leads to the child's development of empathy, which is known to protect a child from aggressive behavior.

Pettit, Bates, and Dodge (1997) have introduced the concept of proactive teaching by parents to indicate their positive attempts to teach their child appropriate behavior to prevent later discipline or conduct problems. They found that this construct is orthogonal to warmth and independently predicts child conduct problems.

### *Family Coercion and Inconsistent Discipline*

In their classic longitudinal study of delinquency, Glueck and Glueck (1950) reported that parents of boys who became delinquent were less consistent in their discipline practices than parents of matched control boys who did not become delinquent. In an experimental follow-up of this hypothesis, Parke and Deur (1972) demonstrated that children are less inhibited from behaving aggressively when an adult is inconsistent in administering punishment. The same point has been made about inconsistency between adults when one adult enforces a standard, but the other does not (Sawin & Parke, 1979).

Patterson (Reid, Patterson, & Snyder, 2000) has offered a theory of coercive social learning that goes well beyond inconsistency in parenting as a core feature of antisocial development. According to this functionalist perspective, children who begin to display antisocial behaviors, such as aggression and disruptiveness, in the early school years have been inadvertently trained in the effectiveness of these behaviors by parents. Snyder, Reid, and Patterson (2003) describe coercion training as a four-step process that begins with the aversive intrusion of a family member into the child's activities (e.g., a mother may scold her child for not going to bed). In the second step, the child counterattacks (e.g., by whining, yelling, and complaining that he or she is being picked

as the only one being made to go to bed). The third step is the crucial one, for it involves the negative reinforcement that increases the likelihood of future aversive responding by the child: The adult stops her scolding and her demands for compliance. The fourth step is reinforcement of the mother's giving in to the child. When the mother ceases her demands, the child stops the counterattack. According to this theory, it is the conditional probabilities in this sequence that distinguish the early parenting patterns of antisocial children from those of normal children. Observational data from clinical samples (Patterson et al., 1992) indicate that a child's aversive responses to the mother's intrusions in the second step occur two to three times more often in distressed families than in normal families. The success of these child counterattacks is reflected in observations documenting that mothers of aggressive boys more frequently reinforce negatively their sons' aversive responses than do mothers of nonaggressive boys (Snyder & Patterson, 1995). Conversely, mothers of nonaggressive boys more often reinforce the prosocial responses (e.g., talking or positive nonverbal communication) of their sons than do the mothers of aggressive boys. The net result is that children in normal families can be successful with their parents in two ways (aversive and nonaversive behavior), whereas the aggressive boys succeed only with aversive behavior. Furthermore, the coercion training process is a reciprocal family dynamic.

### *Physical Punishment and Punitiveness*

The role of physical punishment in promoting or reducing children's aggressive and antisocial behavior has long been a matter of dispute among professionals and laypersons (Straus, 2005). The practice of spanking children is almost ubiquitous in American culture: 94% of parents of 3- and 4-year-olds use spanking as a discipline technique (Straus & Stewart, 1999). Gershoff's (2002) meta-analysis has revealed a consistent correlation between corporal punishment and child aggressive behavior, although the interpretation of that correlation is still in doubt (Benjet & Kazdin, 2003). Longitudinal investigations have consistently supported the relation between early punishment and later antisocial behavior. Data from the 411 London males of the Cambridge Longitudinal Study (Farrington & Hawkins, 1991) point to harsh discipline practices at age 8 as an important predictor of the early onset of delinquency. McCord's (1991) analyses of the Cambridge-Somerville Youth

Study indicated that fathers' use of physical punishment predicted their sons' adult criminal records, even when paternal criminality was controlled.

Although robust, this correlation is moderated by other factors such as the quality of the parent-child relationship and the degree of parent-child warmth (Campbell, 1990). The adverse effects of physical punishment seem to hold only when punishment is administered in the absence of warmth and caring guidance. Deater-Deckard and Dodge (1997) reported that harsh physical discipline was positively correlated with later externalizing problems only among the subset of children who scored below the median in parent-child warmth. Thus, a warm parent-child relationship might buffer a child from deleterious effects of physical punishment.

The cultural context of parenting also moderates the impact of physical punishment. Deater-Deckard, Dodge, Bates, and Pettit (1996) found that physical punishment was positively correlated with later child aggressive behavior among European American families, in which this discipline style occurred relatively rarely. Among African American families, corporal punishment was more common (and normative) and was not correlated with child aggressive outcomes. This finding has been replicated by Lansford et al. (2004), who extended it to other measures of parenting (e.g., including direct observations, responses to hypothetical vignettes, rating scales, and clinical judgments) and later periods in a child's life. The authors hypothesized that it is not physical punishment per se that is responsible for child outcomes. Rather, it is the message that the child receives during the discipline event. Among European American families in which harsh discipline is nonnormative, for a child who receives harsh discipline, the message may be that the parent is rejecting the child. Among African American families, for whom corporal punishment is normative and "good" parenting, the message may be that the parent cares about the child's development. These different messages yield different outcomes, even though the parenting behavior superficially appears the same.

Disentangling the effects of parenting from the behavior of the child that might lead to corporal punishment is yet another problem. P. Cohen and Brook (1995) used cross-lagged analyses of longitudinal data to conclude that physical punishment more strongly predicts growth in conduct problems than the reverse. Stronger evidence regarding the causal role of harsh parenting

comes from intervention experiments. Hinshaw et al. (2000) randomly assigned families of children with ADHD to behavioral or medical treatments. The behavioral treatment taught parents to engage in less negative/ineffective discipline strategies. They found that this treatment led to fewer disruptive behavior problems and measures of negative discipline at the end of treatment mediated the effect of assignment to treatment on those outcomes.

### ***Abusive Parenting***

The distinction between the use of physical punishment and physically abusive parenting is not simply one of degree. With abuse comes out-of-control, emotionally volatile, and nonnormative actions by a caregiver, which appear to have devastating effects on at least some children. Numerous studies have identified the experience of physical abuse as one of the most important parenting factors in antisocial development. Luntz and Widom (1994) found long-term effects of child abuse on antisocial behavior in a 20-year follow-up of children who had been reported as abused or neglected prior to age 11. Compared with control children matched for age, race, sex, and family socioeconomic status, the abused sample had twice the probability of being diagnosed as having an adult antisocial personality disorder. One of the problems with studies using children who have been identified as abused by child protective services (CPS) is that the experience of abuse is confounded with the actions taken by CPS, including being removed from the home, publicly labeled as abused, and aggregated with deviant children in foster and group-home settings. Dodge, Bates, and Pettit (1990) assessed physical maltreatment in a community sample of preschool children through extended clinical interviews and then followed this sample across childhood. They found short-term effects of maltreatment on aggressive behavior in kindergarten and long-term effects through late adolescence that included school suspensions and physical violence (Lansford et al., 2002).

Given the possibilities that children with particular characteristics might elicit abuse and that common genetic characteristics between parents and child might account for the correlation between abusive parenting and child aggression, Jaffee, Caspi, Moffitt, and Taylor (2004b) studied 1,116 twin pairs in Great Britain and found that physical maltreatment plays a strong causal role in the development of children's antisocial behavior.

At ages 5 and 7, mothers' and teachers' scores on the Child Behavior Checklist were .8 standard deviations higher for abused than nonabused children, controlling for genetic and other factors. Furthermore, Jaffee et al. (2004) found evidence for genetically mediated child effects on corporal punishment, but not on physical maltreatment, suggesting that effects of maltreatment cannot be attributed to genes or child effects.

As research on the effects of child abuse has expanded, it has become important to distinguish among several forms of maltreatment (Cicchetti, 1989). Physical abuse has clear effects on subsequent child aggressive behavior, whereas sexual abuse and neglect have different negative consequences. Fagot, Hagan, Youngblade, and Potter (1989) found important early childhood effects in the observed social behavior of preschool children (ages 3 to 5) who had been sexually abused or were victims of physical abuse and neglect. The physically abused children were more aggressive, less communicative, and more passive than either sexually abused or control children, whereas the sexually abused children were simply more quiet and unresponsive to peers. The physically abused children were more apt to respond to conflicts with aggressive behavior than other children. Sternberg et al. (1993) contrasted 8- to 12-year-old children who had been physically abused by parents in the previous 6 months with others who had witnessed spousal violence but not been abused themselves, or had witnessed violence and been abused. Data on abuse and violence for this Israeli sample came from social workers and the outcome data involved self-reports or mothers' ratings of internalizing or externalizing problems. All 3 vulnerable groups showed more self-reported depression than a demographically matched control group, but only the 2 groups that had been physically abused reported more externalizing problems. Mothers, however, reported more externalizing problems in the two groups who had witnessed domestic violence.

The effects of physical abuse, neglect, and sexual abuse also were contrasted in a summer camp study of 235 children 5- to 11-years-old that included a nonmaltreated matched control group (Manley, Cicchetti, & Barnett, 1994). The subgroups differed on counselor ratings of social competence and behavior problems, but did not differ on peer ratings of disruptiveness or aggressiveness. The sexually abused group was rated by counselors as more socially competent and having fewer

behavior problems than the physically abused or the neglected groups, and even somewhat more competent than the nonmaltreated group. The physically abused group had more behavior problems than the nonmaltreated group, with the other two maltreated groups falling between these extreme groups.

### Childhood Peer Factors

The peer social context exerts yet another influence on the child's behavioral development. Kellam and Rebok (1992) have found that kindergarten classrooms naturally vary in the incidence of peer-nominated aggression (e.g., in one school, classrooms ranged from 33% to 85% in the proportion of children rated as aggressive), even when assignment to classrooms is random. Clearly, unidentified factors in the ecology of the classroom context account for these differences in aggressive behavior problems. In turn, the ratio of peers who are aggressive influences a child's growing tendency to become aggressive and to value aggression (Stormshak et al., 1999), and these influences last across several years of elementary school (Kellam, Ling, Merisca, Brown, & Jalongo, 1998).

When young aggressive children enter school, they are likely not only to fail academically but also socially, and these two kinds of failure can interact to accelerate the growth of aggressive behavior. There is substantial evidence that aggressive children are likely to be rejected by their peers (Kupersmidt & Dodge, 2004). Although most of the studies have been correlational, making it difficult to determine whether aggression leads to rejection or rejection to aggression, several laboratory play-group studies demonstrate that early aggression leads to later rejection among new, unfamiliar peers.

Coie and Kupersmidt (1983) assembled groups of previously unacquainted fourth grade boys of known sociometric status, one of whom was rejected, and observed them at play for 6 weekly sessions. By the 3rd week, most of the rejected boys were rejected by their new group mates. Verbal and physical aggression were most characteristic of the rejected boys, and in ratings after the last session, there was consensus among group members that the rejected boys most often started fights. In a second study, Dodge (1983) formed groups of 8 previously unacquainted second grade boys who were not selected for social status and observed them for eight sessions. Boys who were observed to make hostile comments and hit other boys most often in initial ses-

sions were likely to be rejected by their new peers in sociometric nominations by the fourth session of play. In a third study, Dodge, Coie, Pettit, and Price (1990) observed groups of 5 or 6 unfamiliar boys at two grade levels (first and third) for five consecutive play sessions. Negative peer status determined at the end of the sessions was associated with both angry reactive aggression and instrumental aggression. Bullying led to disliking only in the third grade groups, suggesting that bullying becomes socially unacceptable by this age.

Three qualifying points need to be made about the relation between childhood aggression and rejection by peers. First, not all aggressive acts are viewed with disapproval by peers. Aggression in response to direct provocation actually is evaluated positively by peers. Children who are seen as standing up for themselves are generally well-liked (Lancelotta & Vaughn, 1989). Second, not all aggressive children are socially rejected by peers. In fact, only about half of the children named by classmates as being highly aggressive are rejected by them. Leadership and other social skills may enable some aggressive children to avoid being rejected (Kupersmidt & Dodge, 2004). Bierman (1986) found differences in the social behavior of rejected versus nonrejected aggressive boys that account for the different evaluations by peers. For example, Bierman, Smoot, and Aumiller (1993) found that boys rated by peers as both aggressive and rejected were more argumentative, more disruptive, and less socially attentive than boys who were aggressive but not rejected.

Finally, the normativeness and cultural context of aggressive behavior moderate the relation between rejection and aggression. Lancelotta and Vaughn (1989) found the correlation between aggression and peer rejection to be much stronger among girls ( $r = .73$ ) than among boys ( $r = .37$ ). The fact that aggression is generally more normative for boys than girls suggests that deviation from norms is likely to result in rejection. Social contextual norms play a significant role in the factors leading to peer rejection. Wright, Giammarino, and Parad (1986) demonstrated the importance of social context in a study of groups of cabin mates in a summer program for behaviorally disturbed boys. Counselor-reported aggression was negatively correlated with peer status in the groups characterized by low levels of aggression, but aggression was uncorrelated with status in the high-aggression groups. Cillessen and Mayeux (2004) followed 905 children from ages 10 to 14, a period when aggressive behavior grows in normativeness.

They found that aggression was increasingly less disliked as children got older, consistent with the hypothesis that when children behave in accordance with group norms they are not disliked.

Findings consistent with a general person-group similarity model positing that deviancy is rejected only if different from group norms have been found in playgroups by Boivin, Dodge, and Coie (1995) and in classrooms by Stormshak et al. (1999). This model also partially explains the developmental differences in the correlation between aggression and popularity: as aggression becomes more normative in early adolescence, its association with social rejection dissipates. The effectiveness and status of bullies also varies with the cultural context in which bullying occurs. Kim, Koh, and Leventhal (2004) found high (40%) prevalence rates for bullying in a sample of 1,756 Korean middle school students and a positive correlation between bullying and high socioeconomic status. In that context, bullying is common among the successful upper class.

### ***Consequences of Peer Rejection***

The reason for giving special attention to the peer status consequences of aggressive behavior is that peer rejection appears to contribute to subsequent problems of adaptation, including increased antisocial behavior (Haselager et al., 2002). Ladd (1990) found that rejection by peers in the fall of the kindergarten year predicted declining academic adjustment across the school year. Dodge et al. (2003) found that rejection increases aggressive behavior, especially among children who are aggressive initially. They found that peer rejection in early school years (grades K, 1, and 2) predicted increased aggressive behavior in third grade, even when previous aggression was controlled statistically. Similar findings have been reported by Patterson and Bank (1989), Kupersmidt and Coie (1990), Bierman and Wargo (1995), and Coie (2004).

### **Adolescent Family Processes**

Just as early parenting practices contribute to peer relations problems that exacerbate antisocial behavior during the elementary school years, so, too, parents of adolescents are influenced by their aggressive children but also reciprocally contribute to growth in antisocial behavior during adolescence. Two aspects of parenting appear to be critical to controlling child antisocial activity in early adolescence: discipline practices and

parental monitoring. Larzelere and Patterson (1990) used structural equation modeling to find that the linkage between family socioeconomic status, as measured when the boys were in fourth grade, and delinquency, measured in seventh grade from police records and self-report, is mediated by parent management practices measured in sixth grade. Parental management included discipline practices such as consistency, control of parental anger during discipline, and negativity in interactions reflecting aversive comments over trivial incidents, and parental monitoring of the child's activities and associations.

Monitoring is a critical aspect of parenting during adolescence (Dishion & McMahon, 1998). Parental monitoring is particularly important in preventing adolescent involvement with deviant peers. Snyder, Dishion, and Patterson (1986) reported strong path relations between low levels of parental monitoring and increases in deviant peer associations in tenth grade. In their study of 169 adolescent boys living in small, midwestern towns, Simons, Wu, Conger, and Lorenz (1994) found that problems in parental discipline practices (including poor monitoring, harsh discipline, lack of consistency, and ill-defined standards) in seventh grade predicted increased deviant peer associations and police arrests and sanctions in ninth grade.

Not surprisingly, parental monitoring is more important in some circumstances and with some children than others. Pettit, Bates, Dodge, and Meece (1999) found that the positive effects of parental monitoring on keeping antisocial behavior in check were stronger for families living in dangerous neighborhoods than in safe neighborhoods and for children with previous histories of aggressive behavior than nonaggressive children. Thus, youth who are at lower risk do not need, or benefit from, close monitoring as much as high-risk youth. This difference helps explain why parents of low-risk youth (and legislators who fund programs) are sometimes unable to grasp the importance of parent-training and supervised after-school programs for high-risk youth.

Although it is easy to warn parents about the importance of monitoring their adolescents, several studies have demonstrated that it is difficult to monitor certain youth, especially high-risk antisocial youth who begin to engage in covert activities and learn to hide their deviance from their parents (Crouter & Head, 2002). Furthermore, parent-child conflict is extremely stressful for all parties involved, and monitoring can heighten conflict when the parent confronts the youth with evidence

of misbehavior. Not surprisingly, early conduct problems lead to *lower* levels of parental monitoring in adolescence (Stattin & Kerr, 2000). Stattin and Kerr (2000) suggested that monitoring is more a consequence than a cause of child antisocial behavior, but other studies have shown that it increases adolescent delinquency beyond the levels that led to poor monitoring (Laird, Pettit, Bates, & Dodge, 2003). Overall, levels of parental monitoring decrease across adolescence, as parents recognize adolescents' desires for greater autonomy and growing maturity to act responsibly on their own (Laird et al., 2003).

Dishion, Nelson, and Bullock (2004) have provided important observational evidence regarding the pattern of parental disengagement with aggressive boys. They videorecorded families of aggressive and nonaggressive boys during interaction tasks in the laboratory and detected patterns of disengagement by parents of aggressive boys. These patterns predicted growth in associations with deviant peers and delinquent outcomes. Ironically and unfortunately, it is the very families for which monitoring and engagement should be increased that it decreases most rapidly, signaling the growing gap between parent and aggressive youth as antisocial behavior becomes more serious.

The constructs of parental monitoring and engagement turn out to include several distinct parenting patterns, each of which has been related to growth in antisocial behavior. Crouter and Head (2002) distinguished between parental monitoring, which involves surveillance of child activities and whereabouts, and knowledge of one's child, which involves seeking information from teachers and the child. Low levels of both constructs have been correlated with past and future child antisocial behavior. These constructs, and discipline practices, are distinguished from a third construct, psychological control, which involves parents' coercive attempts to use guilt and manipulation to control a youth's whereabouts and activities (Barber, 1996). Pettit, Laird, Bates, Dodge, and Criss (2001) found that psychological control strategies grow out of a parent's relationship with a difficult child but, in turn, exacerbate antisocial development and estrangement between the parent and child. Finally, Shumow and Lomax (2002), in a way that is consistent with Baumrind's (1987) construct of authoritative parenting, have suggested that all of these parenting practices are mediated and organized by a parent's sense of efficacy in parenting, and it is the communication of this sense of efficacy that leads to positive outcomes for the child.

Following from Hirschi's (1969) social control theory of antisocial behavior in which a close bond between parent and adolescent is thought to function as a control on antisocial activity, Hawkins and Lishner (1987) reviewed studies that supported the hypothesis that positive parent-child bonding in adolescence is negatively related to adolescent problem behavior. Dishion, French, and Patterson (1995) have challenged the bonding hypothesis on the grounds that these studies fail to control for previous problem-behavior levels and confound bonding with measures of parental monitoring. They cited a multiagent and multimethod measurement study that indicates that there is considerable overlap among these measures of parenting practices. Thus, they argued that parent-child bonding is an outcome of previous conflicts and does not cause future problems; in contrast, parental failure to monitor a child directly increases associations with deviant peers and antisocial behavior.

An important validation of the causal role of parenting practices on adolescent antisocial activity comes from interventions designed to change these practices and reduce antisocial activity. Patterson, Chamberlain, and Reid (1982) evaluated the effects of parent training that used the coercion model as a basis for altering parent behavior and found significant reductions in observed deviant behavior compared with those youth randomly assigned to community practitioners. In a stronger test of the model, Dishion, Patterson and Kavanagh (1991) randomly assigned parents of preadolescents at risk for substance abuse to training in contingency management techniques and found significant reductions in teacher ratings of antisocial behavior compared with youth whose families were assigned to placebo control conditions. Of greatest significance for the validation of the causal role of parenting to antisocial behavior was the fact that improvements in behavior correlated significantly, controlling for baseline behavior, with improvements in observed discipline practices.

### Adolescent Peer Processes

Whereas in earlier years when the major influence that peers had on antisocial development was to include or exclude a child from social acceptance, during adolescence the chief peer effect comes from the influence of particular kinds of peer groups. Bagwell, Coie, Terry, and Lochman (2000) have developed a method to identify peer cliques based on a consensus of group members and have found that in preadolescence children organize themselves into different peer cliques that have

distinctive features. Aggressive behavior is the primary factor associated with being a central member of deviant peer cliques. Deviant peer cliques offer both a home to attract like-minded antisocial youth (called homophily) and an opportunity to expand the range and severity of antisocial behaviors. The question of social selection versus social influence again looms as a methodological challenge, but current evidence supports both effects. The deviant peer group both assembles antisocial youth and contributes to their antisocial growth. Furthermore, evidence has begun to accumulate that systematic efforts to intervene with antisocial adolescents, which often involve aggregating deviant youth for group interventions, may have iatrogenic effects. This section is organized around the topics of deviant peer group effects, gangs, mechanisms of peer influence in adolescence, and iatrogenic effects of interventions.

### ***Deviant Peer Influences***

As noted above, parenting practices in early adolescence can contribute to the disengagement between parent and youth that contributes to gravitation toward deviant friends and peer groups. Undoubtedly, normal developmental processes of autonomy-seeking during this era also contribute to the tendency to seek highly sensational stimuli and to gravitate toward deviant peers. Highly visible antisocial peers come to be viewed positively by a large segment of the adolescent population. Rodkin et al. (2000) identified a subgroup of popular adolescents who are aggressive, cool, and athletic. Cillessen and Mayeux (2004) have documented a general developmental trend for children to move from censuring aggressive peers during elementary school to giving those peers high social status in early adolescence. They also note that this trend is moderated by gender, ethnicity, and the ethnic mix of the peer group, so that the features of popular adolescents depend heavily on the idiosyncratic culture of the peer setting.

In turn, deviant peers come to influence other adolescents in a deviant direction, especially when those peers are central to one's peer clique or have stable friendships with a child. Berndt, Hawkins, and Jiao (1999) found that children who had a stable friendship with a deviant peer were at increased risk for growing in their own deviant behavior as they made the transition from elementary to junior high school. D. Elliott, Huizinga, and Ageton (1985) suggested that the modeling and reinforcement required to produce stronger and more diverse antisocial behavior does not usually come from the family but resides in the deviant peer context. Their longitu-

dinal data on delinquency and substance use from the NYS point to the incremental predictive role of involvement with deviant peers. In support of this conclusion, Patterson, Reid, et al. (1992) found that involvement with deviant peers in grade six predicted subsequent delinquency even controlling for prior antisocial behavior. The deviant peer association construct in this study was formed from parent, peer, and self descriptions of children who "hang around" with peers who get into trouble. Simons et al. (1994) also found that association with deviant peers predicted subsequent arrests.

Keenan, Loeber, Zhang, Stouthamer-Loeber, and van Kammen (1995) examined the effects of deviant peer associations on the onset of disruptive behaviors in two cohorts of the Pittsburgh Youth Study. The onset of delinquency was assessed at 6-month intervals for five successive waves in data collection beginning in fourth grade for one cohort, or in seventh grade for the other. Authority conflict was twice as likely to occur among those disruptive boys who had truant or disobedient best friends as among those who did not, and the odds ratios for the correlation with covert and overt antisocial behavior were 4.3 and 3.4, respectively. The odds ratios for association with deviant peers on predicting disruptive behavior in the following year were 2.2 and 1.9 for covert and overt antisocial behaviors, respectively. Two important features of this study were the fact that onset was the dependent variable, thus controlling for previous disruptive behavior, and that peer influence was tested in a specific type of antisocial activity as a way of examining the extent to which peers truly were models of deviant behavior.

In a contrasting study, Tremblay, Mâsse, Vitaro, and Dobkin (1995) failed to find peer influence on delinquency in a longitudinal study of preadolescents. Mutual best friends were identified for 758 of the 1,034 French-Canadian boys aged 10 to 12. Self-reported overt and covert delinquency assessed 1 year later were predicted by the participants' earlier peer-rated aggressiveness, but the peer-rated aggressiveness of the best friends did not add to the prediction of either covert or overt delinquency. The delinquency of peers in this study was estimated by aggressive reputation and peer influence was restricted to a single best friend rather than a group of friends; however, it is possible that peer influence may be greater at older ages than those studied here. In a follow-up analysis of the same sample, Vitaro et al. (1999) divided the boys according to teacher ratings of their disruptiveness at ages 11 to 12. When the impact of having aggressive-disruptive friends was analyzed by the

boys' prior history of conduct problems, Vitaro et al. (1999) found that it was the moderately disruptive boys whose delinquent activity at age 13 showed the negative consequences of deviant friends' influence, in contrast to highly disruptive or socially conforming boys. Thus, it may be the marginally deviant youth who are most susceptible to the influence of deviant peers and are damaged most by placement in highly deviant peer settings (Caprara & Zimbardo, 1996).

One limitation in these studies is that direct measures of group affiliation were not used. A problem with relying on adult or peer estimates of deviant peer influence is that these indices are highly correlated ( $r = .89$ ) with ratings of the target individual's own aggressive behavior (Bagwell et al., 2000), making it difficult to partial out the influence of the target's aggression from estimates of deviant peer influence. Cairns and his associates utilized a more complex approach that was less susceptible to stereotyping on the basis of reputation. They used peer informants to identify the peer clique structure for a school-based peer cohort and then used behavioral characteristics of clique members as an index of clique deviance. Using this approach, they demonstrated that aggressive youth not only tend to associate with other aggressive youth (Cairns, Cairns, Neckerman, Gest, & Garipey, 1988) but that deviant peer associations influence dropping out of school (Cairns, Cairns, & Neckerman, 1989).

The relation between association with other deviant youth and delinquent activity is well-established in the literature on gangs. Thornberry, Krohn, Lizotte, and Chard-Wierschem (1993) found that gang members accelerated their illegal activity during the time they were associated with their gang and decelerated this activity when they left the gang and were not enmeshed in the gang environment.

Taken together, these findings suggest two important conclusions about deviant peer associations and antisocial behavior. Friendship activities between antisocial youth serve to promote greater deviant behavior, even though, or perhaps because, the interaction quality of the relationship is abrasive. Second, when youth are in a period of antisocial activity, they tend to associate with other antisocial youth, a phenomenon that Kandel (1978) referred to as homophily (like seeking like), but when they are no longer engaged in antisocial activity, they no longer associate with deviant peers.

Although the term homophily suggests a mutual attraction between antisocial adolescents, the quality of

interactions among aggressive youth suggests both positive friendship features like those of nondeviant friends and aversive qualities that are lacking in the relationship of nondeviant friends. In comparing delinquent and non-delinquent 12- to 19-year-olds, Giordano, Cernkovich, and Pugh (1986) found more self-reported conflict between delinquent friends but also more willingness to confide and equivalent amounts of interaction. Gillmore, Hawkins, Day, and Catalano (1992) interviewed preadolescent youth about their friends and nonfriends and found that those who described themselves as frequently getting into trouble were more attached to their conventional friends than to their friends who also get into trouble. These sentiments about friendship mirror Dishion, Patterson, and Griesler's (1994) conclusion that many antisocial friendships are relationships of convenience and not necessarily the preferred choices of these youth. Many of the chronically antisocial youth in the Oregon Youth Study Sample (Dishion et al., 1994) were rejected at age 10 and age 14, and their friendships were of relatively short duration. Thus, part of the dynamics of peer associations for highly antisocial youth may be that they have limited conventional friendship opportunities. Hawkins and Weis (1985) have argued that delinquency often results from a lack of social bonding to the conventional elements of society. The absence of these bonds leads to a lessened influence of conventional rules for behavior, and this contributes to greater antisocial activity.

The reciprocal influence of deviant peer associations and delinquent activity is illustrated in longitudinal findings from the Rochester Youth Developmental Study. Thornberry, Krohn, Lizotte, and Chard-Wierschem (1993) found that associating with deviant peers leads to increased delinquency, partly through the formation and reinforcement of beliefs that it is not wrong to commit delinquent acts. Across time, adolescents who commit delinquent acts are more likely to associate with peers who are also delinquent. Their analyses suggested that bidirectional relationships are necessary to account for longitudinal changes in delinquency, supporting the idea that a dynamic social developmental process is involved.

### *Delinquent Gangs*

The phenomenon of delinquent gangs, particularly in the United States, is an important contemporary manifestation of deviant peer groups (Klein, in press). As Thornberry, Krohn, Lizotte, Smith, and Tobin (2003) have noted, gangs have changed across the past 50 years, as

have explanations for their existence, one of the most salient changes being the increased involvement with illegal drug sales. Spengel, Ross, Curry, and Chance (1989, as cited in Goldstein, 1994) have found gangs in all 50 states, with most police and other informants indicating that gang participation and activity were on the increase. Males outnumbered females in gang membership by 20 to 1 and gang crime rates by gender mirrored this ratio. The age range of gang members appear to have extended in both directions across time. Goldstein concluded that the reasons youths join gangs are: "peer friendship, pride, identity development, self esteem enhancement, excitement, the acquisition of resources, and in response to family and community tradition. These goals are often not available to young people through legitimate means in the disorganized and low-income environments from which most gang youth derive" (p. 261).

Even though adolescents join gangs for identity and friendship, one effect of gang involvement, like involvement with deviant peers in general, is increased antisocial activity. Spengel et al. (1989) found that individuals in a gang are 3 times more likely to engage in violent offenses than are those persons not affiliated with a gang. Again, issues of selection bias threaten one's confidence in the conclusion of a causal role for gang membership. However, Thornberry et al. (1993, 2003) used longitudinal analyses to show that becoming involved in a gang increases an adolescent's likelihood of violently offending and that leaving a gang leads to decreases in the likelihood of violently offending. Even more convincingly, Gordon et al. (2004) used fixed-effects models that control for selection to conclude that both selection and socialization effects of gang membership occur among the 858 participants in the 10-year longitudinal Pittsburgh Youth Study.

### ***Mechanisms of Deviant Peer Influence***

Since Buehler, Patterson, and Furniss (1966) found that adolescent inmates in a correctional facility tended to reinforce delinquent behaviors and punish behaviors conforming to mainstream social norms, Dishion has examined the interactions of antisocial youth and their friends to understand processes of deviant peer influence. As part of the 13- to 14-year-old assessment of the Oregon Youth Study, friends of the study participants (named by both the boys and their parents) were invited to participate in a peer interaction task (Dishion, Andrews, & Crosby, 1995). Friends of the more antisocial

boys tended to come from the same neighborhood and to provide less satisfying friendships, suggesting that these were friendships of convenience. The behaviors of friends were highly correlated, with antisocial dyads having more negative qualities and more noxious behavior. When highly antisocial dyads (i.e., both had prior police contact and high antisocial ratings) were compared to low antisocial dyads, the high antisocial dyads contingently reciprocated more negative behavior.

In another report of the same set of friendship interaction data, Dishion et al. (1994) found that antisocial dyads engaged in more delinquent talk would tend to reinforce delinquent behavior, than low antisocial dyads. In this latter paper, longitudinal data on antisocial activity and deviant peer associations at ages 10 and 14 suggested a synchrony between the two variables.

Dishion (in press) has proposed a general ecological model of the mechanisms of deviant peer influence that locates the adolescent in a deviant peer group, which, in turn, is located in the larger community. This model posits mechanisms at all levels, beginning with intrapersonal effects of association with deviant peers on cognitive processes by the self and the observing world. Labeling oneself (and of one by others) that comes from mere proximity to a group that is characterized by aggressive behavior may yield self-fulfilling prophecies. Bernberg (2002) found that official processing in juvenile courts systems has adverse effects on subsequent criminal offending once controlling for prior offending, which he attributed to the labeling that comes from the official record. Once the stereotype of a "deviant type" has been established, cognitive processes of stereotype threat (Steele, Spencer, & Aronson, 2002) may operate to disrupt a deviant adolescent's behavior during critical situations, thereby exacerbating deviant behavior. Kaplan and Liu (1994) suggested that self-derogation and helplessness occur when an adolescent is labeled by the mainstream world as a member of a deviant group and that participating in further deviant behavior (in their empirical analyses, drug use and dropping out) restores self-esteem and control.

At the interpersonal level, modeling and positive reinforcement of deviant verbal statements during conversations (called deviancy training) occur in deviant peer groups, leading to increased deviant statements by a youth and serving to mediate the link between early antisocial behavior and young adult problem behavior and adjustment problems (Patterson, Dishion, and Yoerger, 2000). A dynamical systems process has been

observed by Granic and Dishion (2002), in which, once ignited, nonlinear acceleration of deviant talk occurs during peer conversations and sometimes leads to a frenzy of deviant statements. Dishion (in press) suggests that, "what is rewarded is not the behavior but the overall set of values, attitudes, and behaviors that accompany a delinquent lifestyle." A contagion effect results, in which deviant behavior proliferates.

Evidence for more specific social learning from deviant peers comes from analyses by Bayer, Pintoff, and Pozen (2004), who analyzed data from 15,000 juveniles serving sentences in 169 Florida correctional facilities. They used facility fixed effects to find that access to peers in prison who have histories of specific crimes (e.g., burglary, felony drug, or weapon-related) leads to facilitation of later crimes of that very same type. These effects are strongest for adolescents who have had initial experience with that type of crime (suggesting a facilitation effect rather than initial exposure effect) and who are exposed to older adolescents than younger adolescents. These findings suggest that deviancy training extends beyond verbal talk to serious crimes, through processes of social learning.

### *Iatrogenic Effects of Deviant Peer Aggregation*

Growing evidence indicates that peer effects on adolescent antisocial behavior occur not only in naturally formed peer groups but also in groups that are formed by government and interventionists. The frightening possibility that well-intentioned interventions can have harmful iatrogenic effects was proposed by Dishion, McCord, and Poulin (1999), with support from the domains of mental health, education, and juvenile justice. In all of these domains, deviant adolescents are routinely aggregated with each other for intervention purposes (e.g., through tracking and special education placement in education, group therapies and group residential homes in mental health, and incarceration and group placements such as boot camps in corrections). These effects provide strong evidence of deviant peer influences because self-selection biases are eliminated through institutional placements.

In mental health, Dishion and Andrews (1995) randomly assigned 119 high-risk boys and girls to one of four treatment conditions: (1) parent focus only, (2) peer focus only, (3) combined parent and peer focus, and (4) control. Analyses revealed adverse effects for peer-focused interventions at both the 1-year and 3-year follow-up. Specifically, subjects in the peer-focus condition showed increases in tobacco use and teacher reports of

delinquent behavior. Feldman, Caplinger, and Wodarski (1983) assigned youth randomly to one of three treatment groups: one composed exclusively of referred deviant youth, one involving nonreferred youth only, and one involving a mix of referred-deviant and nonreferred youth. Deviant children assigned to all-deviant groups had more adverse outcomes than those assigned to mixed groups. Lavalley, Bierman, Nix, and Conduct Problems Prevention Research Group (2005) found that, although random assignment to social skill training groups led to improvements in aggressive behavior overall, the magnitude of this improvement was moderated by characteristics of the peers with whom a child was aggregated. Children assigned to groups with higher levels of peer aggressive behavior improved less.

In education, both tracking children based on academic achievement (Kerckhoff, 1988) and assignment to classrooms with deviant peers for special education (Peetsma, Vergeer, Roeleveld, & Karsten, 2001) are associated with growth in antisocial behavior, including school crimes. Arum and Beattie (1999) found that high school suspensions, which typically involve temporary placement with other suspended students, are associated with a 200% increase in the likelihood of adult incarceration, even after controlling for related risk factors such as family characteristics, socioeconomic status, prior delinquency, and years of education.

In corrections, randomized experiments with juvenile delinquents have demonstrated that assignment to prison visitation and exposure to more deviant inmates (e.g., the "Scared Straight" Program) leads to harmful effects that include later crimes (Petrosino, Turpin-Petrosino, & Finckenauer, 2000). In the most comprehensive meta-analysis to date, Lipsey (in press) examined 396 intervention studies, contrasting group-aggregation versus individually based programs for juvenile delinquency. Studies of prevention programs that intervene with youth in groups show a general pattern of main effects on subsequent offense rates that average about one-third smaller than those of comparable programs that intervene with juveniles individually. Analysis of interactions showed that this effect is concentrated in programs that work with younger juveniles (e.g., age 15 and under) and those that work with lower risk juveniles.

### **COGNITIVE-EMOTIONAL PROCESSES AS MEDIATORS**

A large body of evidence from laboratory, longitudinal, and intervention-experiment studies has accumulated to

support the hypotheses that (a) cognitive-emotional processes contribute to antisocial behavioral responding in specific situations, (b) individual differences in cognitive-emotional processes account for a significant proportion of chronic individual differences in aggressive behavior, and (c) cognitive-emotional processes at least partially mediate the effects of socialization on aggressive behavior outcomes. These processes include a variety of constructs from online processing of current social stimuli to latent knowledge structures in memory. This review begins with a discussion of social-situational factors that proximally influence cognitive-emotional processes and then moves to a review of social information processing, followed by a discussion of latent mental structures that guide processing.

### **Social-Situational Factors That Alter Cognitive-Emotional Processes**

Several kinds of situations instigate aggressive behavioral responses through their impact on various aspects of social information processing. These situations are reviewed next.

#### ***Factors That Enhance the Attribution of Threat***

One of the most consistent findings from laboratory studies is that provocation leads to retaliatory aggression, even in young children (Ferguson & Rule, 1988). Frustration and goal-blocking have long been known to induce anger under both experimental and natural conditions (Berkowitz, 1962). Studies over the past 3 decades have indicated that the *perception* of provocation is far more important than the provocation itself in instigating aggression (Dodge, Murphy, & Buchsbaum, 1984). If a child who is pushed from behind in line at school or who receives an excessively severe punishment from a teacher interprets such an environmental threat as malevolently intended and foreseeable, that child is likely to retaliate aggressively (Dodge et al., 2003). Even kindergarten children can refrain from aggressing when they make a nonmalevolent interpretation of a negative event (Shantz & Voydanoff, 1973). Environmental factors that facilitate a hostile attribution include information about the provocateur as acting consistently negatively over time, distinctively negatively toward the perceiver, and others consensually interpreting the provocateur's actions similarly (Kelley, 1973). Inferences of hostile intent are more likely when the provocateur continues to harm the perceiver despite feedback or

threats of punishment, exerts special effort to cause the harm, or seems happy when causing the harm (Rule & Ferguson, 1986). Children also learn when to attribute hostile intent and make moral judgments of a provocateur through socialization (Rule & Ferguson, 1986). Berkowitz (1993) suggested that environmental conditions leading to pervasive negative affect (such as high temperatures, unpleasant living conditions, and foul odors) will also increase the likelihood of anger responses to current threats, even when the unpleasant environmental condition is unrelated to the current threat. He argues that the conscious ascription of blame to the provocateur is not as essential as the experience of displeasure during the time that the stimulus is presented.

It is only a short inferential leap to suggest that attributions of hostile intent and experiences of anger in response to current provocative stimuli become more likely when a child is growing up under circumstances of pervasive violence, harm, and deprivation, such as when others regularly assault the child, when assaults regularly occur toward the child's family, peers, and ethnic group, and when peer groups and family also interpret provocateurs as being hostile. Longitudinal evidence is consistent with this hypothesis. Dodge, Price, Bachorowski, & Newman (1990) found that a history of physical maltreatment in the first 5 years of life leads to hostile attributional biases during elementary school. Dodge et al. (2003) found that chronic peer social rejection during early elementary school years leads to hostile attributional biases during later elementary school. Aber, Gershoff, Ware, and Kotler (2004) found that witnessing family violence around the time of the September 11th disaster predicted children's tendencies to display hostile attributional biases a year later. Cassidy, Kirsh, Scolton, and Parke (1996) found that an early history of insecure attachment to one's mother and the experience of parental rejection were both antecedents of the tendency to display hostile attributional biases during elementary school. Finally, MacBrayer, Milich, and Hundley (2003) found that modeling of hostile attributional biases by mothers is correlated with a child's own tendency to attribute hostility to others.

#### ***Factors That Increase the Accessibility of Aggressive Responses***

A second mechanism leading to aggressive responding is the accessing of aggressive responses from memory during interpersonal exchanges. Bandura's classic studies (1973, 1983) indicate that "children can acquire entire repertoires of novel aggressive behavior from observing

aggressive models and can retain such response patterns over extended periods" (Bandura, 1983, p. 6). Imitation is an evolved characteristic that is present even among neonates (Meltzoff & Moore, 1977). Aggressive models can be observed in a child's family members, community subculture, or mass media. Social learning theory (Bandura, 1983) articulates four processes by which modeling can activate aggressive behavior: (1) directive functions, through which an aggressive response enters a child's repertoire because of the positive consequences for aggressing that are vicariously taught; (2) disinhibitory functions, in which modeled aggression reduces fear of negative consequences; (3) emotional arousal, in which the aggressive model facilitates aggression by arousing observers; and (4) stimulus-enhancing effects, in which the objects used in aggression receive heightened attention and provide instruction for the aggressive use of these objects.

Aggressive models teach more than just specific behaviors. They teach general strategies for acting; when observers synthesize modeled behaviors into patterns that follow regularized sequences, those patterns form *scripts* that are laid down in memory (Huesmann, 1998). Information about the category of aggression, its elicitors, and its consequences constitutes aggressive *schemas* (Shank & Abelson, 1977), which guide attention and interpretation to future stimuli and can therefore enrich scripts for action. Through observation and experience, children develop an understanding of aggression that includes expectations for what produces aggression, how aggression is performed, elements of an aggression category (including emotions and actions), and the likely consequences of this behavior (Rule & Ferguson, 1986). Once having acquired an aggression script, when a child encounters difficult situations, that script governs expectations and prescribes behavioral strategies. Strongly developed scripts, acquired through observational learning, can lead to aggressive responding.

Huesmann (1988) suggested that aggression scripts are developed through active attention to aggressive models. Aggressive behaviors can be acquired through repeated exposure to multiple stimulating aggressive acts in diverse contexts displayed by models who are both heroes and identification figures for the observer, followed by opportunities to practice aggressing with impunity so that complex scripts for aggressing become part of a child's memorial repertoire for extraction in future situations. Living with a violent family or in a

neighborhood in which the heroes are violent, interacting with antisocial peers who present repeated chances to act aggressively, and watching TV violence all represent opportunities to learn aggressive scripts.

### *Priming of Aggressive Constructs*

The extraction of aggressive scripts and specific aggressive responses from memory can occur either through active problem solving (Rubin & Krasnor, 1986) or non-conscious priming. Graham and Hudley (1994) demonstrated that "priming" the perception that others' negative actions are intentional can lead to hostile attributional biases, which, in turn, have been related to aggressive behavioral responses.

Berkowitz (1993) suggested that certain stimuli induce an associative network of internal responses that he calls "the anger/aggression syndrome," which include physiological reactions, motor tendencies, feelings, thoughts, and memories. Wyer and Srull (1989) have suggested that these responses are activated through an association in memory between a stimulus and one aspect of the response, which then spreads the activation to the entire syndrome through secondary associations. Priming effects are short-lived but powerful and automatic (Bargh, Chaiken, Raymond, & Hymes, 1995). Wann and Branscombe (1990), for example, found that experimentally giving students the names of aggressive persons in sports increased the likelihood that the student would subsequently attribute hostile intent to an ambiguous target person.

Many factors influence the probability that a particular stimulus will prime aggressive responses. Aggressive script responses that are laid down in memory with great frequency, drama, and recency are likely to be at the top of the "storage bin" and primed (Wyer & Srull, 1989); scripts that have multiple complex associations in memory are likely to be easily and chronically accessible (Bargh & Thein, 1985) because many stimuli can instigate associations to the script. Thus, growing up in an environment in which violence is normative will increase the accessibility of aggressive constructs in future situations. Certain persons who are nonreflective about their own behavior or are in impaired pathological states (Bargh, 1989) are "ripe" for priming effects. Stressful environments may render children vulnerable to aggressive priming. Finally, situational cues that are self-relevant (Strauman & Higgins, 1987), not overly engrossing, but are aggression-related (such as easy access to weapons; Goldstein, 1994) or semantically re-

lated to one's ideographic aggressive schema (Carver, Ganellan, Froming, & Chambers, 1983), are likely to have priming effects.

### ***Factors That Dysregulate Emotion Control***

Lemerise and Arsenio (2000) suggested that a variety of emotion-related processes mediate aggressive behavior. Although they integrate these processes with a more general social information-processing framework, they argue that the dysregulation of emotion plays a special role that differs from other cognitive processes. They cite studies that relate child aggression to the child's ability to regulate emotion, to understand others' emotion, and to express emotion accurately. The work of Eisenberg et al. (2003, 2004) buttresses the role of emotion-regulatory processes in mediating the development of antisocial behavior. Other studies indicate that these processes develop through experience and account for the relation between life experiences and later behavior; for example, Cummings and Davies (2002) have argued that emotion dysregulation is the process that mediates the relation between witnessing marital conflict and child aggression.

### ***Factors That Enhance the Attractiveness of Aggression***

Assessing aggressive behavior from memory is only partly a function of its salience and priming potential; it is also a function of the salience and accessibility of alternatives to aggression, enhanced by modeling. Furthermore, social learning theory stipulates that environments induce aggression by promoting the belief that aggression is normative, morally appropriate, and will lead to desired positive consequences (through reinforcement). According to Bandura (1983), "(In) societies that provide extensive training in aggression, attach prestige to it, and make its use functional, people spend a great deal of time threatening, fighting, maiming, and killing each other" (p. 11).

Bandura (1983) hypothesized that reinforcement can take the form of tangible rewards, social and status rewards, reduction of aversive treatment, and expressions of injury by the victim. Patterson, Littman, and Bricker (1967) found that children who were victimized by peers and who occasionally succeeded in stopping those attacks through counteraggression became more likely to fight in the future; in contrast, those children who avoided peers and thus avoided victimization did not become aggressive over time. Just as powerful as direct reinforcement is the observation of other persons being

reinforced for aggressing. In this case, the person learns through vicarious means that aggression leads to desired consequences. Neuroimaging studies have revealed that the "positive consequences" of aggressing could also be entirely intrapersonal—through activation of the dorsal striatum region of the brain (de Quervain et al., 2004). In other words, no external reward is necessary to reinforce reactive aggressive behaviors, which instead may be reinforced merely by brain activation that is experienced as the intrinsic pleasure experienced in revenge.

### **Social Information Processing**

Social information-processing models of aggressive behavior were initially developed to describe at a proximal level how cognitive and emotional processes lead a child to engage in aggressive behavior in a social event (e.g., Dodge, 1986; McFall, 1982). The conceptual grounding for these models is work in cognitive science on how individuals store and retrieve information (Tulving & Thomson, 1973), distribute processing in parallel and hierarchical fashion (Rumelhart & McClelland, 1986), and ultimately solve problems (Newell & Simon, 1972).

According to current formulations (Dodge & Pettit, 2003; Gifford-Smith & Rabiner, 2004), an individual comes to a social situation with a set of neural pathways that have been honed over time through genetic and experiential factors and a history of social experiences that are represented in memory. The individual is presented with a new set of social cues (e.g., peers gently tease a boy on the playground about his ugly shoes) and responds behaviorally as a function of how he or she processes those cues, which, in turn, is a function of the interaction among biological, memorial, and current-cue factors. Because processing occurs in real time, it can have both conscious and unconscious (and controlled and automatic) components (Rabiner, Lenhart, & Lochman, 1990). As Piaget (1965; Cowan, 1979) noted, processing is a fully emotional, as well as cognitive, phenomenon.

The first step of processing is encoding of the cues. Because the cue array is so overwhelming, the individual employs heuristics to encode only relevant portions. Both deficits (e.g., failure to encode mitigating cues) and biases (e.g., selective attention to hostile features of others' behavior) in encoding could lead an individual to respond aggressively; different biases (e.g., selective failure to encode actual hostile cues) could lead to nonaggressive responding. As cues are encoded, they

are interpreted, so the next step is mental representation of the meaning of the cues, particularly with regard to threat and others' intentions. Both biases (e.g., a hostile attributional bias, as dubbed by Nasby, Hayden, & DePaulo, 1979) and errors (e.g., misinterpreting a benign teasing stimulus as malicious) in mental representation could enhance the likelihood of aggressive responding. The next step in processing is accessing of one or more possible behavioral responses from memory. Through exposure, experience, and evolution, one's interpretation of a stimulus becomes associated with emotional and behavioral responses (e.g., threat-retaliate, disrespect-anger; see desired object, grab it); in some cases, the individual actively generates responses, as in problem solving. Often, single behavioral responses are not accessed; rather, a program of behaviors and expected responses to those behaviors is accessed, as in a script (Huesmann, 1988). Obviously, patterns of response access will be closely linked to the probability of aggressive responding. Accessing a response does not destine one to that response, so the next step of processing is response decision. The individual might evaluate a potential response by its moral acceptability and its instrumental, interpersonal, and intrapersonal outcomes, weight the values of those outcomes, and decide on a course of action. The response that is most positively evaluated (e.g., a boy evaluates that hitting a peer will save face, which is more important than being punished by authority, so he decides to aggress) will likely be enacted. An individual might consider responses simultaneously or sequentially, with varying thresholds of acceptability for enactment. In this context, impulsivity is defined as the lowest possible acceptability (i.e., a child responds with the first response that comes to mind, with no further evaluation). Thus, patterns of impulsivity or positive evaluation for aggressing are likely to eventuate in aggressive behavior. Also, rehearsal of behaviors in one's mind enhances the likelihood of selection, without regard to its likely consequences (Huesmann, 1988). Finally, the selected response gets transformed into behavior, which requires motor and verbal skills. Skill deficiencies in enacting aggressive responses could inhibit those behaviors, whereas skill deficiencies in enacting competent, nonaggressive alternatives could enhance aggressive responding through default.

Because the model describes social behavior as it unfolds in real time, the steps of processing are hypothesized to recycle iteratively (e.g., the child's behavioral

response gets a reaction from another person, which becomes the next cue for further encoding) and most likely occurs simultaneously with feedback loops in parallel processing (e.g., in the microsecond of evaluating a potential response, the child encodes a change in a peer's facial expression). As a description of social events, the model has heuristic strength (see Crick & Dodge, 1994, for a review). In addition, the model proposes that individuals develop characteristic styles of processing cues at each step, in domains of situations, and that these processing styles will correlate with individual differences in aggressive behavior. This hypothesis has generated over 200 empirical studies, with generally supportive findings (see reviews by Gifford-Smith & Rabiner, 2004; Dodge & Pettit, 2003).

### *Selective Attention and Encoding*

Using videotaped stimuli to assess the first step of processing, Dodge et al. (2003) found that aggressive children are less able than nonaggressive children to recall relevant social cues. Aggressive children have also been found to attend selectively to aggressive social cues in a stimulus array more than nonaggressive peers do and have difficulty diverting attention from aggressive cues (Gouze, 1987). When encoded cues are used to make interpretations of others' actions, aggressive children use fewer external cues than others do (Dodge & Newman, 1981) and instead rely more on their own stereotypes or simply use the most recently presented cue (Dodge & Tomlin, 1987).

Pollock has creatively used selective attention paradigms with emotional faces as stimuli to understand the influence of physical abuse on selective attention to threat cues as a mechanism in the development of aggressive behavior. Pollak and Tolley-Schell (2003) found that physically abused children demonstrate selective attention to angry faces and reduced attention to happy faces. Further, abused children display relative difficulty in disengaging from angry faces.

### *Attribution of Intent*

Over three dozen studies have shown that, given ambiguous provocation circumstances, aggressive children are more likely than nonaggressive children to make a hostile interpretation of another's intentions. In a typical study, participants are asked to imagine being the object of an ambiguous provocation (e.g., a peer spills water on you) and to make an interpretation of the peer's likely intent (Dodge, 1980). Positive correlations

between hostile attributional biases and aggressive behavior have been found in many school-based samples, including 8- to 12-year-old children (Guerra & Slaby, 1989), White children (Dell Fitzgerald & Asher, 1987), African American middle school boys (Graham & Hudley, 1994), Latino children (Graham, Hudley, & Williams, 1992), and British 8- to 10-year-old children (Aydin & Markova, 1979). Hostile attributional biases have also been found in aggressive clinical samples, including children with diagnosed disruptive behavior disorders (MacBrayer et al., 2003), adolescent offenders (Dodge, Price, et al., 1990), incarcerated violent offenders (Slaby & Guerra, 1988), and aggressive boys in residential treatment (Nasby et al., 1979). The findings extend beyond hypothetical situations: Steinberg and Dodge (1983) found similar evidence using a laboratory-based actual social interaction, in which children made attributions about a peer partner.

Although reciprocal effects are likely, prospective analyses by Dodge, Pettit, Bates, and Valente (1995) indicate that hostile attributional biases predict growth in aggressive behavior over time. Finally, experimental intervention with aggressive African American boys in which the focus was to reduce hostile attributional tendencies led to decreased aggressive behavior, relative to a control group (Hudley & Graham, 1993).

Several studies have found that aggressive children also erroneously interpret hostile intent when the stimuli clearly depict benign intentions (Dodge, Murphy, & Buchsbaum, 1984; Dodge, Pettit, McClaskey, & Brown, 1986). Statistical controls indicate that this intention-cue detection deficiency cannot be accounted for by general information-processing deficits or impulsivity (Waldman, 1988) or verbal intelligence (Dodge, Price, et al., 1990).

### ***Accessing Goals***

A growing body of research has correlated children's goals with individual differences in aggressive behavior (Erdley & Asher, 1999). Aggressive behavior has been linked to present-oriented (versus future-oriented) goals (Caprara & Zimbardo, 1996), goals in friendships (Rose & Asher, 1998), less-social goals (Murphy & Eisenberg, 2002), and performance-competitive (rather than relational) goals (Asher & Renshaw, 1981). Crick and Dodge (1994) introduced the process of goals accessing as the next step of processing, once the individual has mentally represented the stimulus set. Thus, goals are dynamically formulated online as a joint function of preexisting long-term plans that may reside in memory

and the immediate circumstances of a particular social stimulus. A child may enter a situation with preexisting hopes of establishing a friendship with a peer partner in a game, but the stimulus of losing a game under questionable circumstances may lead the child to formulate a goal of revenge that overwhelms other goals. All situations require the balancing of multiple goals, but little is known about how children redirect their goals during social interactions. Research on executive function deficits in aggressive children suggests that this process may be difficult for aggressive children. Indeed, Taylor and Gabriel (1989) found that aggressive children have difficulty coordinating multiple goals.

### ***Response Access***

The next step of processing is behavioral response access. Both the automatic association between social cue representation and aggressive responses and the conscious generation of aggressive solutions to social dilemmas have been implicated in the genesis of aggressive behavior. Shure and Spivack (1980) have found that among preschool children, the number of responses that a child generates to hypothetical social problems is inversely related to that child's rate of aggressive behavior. Among children in elementary school, the quality, not quantity, of responses is linked to aggressive problems. Aggressive children generate high proportions of atypical responses (Ladd & Oden, 1979), bribery and affect manipulation responses (Rubin, Moller, & Empage, 1987), direct physical aggression responses (Dodge et al., 2003; Waas, 1988), and adult intervention responses (Asher & Renshaw, 1981). They access fewer competent responses, including nonaggressive assertion (Deluty, 1981) and planning responses (Asarnow & Callan, 1985).

### ***Response Decision***

There are crucial differences between accessing a response and selecting it for enactment. Across development, children learn to lengthen the time between response accessing and behavior or to withhold impulses altogether, pending a mental evaluation of the likely effects. Barkley et al. (2002) have argued that the inability to inhibit accessed responses is the single major component of ADHD that is responsible for the aggressive behavior problems of these children. Self-reports by aggressive children (Perry, Perry, & Rasmussen, 1986) support the hypothesis that aggressive children have difficulty inhibiting aggressive responses. Slaby and

Guerra (1988) found that aggressive adolescent offenders generate fewer possible outcomes for their own behaviors than others do, suggesting a failure to consider consequences by this group.

Wilson and Herrnstein (1985) proposed that criminal behavior (and aggression more broadly) involves a rational decision in which the participant considers the expectation of benefits and their probabilities (e.g., peer approval or instrumental gain) versus the expectation of costs and their probabilities (e.g., legal punishment or parental disapproval). Crick and Dodge (1994) proposed that children may consider instrumental, interpersonal, intrapersonal, and moral outcomes in their evaluations. They may evaluate a possible behavior by these various outcomes, assign weights (estimates of value) to these categories, and perform mental arithmetic to decide on a behavioral response. Thus, environments that afford a positive cost/benefit ratio will show high rates of aggression. Clarke and Cornish (1983) conducted a rational decision analysis of youthful burglary and found that important deciding factors included whether a house was occupied, whether it had a burglar alarm or dog, and whether it reflected affluence. Not surprisingly, Becker (1974) concludes that offenders typically estimate the risk of being caught as very low (whether valid or not); thus, a rational analysis can still lead to risky (and ill-informed) behavior by some individuals.

As young children develop the ability to represent mentally the anticipated consequences of their behavior (usually, between ages 5 and 10; Werner, 1961), they become more skilled at deciding when to aggress. The rate of their aggression might not necessarily decrease, but their behavior will become more reasoned.

One of the mental actions that can occur during decision making has been called moral disengagement by Bandura (2002). Through socialization, most children learn self-restraints on aggressive behavior that involve anticipatory self-censuring and evaluations that aggression will be punished. Bandura (2002) argued that otherwise moral children perform aggressive acts through processes that disengage the usual self-reactions from such conduct. Several processes can contribute to moral disengagement. Cognitive restructuring can involve justifying aggressive action on the grounds that it will lead to a higher moral end (e.g., self-respect). This restructuring involves the minimization of one's own moral violations by comparing them to more reprehensible acts. This minimizing is particularly easy when a child is growing up amidst truly flagrant inhumanities (e.g.,

child abuse, homicide, rape, or discrimination). Euphemistic labeling (e.g., "trains," "get-back," "just teaching him a lesson"; McCall, 1994) further minimizes the perceived seriousness of the act.

A second set of dissociative processes involves distorting the relation between actions and their effects. When aggressing in a group, individuals can diffuse their own responsibility for their actions or deflect responsibility elsewhere (e.g., to authority, as in Milgram's, 1974, obedience experiments, or to society more broadly in war). A third set of disengagement processes operates on the perceptions of the victims. Dehumanization through labels (e.g., "cracker," "nigger") can lead to self-exoneration for inhumane acts. Modern urban life tends to foster such dehumanization processes as a result of high social mobility, anonymity, and the castelike categorization of persons into in-group and out-group members. Finally, aggressive actions are justified by attributing blame for the action to the victim. Because most aggressive acts occur in a sequence of escalating interpersonal exchanges, aggressors often find it easy to select from the chain of events an act by the victim that "merits" aggressive retaliation. Studies by Bandura, Barbaranelli, Caprara, and Pastorelli (1996) demonstrate that measures of moral disengagement by children based on these concepts are linked to their rates of aggressive behavior and emotional irascibility.

Moral disengagement can occur quickly in a social exchange, but more frequently it evolves gradually through cultural influence and reinforcement for partial disengagement. Children learn across time whether disengagement is allowed, and they learn to disengage more quickly and with less apparent justification in environments that provide little opposition. During this process, the individual misrepresents, minimizes, and disregards the injurious effects of aggression while selectively focusing on the self-enhancing outcomes; diffuses responsibility for the outcomes of aggression; generates palliative comparisons for one's own act of aggression; places euphemistic labels on one's own aggression; and vilifies and dehumanizes the victim of aggression. Bandura et al. (1996) have demonstrated in a longitudinal study of children outside of Rome, Italy, that these processes predict interpersonal aggressive behavior. Even otherwise moral human beings have been found to engage in these processes selectively during the course of morally defended aggressive acts (Bandura, 2002).

When they are experimentally forced to make evaluations and consider consequences, aggressive children,

relative to nonaggressive peers, evaluate aggressive responses as more legitimate (Erdley & Asher, 1998), less morally "bad" (Deluty, 1983), more "friendly" (Crick & Ladd, 1990), and globally more acceptable (Crick & Werner, 1998). They expect more positive instrumental outcomes (Egan, Monson, & Perry, 1998), more positive intrapersonal outcomes (Fontaine, Burks, & Dodge, 2002), fewer negative interpersonal outcomes (Quiggle, Panak, Garber, & Dodge, 1992), and fewer sanctional outcomes (Perry et al., 1986) for aggressing. In contrast, aggressive children report lower levels of perceived self-regulatory efficacy for prosocial behaviors and resisting peer pressure (Caprara, Regalia, & Bandura, 2002). Ethnographic analyses of urban communities also support the notion that "codes of violence" support aggressive behavior as the only means of gaining status and avoiding victimization (E. Anderson, 1990).

### ***Enactment***

The final step of processing is to transform a selected response into motor and verbal behavior. Socially rejected and aggressive children have been shown to be less competent when asked to enact and role-play nonaggressive socially appropriate behaviors in laboratory settings (Burlison, 1982). One of the difficulties with these studies is that children's enactments may be confounded by other mental processes, such as their expectations about the likely outcomes of behavior, even in laboratory role-play settings.

### **Mediation of Life Experiences through Acquired Processing Patterns**

Each of the processing-aggressive behavior correlations previously described is rather modest in magnitude. These correlations are enhanced by considering the situational context, the type of aggressive behavior, and the profile of processing patterns. Dodge et al. (1986) found that the correlation between processing and aggressive behavior is stronger in situations than across situations (i.e., processing about teasing events relates more strongly to aggressive behavior in response to teasing than to aggressive behavior in peer group entry situations). Also, early-step processing variables (i.e., encoding and hostile attributions) relate more strongly to reactive anger, whereas later-stage processing variables (i.e., response evaluations) relate more strongly to proactive aggression (Crick & Dodge, 1996). Finally, when profiles are assembled or multiple regression tech-

niques are used, the predictability of aggressive behavior from aggregated processing measures is great (Dodge et al., 1986). Findings from 9 samples (1 from Dodge & Price, 1994; 3 from Dodge et al., 1986; 2 from Dodge et al., 2003; 1 from Slaby & Guerra, 1988; and 2 from Weiss, Dodge, Bates, & Pettit, 1992) indicate that processing variables from different steps provide unique increments in predicting aggression, such that multiple correlations range up to .94.

Several studies have found that the effects of adverse life experiences on growth in aggressive behavior are mediated by the child's development of patterns of processing social information. Dodge, Bates, et al. (1990) found that the experience of physical maltreatment is associated with an acquired tendency to become hypervigilant to hostile cues, to attribute hostile intent to others, to access aggressive responses readily, and to evaluate aggressive responses as instrumentally successful. In turn, these social information-processing patterns were found to lead to later aggressive behavior and to account for the effect of maltreatment on aggression in middle school (Dodge et al., 1995).

Eisenberg et al. (2003) found that parents' negative expressed emotion influences the child's social adjustment through its mediating effects on the development of self-regulatory processes, including attention focusing, attention shifting, and inhibitory control. In yet another study, Snyder, Stoolmiller, Wilson, and Yamamoto (2003b) found that parents' responses to child misbehavior lead to growth in the child's antisocial behavior through the mediating process of children's anger regulation.

### **Latent Knowledge Structures**

A growing body of evidence suggests that children's life experiences lead to represented memories that predict future behavioral tendencies through an influence on the way that future social information is processed. This work has been conducted under several different rubrics.

### ***Schemas and Scripts***

Social-cognitive theories in psychology (Bargh et al., 1995) suggest that processing of social cues is guided by latent knowledge structures, variously called schemas and scripts, that are stored in memory (Abelson, 1981). These structures are hypothesized to be the evolving representational products of experience, which guide processing of new cues. Baldwin (1992) has described

several ways that social knowledge structures exert an impact on social information processing, including selective attention to cues, premature judgments about stimuli, biased interpretations of ambiguous information, and biased expectancies for the outcomes of events.

Huesmann (1988, 1998) has articulated the hypothesis that early development leads children to represent in memory scripts for aggression that include acceptable antecedents, details of context and action, and likely consequences. Graham and Hudley (1994) employed priming techniques from cognitive-social psychology to ascertain that aggressive children have highly accessible aggressive constructs represented in memory. Stromquist and Strauman (1992) asked children to describe freely their social relationships and found that the tendency to use aggressive constructs (both in commission and omission, e.g., “he hits others” and “he stays away from fights”) is correlated with aggressive behavior. Burks, Laird, Dodge, Pettit, and Bates (1999) used the Stromquist-Strauman method to find that hostile representations of peer relationships predict later aggressive behavior toward peers. MacKinnon-Lewis, Rabiner, and Starnes (1999) found that cognitive representations of familiar and unfamiliar peers are associated with social maladjustment. Specifically, boys who held negative feelings about known peers at the beginning of the school year were less likely to be accepted by peers 6 months later.

### *Self-Concept*

Self-concept is a knowledge structure that has been hypothesized to relate to aggression (Harter, 1982). However, despite the speculation of psychodynamic theorists (Keith, 1984) that aggressive children must have miserable self-concepts, empirical assessments have not borne out this hypothesis (Crick & Dodge, 1996; Zakriski & Coie, 1996). Even aggressive children who are also socially rejected by peers do not seem to recognize that they are rejected by peers. Zakriski and Coie (1996) reported that aggressive-rejected boys did not see themselves as having been rejected by an experimental confederate playmate even when this was observed to have happened. Hymel, Bowker, and Woody (1993) found that unpopular aggressive children received self-concept scores in academic, athletic, appearance, and social competence domains that were as high as those of average peers, even though objective assessments of their competence in these domains indicated otherwise. Aggressive children appear to blame others rather than

themselves for their negative outcomes (Cairns, 1991). The possibility that other-blaming may represent self-defensive mechanisms in aggressive children (Keith, 1984) indicates the inherent difficulty in measuring this latent knowledge structure.

### *Normative Beliefs*

Huesmann (1998) has proposed that children's beliefs about consensual social norms influence children's aggressive behavior. Children learn these norms through perception, identification with reference groups, and personal evaluation. Guerra et al. (1995) assessed children's normative beliefs about the consequences of aggressing and found that (a) the male culture more strongly endorses the use of aggression than does the female culture, (b) the normative endorsement of aggression increases across age during the school years, and (c) these beliefs correlate with aggressive behavior. Zelli, Dodge, Lochman, Laird, and the Conduct Problems Prevention Research Group (1999) found that third graders who hold normative beliefs that aggression is acceptable are relatively likely to engage in deviant social information processing in fourth and fifth grade, which, in turn, is related to aggressive behavior and mediates the effect of beliefs on aggression. The converse relation did not hold as strongly.

### *Working Models*

Bowlby (1980) proposed that early life experiences, especially with regard to an infant's attachment with a caregiver, lead to the formulation of working models of how social relationships operate. These models reside in memory and guide future social behavior. Cassidy, Ziv, Rodenberg, and Woodhouse (2003) found that measures of working models correlate with indices of children's social adjustment. Cassidy et al. (1996) found that children classified as insecurely attached or who reported experiencing parental rejection were more likely to make hostile attributions in response to hypothetical, ambiguous provocations than were other children.

### *Moral Development and Perspective Taking*

Arsenio and Lemerise (2004) have proposed that moral development acts as a distal latent knowledge structure to guide more proximal online processing of social information. The structuralist perspective on cognitive development evolving from Piaget's (1965) theory and research has contributed two major ideas to the quest for understanding the development of antisocial behavior

(Nucci, 2001). First, social and cognitive egocentrism, or the failure to recognize the perspective of social others, has been related to the development of antisocial behavior. Chandler (1973) found that aggressive children's social perspective-taking level, scored in terms of Piagetian developmental levels, was lower than their peers. He then developed an intervention showing young adolescent delinquents videotapes of their own behavior, followed by discussion in which participants were encouraged to take each other's roles, to improve their perspective-taking levels. Those adolescents who participated in the intervention displayed fewer delinquent acts 18 months later than did a control group. Others (e.g., Iannotti, 1978) have been unable to obtain shifts in aggression through role-taking training. There have been some attempts to make children less aggressive by training them to take the affective perspective of others (e.g., Feshbach & Feshbach, 1982), but the results of these efforts have been mixed, at best.

The second major contribution of the structuralist perspective has been to relate moral development to antisocial behavior. The basic hypothesis has been that developmental lags in stages of moral development will lead to antisocial behavior. Blasi (1980) reviewed studies testing the relation between moral judgment and moral action and concluded that a majority of these studies supported Kohlberg's (1986) thesis that higher moral reasoning would lead to personal honesty and altruism. The fact that moral reasoning *per se* does not always relate to apparently altruistic behavior or resistance to temptation has led to an elaboration of the theory in terms of personal identity: Moral reasoning is related to moral behavior in individuals for whom moral values are central to their self-understanding (Blasi & Oresick, 1986). Recent studies have found correlations between moral reasoning in domains of social encounters (Horn, 2003) and racial exclusion (Killen, Lee-Kim, McGlothlin, & Stangor, 2002) and social adjustment.

## TREATMENT AND PREVENTION OF ANTISOCIAL BEHAVIOR

The past decade has witnessed an explosion of randomized trials testing interventions to prevent aggressive behavioral development and to treat conduct disorder. Hinshaw (2002) has noted that intervention experiments offer the opportunity not only to apply the developmental knowledge reviewed in this chapter to improve children's

lives but also to test developmental hypotheses more rigorously. A comprehensive review is beyond the scope of this chapter. Instead, the intervention experiments that will be highlighted are those that include a theoretical basis in a developmental model, random assignment, evaluation of all children assigned to intervention (whether they received it or not), independent replication, long-term follow-up, and blind assessment of outcome. These studies have in common the hypotheses that conduct problem behavior develops (or is maintained) by one or more of the developmental factors reviewed here and that intervention to alter those developmental factors will indirectly lead to the prevention or reduction of aggressive behavior. The interventions range from universal (population-based) to selected (groups identified based on risk factors) to indicated (groups identified based on aggressive behavior) approaches.

### Stimulant Medication

The success of psychostimulant medication in treating attention deficits (Frick, 2001), coupled with the known association between early biologically based attention deficits (ADHD) and CD has led to the hypothesis that psychostimulant medication could indirectly reduce conduct problems. The Multimodal Treatment Study of Children with Attention Deficit Hyperactivity Disorder (MTA) is the largest randomized trial test of this hypothesis, albeit with a subgroup of conduct-problem children who have comorbid ADHD. Although psychostimulant treatment (relative to no treatment) was found to be effective in altering attention deficits in this group of 7- to 10-year-olds, by itself it had no substantial impact on oppositional and aggressive behavior (MTA Cooperative Group, 1999). Other trials (reviewed by Frick, 2001) indicate some success of psychostimulants in reducing disruptive behavior; however, Frick points out that "the medication's primary effect may be to enhance the child's responsiveness to other interventions" (p. 600) and that "there is little evidence to date that stimulants reduce conduct problems in children without a comorbid diagnosis of ADHD" (p. 600).

### Parent-Based Approaches

A variety of family interventions designed to improve parents' discipline strategies, the quality of parent-child relationships, and parents' monitoring and supervision

of children have proven efficacious in reducing aggressive behavior. The basis for most of these interventions is coercion theory by Patterson et al. (1992) and Forehand and McMahon's (1981) behavioral approach. The primary goal of Parent Management Training (PMT) is to alter the pattern of exchanges between parent and child during discipline events so that coercive behavior by each party is extinguished in favor of contingent, consistent, and clear rules that lead to compliance. Parenting behaviors are taught through role-play, practice, completion of homework, and discussion, sometimes with the child present.

Rigorous evaluations have proven this approach to be efficacious. "PMT is probably the most well-investigated therapy technique for children and adolescents . . . and has led to marked improvements in child behavior" (Kazdin, 2003a, pp. 261–262). A meta-analysis by Serketich and Dumas (1996) yielded a large mean effect size of .86 standard deviations for programs with young children (up to age 10). A meta-analysis of programs for delinquent and conduct-disordered children aged 10 to 17 by Woolfenden, Williams, and Peat (2002) yielded a mean effect size of .56. The meta-analysis of 40 studies by Farrington and Welsh (2003) yielded a mean effect size of .32 in preventing delinquency outcomes.

Kazdin (2003b) notes that one of the major problems with PMT approaches is getting families to participate and to complete the intervention. Issues of cultural relevance loom large, and practices to engage parents by focusing on family relationships (as in functional family therapy; Alexander & Parsons, 1982), and by attending to their stressors (Kazdin & Whitley, 2003) have proven important.

Several mediational analyses of PMT have supported the developmental hypothesis that parenting practices themselves play a role in aggressive behavioral growth. Hinshaw et al. (2000) found that child disruptive behavior gains in school as a function of randomly assigned treatment could be accounted for by improvements in parenting practices. Dishion and Kavanagh (2000) reported that changes in parenting accounted for the positive effects of the parent intervention of the Adolescent Transitions Program (ATP) on child antisocial behavior.

For families facing extremely high levels of antisocial behavior in adolescents who are on the verge of incarceration, multisystemic therapy (MST) has proven efficacious (Henggeler et al., 1997, 1998). It is an intensive home-based approach based on an ecological model

of possible individual, family, peer, school, and community risk factors in antisocial behavior. A meta-analysis of 11 outcome studies revealed a mean effect size of .55 in reducing antisocial outcomes (Curtis, Ronan, & Bourduin, 2004).

For antisocial youth who are already in the child welfare system, multidimensional treatment foster care (MTFC) has been developed. The MTFC model was originally funded by the Oregon Youth Authority in 1983 to provide a community-based alternative to incarceration for boys with serious and chronic delinquency (Chamberlain, 2003). Two randomized trials have supported the efficacy of MTFC. In the first trial, MTFC boys had significantly lower rates of official and self-reported delinquency in a 12-month follow-up and lower rates of violent offending in a 24-month follow-up than did group-care youth (Chamberlain & Reid, 1998; Eddy, Whaley, & Chamberlain, 2004). A second trial with adolescent girls found that MTFC girls spent fewer days in locked settings, had fewer parent-reported delinquent behaviors, and showed a trend toward fewer arrests at the 12-month follow-up (Leve & Chamberlain, 2005). Eddy and Chamberlain (2000) examined mediational factors in the boys' sample, with several factors mediating the relationship between group condition and boys' criminal referral and self-reported delinquency rates. Mediating variables included close and consistent supervision, effective discipline, adult mentoring, and separation from delinquent peers, all consistent with the developmental model described in this chapter.

Webster-Stratton (1998) has led the move to bring these principles to preventive intervention with high-risk families of preschool-aged children (such as Head Start), with marked short-term success as evaluated by randomized trials. The Triple P-Positive Parenting Program by Sanders, Markie-Dadds, Tully, and Bor (2000) has been adapted for use in universal settings (media), on a selected basis for concerned parents, or in primary care settings, also with success. A different parent-based approach was taken by Olds et al. (1998), who made weekly home visits by a nurse-practitioner to high-risk mothers beginning in pregnancy for 3 years. The visitor provided information about child-rearing, helped problem solve parenting and family issues, and helped bring mothers to financial self-sufficiency. A randomized trial revealed no positive effects on children's conduct problems during elementary school (Kitzman et al., 1997), but, by age 15, 45% of the control group children had been arrested in contrast with just 20% of the inter-

vention group children (Olds et al., 1998). Other home-visiting programs have yielded less favorable long-term effects (Stone, Bendell, & Field, 1988).

### School-Based Approaches

The largest school-based approach to reducing aggressive behavior is that implemented by Olweus (1993), which involved the distribution of booklets and videos to teachers and parents in all schools in Norway, focusing on targeted parenting and discipline practices to reduce bullying behaviors. Cross-time evaluations suggest positive effects, but this program has not been evaluated by a randomized trial.

The most well-known classroom-based approach is the Good Behavior Game (GBG), which is a behavior management program designed to reduce disruptive behavior and promote prosocial behavior by group-level contingencies. When implemented in first grade classrooms in randomized trials, it has proven efficacious in reducing disruptive behavior at both proximal (Ialongo et al., 1999) and distal (Ialongo, Poduska, Werthamer, & Kellam, 2001) time points. Van Lier, Muthén, van der Sar, and Crijnen (2004) found that these positive effects could be sustained across 24 months and were strongest for the most disruptive children.

Universally-administered classroom curricula have been developed to teach social-cognitive and social-emotional skills for the purpose of preventing aggressive behavior. Greenberg and Kusche (1993) have found success with their PATHS Program (Providing Alternative Thinking Strategies) in increasing prosocial behavior, and the Conduct Problems Prevention Research Group (1999b) has demonstrated classroom-level success in reducing aggressive behavior with its adaptation of this approach.

### Social Cognitive Skills Training

A key component of developmental models of aggressive behavior is the child's social-cognitive skill deficits, including attributional biases, problem solving, and decision making. Based on this model, numerous interventions have been developed to prevent aggressive behavior through enhancement of these skills and reduction of deficits and biases. Graham and Hudley (1993) developed an intervention designed to reduce hostile attributional biases in African American children, with demonstrated short-term success in a randomized trial.

Lochman has developed the Coping Power Program, which is designed to enhance an array of social-cognitive skills in aggressive fourth- and fifth-grade boys. Lochman and Wells (2004) have found positive effects of this program in reducing aggressive behavior as rated by school teachers, which persisted into the following school year, with an effect size of .42. Ross and Ross (1998) used a randomized trial to demonstrate positive effects in preventing reoffending for their program aimed at helping youth to stop and think about social problems, consider alternative strategies, and consider consequences of their actions.

Kazdin (2003a) has developed a variant of this approach that he calls Problem-Solving Skills Training (PSST). When implemented with aggressive children in randomized trials, he has found success in reducing aggressive behavior in both home and school settings that lasts over 12 months, in at least five replicated studies.

### Combining Approaches

The developmental model described in this chapter posits risk factors and processes from multiple domains that provide unique, incremental power in predicting aggressive behavior outcomes. Given that single-domain approaches have proven modestly efficacious, several intervention scientists have hypothesized that comprehensive approaches that cross multiple domains would have even more powerful effects. In the MTA Study (Hinshaw et al., 2000), a combined program that included both stimulant medication and parent management training yielded more positive effects on child disruptive behavior than either approach alone. Lochman and Wells (2004) contrasted their child-focused Coping Power program with an enhanced program that added 16 parent-group sessions based on behavioral principles. The comprehensive program yielded more positive effects on child self-reports of covert delinquency than either the child-focused program or a control. Likewise, Kazdin (2003a) found that an intervention that combined parent management training with child problem-solving skills training tended to be more effective than either intervention alone.

Tremblay et al. (1995) implemented an important intervention that combined parent management training based on Patterson's principles with social and problem-solving skills training with groups of 7-year-old boys over a 2-year period. In contrast with a randomly assigned control group, by age 12 the intervention group

committed less burglary and were in fewer fights. By age 17, analyses of developmental trajectories revealed that fewer intervention-group boys (16.6%) than control boys (29.5%) followed a trajectory of high levels of physical aggression.

### **Comprehensive Approaches to Prevention**

Several interventions have gone beyond the simple combination of two approaches toward comprehensive approaches that last multiple years. These approaches tend to have greater and longer-lasting impact than other programs.

#### ***Reaching Educators, Children, and Parents Program***

The RECAP Program (Reaching Educators, Children, and Parents; Weiss, Harris, Catron, & Han, 2003) provided semistructured training with individual children, small peer groups, classroom groups, classroom teachers, and parents. Child components focused on social skills, reattribution training, communication skills, self-control, affect recognition, and relaxation. Parent and teacher components focused on using praise and punishment appropriately, improving adult-child communication, and strengthening the adult-child relationship. This program was administered to children with comorbid externalizing and internalizing problems in a randomized trial that revealed positive effects on teacher, self, and peer ratings of externalizing problem behaviors at 1-year follow-up.

#### ***Metropolitan Area Child Study***

The Metropolitan Area Child Study (MACS; Metropolitan Area Study Research Group, 2002) nested interventions in a research design that contrasted no treatment, a classroom program, a classroom-plus-small-group peer-skills training program, and a classroom-plus-small-group plus family-intervention program delivered in grades two and three and/or grades five and six. The peer-group component focused on altering normative beliefs about aggression and improving peer social skills, and the family intervention focused on parenting skills and parent-child communication. Outcome analyses revealed that only the fully combined intervention, when delivered in a community-rich context in the early grades, had a positive effect on reducing peer- and teacher-rated aggression, relative to a randomly assigned control group. The peer-group component appeared to have an iatrogenic effect on increasing

aggression when administered to older youth in an inner-city context, a finding that is consistent with the deviant peer-contagion hypothesis that bringing deviant peers together only enhances problem outcomes.

#### ***Social Development Model***

Hawkins, von Cleve, and Catalano (1991) combined parent training in behavior management, teacher training, and child interpersonal cognitive problem-solving skills training with first-grade children in the Social Development Model program. O'Donnell et al. (1995) reported that, by sixth grade, intervention boys from low-income families reported less delinquency than low-income control boys. By age 18, Hawkins, Catalano, Kosterman, Abbott, and Hill (1999) found that the full intervention group (receiving intervention for 6 years from grade one to grade six) reported less violence than a no-treatment control group and an intervention group that received intervention only in grades five and six.

#### ***Fast Track***

The Conduct Problems Prevention Research Group (CPPRG) designed a 10-year-long intervention that combined family, peer, academic, classroom, and child social-cognitive skill-training components of the developmental model into a cohesive and comprehensive intervention called Fast Track. It was delivered to 445 first-grade children at high risk for adolescent violence and contrasted with a similar number of randomly assigned control-group children. After the 1st year of intervention, compared with the control group, the intervention group displayed higher levels of targeted skills in parenting, social cognition, and reading, and less aggressive behavior (CPPRG, 1999a). These effects on aggressive behavior persisted through third grade (CPPRG, 2002a) and appeared to hold equally well across gender, ethnic, and severity-level groups. Effects have persisted through fifth grade, with about a 25% reduction in cases that could be classified as clinically deviant (CPPRG, 2004). Mediation analyses revealed that intervention effects on outcomes could be partially accounted for gains in targeted areas of intervention, consistent with the premises of the developmental model (CPPRG, 2002b).

### **Early Comprehensive Approaches**

Finally, given the importance of early lack of stimulation of cognitive and social skills in developmental mod-

els of aggressive behavior, several comprehensive programs that provide enriched preschool environments coupled with home-visiting for parent support have been evaluated for effects on aggressive behavior.

### ***Perry Preschool Project***

The Perry Preschool Project is the most well-known of these efforts. Three-year-old African American children living in poverty were randomly assigned to intervention or control groups. The intervention group was provided daily preschool and weekly home visits for 2 years. The intervention group was rated as less aggressive by teachers at ages 6 to 9, rated as less delinquent by self-report at age 15, had fewer arrests at age 19, and had only half as many arrests by age 27 (Schweinhart, Barnes, & Weikart, 1993).

### ***Child-Parent Center***

The Child-Parent Center approach is similar to the Perry Preschool approach in providing preschool along with family support. Long-term evaluations reveal that by age 18 program participants, compared with randomly assigned controls, had fewer nonviolent (17% versus 26%) and violent (9% versus 15%) arrests. A program in Syracuse, New York, revealed similar positive effects (Lally, Mangione, & Honig, 1988), but the well-administered Infant Health and Development Program (IHDP) found no positive long-term effects on conduct problems (McCarton et al., 1997).

## **CONCLUSIONS AND FUTURE DIRECTIONS**

Recent advances reported in this chapter indicate a wide range of risk factors for aggressive and antisocial behavior and numerous processes in its development across the life-span. These factors cover domains as broad as genes, acquired neuropsychological deficits, personality characteristics, ecological and cultural contexts, family demographics, parenting strategies, peer relations, situational characteristics, and cognitive-emotional skills and biases. The processes range from neurological to social, at intrapersonal, interpersonal, and institutional levels. A simple summing of the bivariate effect sizes of these risk factors in predicting aggressive behavior would reveal a striking paradox. On the one hand, the separate effect sizes would sum to well beyond 100% of the variance in aggression; on the other hand, the sum would not come close to accounting for all of the variance in aggressive behaviors. How can genes account for a full half of the variance while life experiences and situational parameters

account for well over half of the variance, too? Four general conclusions may resolve this paradox, but it is important to recognize that our review of determinant factors includes studies that vary in the degree to which they might evidence causality rather than statistical correlation.

A number of developmental theorists have argued for research designs that strengthen the implication of causality for individual risk factors, but this is not always a straightforward issue because, as Rutter et al. (1998) have noted, “causal processes are neither simple nor unidirectional. They involve indirect chain effects rather than one basic cause, and they can also reflect a two-way interplay between underlying biological features and behavior” (p. 378). The kinds of ABAB designs that were used in behavioral analysis designs to demonstrate causality of situational factors, such as reward contingency, are not applicable to the study of individual differences. Intervention designs have been proposed as one way to approximate this kind of rigor, but interventions that attempt individual change across multiple contexts and across time, as contrasted with lab analogue studies, typically address multiple aspects of the individual or parent functioning. Nonetheless, most of the factors reviewed rely on longitudinal studies that attempt to control for other related risk factors to demonstrate some independence of influence. Some, such as the impact of peer factors, have tracked changes in individual aggressive or antisocial behavior across time in relation to the hypothesized risk factors. Some factors, such as TV viewing, are inextricably confounded with other factors, such as the propensity to choose to watch violent programs or the correlate changes in acceptability of violence in the surrounding culture, and this makes it difficult to determine causality even though the potential for causality seems so inherently compelling.

### **Conclusion 1: Predictors Differ across Aggressive Acts, Personalities, and Patterns**

First, it is necessary to distinguish among predictors of aggressive acts, aggressive personalities, and aggressive patterns. Aggressive acts are largely situationally and contextually determined. Handgun homicides are well modeled by variations in laws, policies, and access to handguns across the world. The probability of an antisocial act of looting is much greater during an electrical blackout than during a well-policed spring afternoon. The occurrence of an act of reactive aggression almost

always follows some kind of provocation stimulus and almost never occurs in the absence of such a stimulus. In a hypothetical experiment in which all individuals are exposed equally to all possible situational stimuli, most of the variance in single acts of aggression would occur within (not between) individuals. Individual acts of aggression are poorly predicted by heredity.

Second, stable patterns of aggression are well predicted by individual difference factors like heredity and dispositions. These stable patterns emerge when acts of aggression are aggregated across time and situations. When we look at these personalities, derived by averaging across time and situations, we see the importance of between individual factors. Just as some situations are more likely to lead to aggression, so some people are more likely to act aggressively.

Yet a third kind of aggressive behavior occurs as a contingent pattern. Developmental studies suggest that life experiences have the effect of altering a person's behavior in particular contexts for as long as the contextual parameters remain the same. As an example, the experience of physical abuse teaches a child that the social world is threatening and that aggressive behavior toward peers protects oneself from harm. This pattern of preemptive reactive aggressive behavior will endure as long as the balance of a child's life experiences continues to be threatening. As a second example, contingent reinforcement of aggressive behavior as described in Patterson's coercion theory (Patterson, Reid, & Dishion, 1992) will lead to a pattern of high rates of aggressive behavior, *as long as the contingencies remain in place*. Further complicating the picture is empirical evidence suggesting that these children may inadvertently act in such a way as to maintain the occurrence of threats from others or contingent reinforcement for their aggressive behavior.

### **Conclusion 2: Risk Factors Operate in Biopsychosocial Symbiotic Development**

The second resolution of the paradox in risk factors for aggression comes from an understanding of how risk factors co-occur, interact, and transact. First, the co-occurrence, or correlation, among risk factors suggests that they might share a common origin and might not account for unique portions of the variance in aggressive behavior. Empirical evidence indicates that, for example, the effects of low socioeconomic status, large family size, single-parent status, teen-age-parent status, and lack of

parental social support on antisocial behavior are highly redundant and can be accounted for by their correlation with inadequate parenting. Redundancy across all risk factors is not nearly complete, as indicated by the cumulative risk factor modeling pioneered by Rutter (1989).

Second, a large portion of the variance in aggressive behavior is accounted for by interaction effects among risk factors. Merely cumulating nonredundant risk factors will not exhaustively account for the variation in aggressive behavior; rather, one of the most important findings of the past decade is that risk factors often exert their influence contingently—only in the context of another risk factor. Caspi et al.'s (2002) findings that child maltreatment leads to child CD only in the presence of the MAO-A genotype is a prime example. Another example is Dodge et al.'s (2003) finding that peer social rejection enhances risk for growth in aggressive behavior only among a subgroup of children evaluated by their mothers as showing difficult temperament. A third example is Lynam et al.'s (2000) demonstration that impulsivity is a risk factor for delinquency primarily in neighborhoods characterized by poor informal controls.

Third, risk factors transact—they reciprocally influence each other across time. Harsh discipline of a child may lead that child to fail to develop social skills of relating effectively with other persons. In turn, a child who lacks social skills may get into conflicts with peers and adults, leading adults to apply more harsh discipline. Further, these transactions may lead to a transformation in the risk factors. The parent who applies harsh discipline in the above example may find that, over time, repeated conflicts with a child are very stressful and disruptive to family life. As this child moves into adolescence, empirical evidence suggests that this parent may withdraw from interaction, monitoring, and supervision of this child, perhaps to minimize overt conflicts. The child may also play a role in becoming adept at making it difficult for a parent to monitor his or her behavior. The parents' lack of monitoring, coupled with the child's own social rejection by mainstream peers, may lead the child to gravitate toward deviant peers, thus transforming the child's peer status from social rejection to member of a deviant peer group.

The co-occurrences, interaction effects, and transactional mediation effects among risk factors described here are more the rule than the exception in antisocial development. They explain why a simple summing of bivariate effects would yield well beyond 100% of vari-

ance “explained” and yet would not exhaustively describe how chronic antisocial behavior develops.

### **Conclusion 3: A General Consensus Model of the Development of Aggressive Behavior Patterns Is within Reach**

Instead of a haphazard array of risk factors that may cumulate, interact, and transact in unknown ways, a rapidly growing body of theory is developing in the field such that a consensus model of the development of aggressive behavior patterns may well cohere in the next decade. The components of this model are described in this chapter, and they include genetic factors, sociocultural contexts, early life experiences (both biological exposures and psychosocial experiences in family and peer domains), middle childhood experiences (in family, peer, and school domains), adolescent experiences (in family, peer, school, and community domains) and transient situational stimuli. The mediating processes of these influences are likely to be intrapersonal, at both neuropsychological and cognitive-emotional levels.

### **Conclusion 4: The Most Important Discoveries in the Next Decade Will Come from Studies of Gene-Environment Interactions, Modeling of Developmental Trajectories, and Prevention Experiments**

Finally, this chapter points to the areas where the most exciting discoveries are likely to occur in the next decade. Three areas seem especially ripe. First, as recent technological advances make it easier and less expensive to identify specific genotypes, studies are likely to test the correlation between various genotypes and indices of aggressive behavior and risk factors associated with aggression. The studies by Caspi et al. (2002), reported in this chapter, provide models for this work. These studies are likely to yield important findings if they are completed with samples for which the measurement of the environment is equally precise. It is anticipated that such studies will reveal interaction effects between genotypes and environmental factors. Replicating such findings and integrating them into coherent theories will challenge this field.

Second, recent methodological advances in the modeling of developmental trajectories and changes in latent classes across time will be applied to longitudinal data

sets to reveal patterns in antisocial development, factors that predict trajectories, and life experiences that deflect individuals away from antisocial lives.

Finally, prevention science is maturing at a rapid rate. Randomized clinical trials are proliferating, providing opportunities to test developmental theories. These trials include both large-scale implementations of broad models of multiple risk factors and single-component trials designed to identify specific clinical techniques for achieving behavior change. Evidence is strong that changing parenting behavior and improving social-cognitive skills can alter trajectories of antisocial behavior, supporting the causal role of these factors. Future trials will refine developmental models through the rigor of experiments and will bring the fruits of developmental psychopathology to bear on the crucial problem of violence in children's lives. We anticipate that the next decade's edition of this chapter will benefit greatly from these advances.

Social Practices and Cultural Coherence	814
Emotional Forms, Intuitions, and Rapid Processing	816

Philosophers have been concerned with the topic of morality for a long time. Socrates is referred to as the “patron saint of moral philosophy” (Frankena, 1963, p. 1). The moral philosophies of Plato and Aristotle included concerns with how individuals acquire or develop morality and how to create the best educational conditions for its acquisition. Moral development has been of central concern in the major psychological theoretical perspectives since the beginning of the twentieth century. Psychoanalytic, behavioristic, Gestalt, and structural-developmental theorists made the study of morality central. The major figures in these approaches, including Sigmund Freud, B. F. Skinner, and Jean Piaget, provided accounts of moral development. Many of

the problems raised by them and by moral philosophers over the ages remain part of contemporary discussion.

Psychological research in recent years has produced new findings and changes in assumptions about children's social propensities, social experiences, and ways of framing features of moral development. Nevertheless, many of the issues around definitions of morality, influences of emotions and thought, and the roles of society or cultures are still debated. In these regards, little has changed in theory and research on moral development since the publication of the previous volumes of the *Handbook of Child Psychology* in 1998. This chapter, therefore, covers much of the same ground as the previous version, with an updating of the

literature since that time. Because most of the theorizing and research discussed in the previous version of this chapter remains relevant, changes in this version primarily reflect the inclusion of new research conducted during the past few years.

## SETTING THE STAGE

Sigmund Freud wrote extensively about morality, incorporating it into his general formulations of individual development in society. Central to his view were the concepts of conscience (tied to the idea of a duality) and concomitant tension between an individual and society. The root of this tension is the incompatibility of psychological and biological needs of individuals and strivings for long-term survival of individuals and the species. The collectivity largely has the function of ensuring survival and protecting people from each other's aggressive tendencies. Through the influences of the collectivity, particularly as reproduced in a family, the individual's needs for instinctual gratification become transformed and displaced in the developmental process to make room for internalized standards (via parents as representatives of society) and internalized emotional mechanisms for regulating behaviors. This transformation, which is grounded in emotions of fear and anxiety and facilitated by positive emotions of love and attachment, largely stems from emotional conflicts producing psychological transformations through the acquisition of a mental agency, a superego, and incorporating moral ideals and guilt as the means for the regulation of conduct.

In the Freudian view, the acquisition of morality results in a duality in the individual, including the forces of the superego and needs for instinctual gratification. The moral side of the duality entails duties to uphold societal norms. Although fulfilling duties entails deep conflicts (most often of an unconscious nature), the duties are felt as inexorable and impersonal. An appropriately internalized morality is invariable and applied inflexibly. In this regard, Freud proposed that women do not adequately internalize a superego. In what has become an infamous statement about gender differences in morality, Freud (1925/1959) said:

I cannot escape the notion (though I hesitate to give it expression) that for women the level of what is ethically normal is different from what it is in men. Their superego is never so inexorable, so impersonal, so independent of its emotional origins as we require it to be in men. (p. 196)

The important question of gender differences is discussed later with regard to contemporary analyses and debates. Gender is important in analyses of morality because females are in subordinate positions in the social hierarchies of most societies and thereby are not treated equally with males. Inequalities that stem from such social hierarchies or cultural practices and affect women and others (e.g., minorities and people of lower social castes or classes) are discussed in this chapter. In particular, research is considered that has examined the perspectives and moral reactions (through social opposition, resistance, and subversion) of those in subordinate positions.

B. F. Skinner (1971, Chapter 6) presented his position on morality in the latter part of his career and in a largely nontechnical book for a popular audience. In keeping with his behavioristic formulations, Skinner proposed that morality reflects behaviors that have been reinforced (positively or negatively) by value judgments associated with cultural norms. Actions are not intrinsically good or bad but are acquired and performed as a consequence of contingencies of reinforcement. Certain contingencies, consistent with the mores of the group, are social in that they pertain to relationships with others and are governed by verbal reinforcers such as good, bad, right, and wrong. Moreover, social control over behavior is particularly powerful when it is exercised by institutional forces (e.g., religious, governmental, economic, or educational). This is because the reinforcers of "good" and "bad" also take the form of legal, illegal, pious, or sinful acts with their associated rewards and punishments. Learned behaviors stemming from the customary practices of a group are invariant because reinforcement contingencies are maintained. For Skinner, however, learned behaviors do not constitute duties or obligations nor reflect a person's character; rather, they are due to the arrangement of effective social contingencies.

Knowledge and judgments about social relationships were considered central to morality by Jean Piaget, who wrote about the topic mainly in the early part of his career (Piaget, 1932; see also Piaget, 1951/195a, 1960/1995b). In keeping with his general views of development as stemming from reciprocal interactions of individuals and multiple features of social experiences (entailing constructions of understandings of experiences), Piaget analyzed morality from the perspective of how experiences result in the formation of judgments about social relationships, rules, laws, authority, and so

cial institutions. Piaget's formulations on moral development included the idea that social transmission does not solely result in the reproduction of that which is transmitted but also entails reconstructions. He also proposed that moral development is influenced by a variety of experiences, including emotional reactions (e.g., sympathy, empathy, and respect), relationships with adults, and relationships with other children. In Piaget's view, moral judgments are fundamentally about relationships, with development progressing (a) toward feelings of mutual respect among persons (with a developmentally prior set of feelings entailing a sense of unilateral respect from child to adult or authority), (b) toward concerns with attaining and maintaining social relationships of cooperation (with rules and laws serving ends of cooperation rather than seen as fixed and categorical), (c) toward the formation of concepts of justice, and (d) toward an ability to consider the perspectives of others as possibly different from one's own (thus accounting for subjectivity and intentionality rather than viewing all perspectives as reflecting objective reality). As based on mutual respect, cooperation, and concepts of rules, laws, and duties as serving ends of fairness and justice, the developmentally advanced form of morality, in Piaget's view, is both inexorable and flexible. Moral concepts and goals have an obligatory quality to individuals but are applied flexibly in accord with requirements of situations, appraisal of intentions, and varying perspectives. The less developmentally advanced heteronomous morality of the young child entails conceptions of fixed rules, duties, and obedience to authority. In this regard, too, Piaget proposed gender differences of a less straightforward kind than those proposed by Freud. In some respects, Piaget (1932) viewed the morality of school-age girls as less advanced than boys (specifically, "the legal sense is far less developed in little girls than in boys"; p. 69), whereas in other respects he viewed girls as more advanced than boys (specifically, girls more readily subordinate rules to cooperation and mutual agreement and are "more tolerant and more easily reconciled to innovations"; p. 75).

Another aspect of Piaget's formulation especially relevant to contemporary analyses of culture and morality is the concept of autonomy. Piaget proposed that as morality develops, there is a shift from a heteronomous to an autonomous orientation. Autonomy in this context does not mean that individuals' conceptions of morality are based on the independence of individuals. Indeed,

the ideas of mutual respect and cooperation, key to Piaget's formulation, imply interdependence rather than independence. By autonomy, Piaget (1960/1995b) meant "that the subject participates in the elaboration of norms instead of receiving them ready-made as happens in the case of the norms of unilateral respect that lie behind heteronomous morality" (p. 315). Therefore, Piaget used autonomy in reference to a process in which norms furthering interdependence are elaborated with the participation of the child.

The concept of autonomy, along with the propositions that obligatory moral judgments are applied with flexibility of thought in social contexts, makes for a fundamental contrast between Piagetian and Freudian or behaviorist approaches. In both the Freudian and behaviorist conceptions, the individual's morality is under some kind of psychological compulsion: In the Freudian view, an internalized conscience or superego compels behavior, and in the behavioristic conception, actions are compelled by habits of behavior. Contemporary analyses discussed in this chapter can also be contrasted on these dimensions as well. Contemporary researchers have examined moral judgments and how they are applied in situational and cultural contexts. There are also various psychological and/or biologically based explanations of moral functioning that are based on how psychological mechanisms compel actions. These include genetic traits and genetically based intuitions and emotions. Some explanations are based on propositions of acquired, learned, or internalized features, such as character traits and conscience. Some are based on internalized values, norms, or rules, such as from parents, society, and culture. Some of these explanations imply moral absolutism, such as genes are fixed and conscience or traits of character are regarded as unvarying. Other explanations imply a degree of moral relativism, such as different parents, societies, or cultural ways result in different groups being compelled in different ways.

As already noted, many issues and questions addressed by Freud, Skinner, and Piaget persist in contemporary analyses of moral development. Their theoretical approaches influenced subsequent researchers working from the 1950s to the 1970s, which in turn have influenced contemporary researchers. The following section presents a brief historical overview connecting the ideas of Skinner and Freud to subsequent research of behavioristically oriented thinkers, who also attempted to account for psychoanalytic concepts. The overview includes a consideration of connections

between the ideas of Piaget and subsequent cognitively oriented thinkers.

### **HISTORICAL OVERVIEW: THE FIRST AND SECOND PARTS OF THE TWENTIETH CENTURY**

Freud's and Piaget's formulations of morality were produced in the context of a fair amount of interest in the topic among social scientists writing in the early part of the twentieth century (Baldwin, 1896; McDougall, 1908). Another influential direction was established by the French sociologist Emile Durkheim (1925/1961, 1912/1965), whose ideas contrasted with those of Piaget (see Piaget, 1932, chap. 4, for his critique of Durkheim's position). Durkheim conceptualized morality as largely based on sentiments of attachment to the group and respect for its symbols, rules, and authority. According to Durkheim, children's immersion in the group and participation in social life produce a natural attachment to the group and a willing adherence to its moral norms.

Many of the issues put forth in the first part of the twentieth century by Freud, Piaget, and others had a major influence on later research on moral development. It took some time, however, for those influences to have their impact. Whereas there was little research from about the early 1930s until the late 1950s, a great deal of research on moral development has been conducted since the late 1950s to the time of this writing. During the late 1950s and early 1960s, there was steadily increasing interest in the child-rearing antecedents of conscience, guilt, and internalized moral values and behaviors (e.g., Hoffman, 1963; Sears, Maccoby, & Levin, 1957). Although the influence of psychoanalytic theory waned over the years, many of Freud's ideas were incorporated into the work on child rearing, alongside the increasingly influential behavioristic theories of that time. Emphasis was placed on identification as a mechanism for the acquisition of moral values and on guilt and anxiety as the basic motives for the child's inhibition of needs or impulses and adherence to moral values. At about the same time, several researchers turned their attention to direct applications of behavioristic learning principles for explanations of the acquisition of moral behaviors and the role of anxiety and guilt in moral actions (e.g., Aronfreed, 1961; Bandura & Walters, 1963).

The dominant conceptions of morality were, therefore, either based on psychoanalytic explanations of conscience and guilt, as transformed by learning theories, or straightforward behavioristic explanations of moral learning. In either type of formulation, moral development was assumed to be a function of societal control over the individual's interests, needs, or impulses. Since then a major shift, brought about in no small measure by the work of Kohlberg, has occurred in psychologists' approach to morality. Kohlberg critiqued the dominant behavioristic and psychoanalytic conceptions of morality (Kohlberg, 1963, 1964), argued for the need to ground empirical study of moral development on sound philosophical definitions of the domain (Kohlberg, 1970, 1971), and presented his own formulations of the process of moral development (Kohlberg, 1963, 1969), entailing modifications and elaborations of Piaget's (1932) earlier formulations.

Kohlberg provided a comprehensive review of research pertaining to what was then the common wisdom that parental practices of discipline determined the strength and accuracy of the acquisition of conscience and moral behaviors. Kohlberg's review documented that there were no consistent relations between those parental conditions of child rearing postulated to lead to learning and the various measures of conscience or internalized values used at the time (see Kohlberg, 1963, for details). Kohlberg also argued that the measures of moral development generally used in that body of research were inadequate because they entailed projective tests of guilt or anxiety, reactions to story stimuli of little moral importance, ambiguous self-reports by parents of their past child-rearing techniques, and contrived experimental situations of little meaning to children.

The message Kohlberg wanted to convey regarding his methodological critique was not only methodological. The inadequacies in methods were, in Kohlberg's view, tied to theories that were not grounded in any substantive epistemology of the domain. Whereas morality was treated as a substantive epistemological category by many philosophers—from Plato and Aristotle to Hume, Mill, and Kant and contemporary philosophers (e.g., John Rawls)—psychologists attempted to explain its acquisition without considering the definition or meaning of that which is acquired. Kohlberg argued that we could not consider mechanisms of moral acquisition without concern with definitions, meanings, and the substance of morality. This idea was also based on psychological considerations. Kohlberg presumed that social scientists

and philosophers were not the only ones who engage in systematic thinking about psychological, social, or moral matters: Laypersons do, too. He rejected the implied duality between the psychologist and the layperson evident in most psychological explanations.

Kohlberg (1968) coined the phrase “the child as a moral philosopher.” However, the metaphor was not meant to convey the idea that children engage in reflective intellectual deliberations or formulate conceptual systems of the type seen in the writings of professional moral philosophers. Rather, it was meant to convey the idea that children form ways of thinking through their social experiences, which include substantive understandings of moral concepts like justice, rights, equality, and welfare. Implicit but important assumptions in this formulation are that morality is not solely, or even mainly, imposed on children and that morality is not solely based on avoiding negative emotions like anxiety and guilt. As part of their orientation to social relationships, and especially through taking the perspectives of others, children generate judgments, built on emotions like sympathy, empathy, respect, love, and attachment to which they have a commitment and which are not in conflict with their “natural” or biological dispositions (recall Piaget’s definition of moral autonomy).

Kohlberg studied moral development by focusing on how children and adolescents make judgments about conflicts, in hypothetical situations, around issues of life, interpersonal obligations, trust, law, authority, and retribution. He proposed a sequence of six stages, depicting a progression of judgments. Stages 1 and 2, grouped into a “preconventional” level, were primarily based on obedience, punishment avoidance, and instrumental need and exchange. Stages 3 and 4, grouped into a “conventional” level, were based on role obligations, stereotypical conceptions of good persons, and respect for the rules and authority legitimated in the social system. Stages 5 and 6, grouped into a “postconventional” level, were based on contractual agreements, established procedural arrangements for adjudicating conflicts, mutual respect, and differentiated concepts of justice and rights. This sequence was also a reformulation of Piaget’s progression from heteronomy to autonomy (Kohlberg, 1963). Kohlberg maintained that respect for rules and authority, which Piaget had attributed to young children at the heteronomous level, does not come about at least until adolescence (Kohlberg’s conventional level), and that young children’s moral judgments are characterized, instead, by a failure to distinguish

moral value from power, sanctions, and instrumental needs. In turn, Kohlberg proposed that mutual respect and concepts of justice and rights as part of an autonomous system of thought, whose emergence Piaget had placed in late childhood or early adolescence, do not come about until, at the earliest, late adolescence and usually not until adulthood (Kohlberg’s postconventional level).

Kohlberg also proposed that the stages represent universal forms of moral judgment among individuals participating in social interactions and perspective taking. He proposed that the stages defined structural features of moral thought, which represented commonalities among cultures in the context of possible differences in the content of morality. By undertaking a series of studies in several cultures, some Western and some non-Western (Kohlberg, 1969), Kohlberg gave greater emphasis than existed before to empirical data to test propositions regarding cultural differences or commonalities in moral judgments. Kohlberg’s research, as well as many studies conducted by others, suggested both that there may be similarities across cultures in development through the first three or four stages and that there is much ambiguity of thought corresponding to the higher stages (see Snarey, 1985). As discussed in subsequent sections, the question of cultural differences and commonalities has provoked much controversy. Nevertheless, Kohlberg’s work in this regard has been influential in framing discussions of morality and culture around empirical findings.

Kohlberg’s influence on subsequent research and theories is, in important respects, separate from the influence of his particular formulation of stages of moral development or even from the general theoretical viewpoint he espoused. Many advance alternative theoretical paradigms, including paradigms based on the idea of the internalization of conscience and values or the idea of culture-based morality. Among those who advance developmental positions influenced by Piaget’s theory, many propose formulations divergent from that of Kohlberg. Yet, Kohlberg has influenced discourse about the psychology of moral development in several ways. One is that there is greater recognition of the need to ground psychological explanations in philosophical considerations about morality. Another influence is that in many current formulations morality is not framed by impositions on children due to conflicts between their needs or interests and the requirements of society or the group. Many now think that children are, in an active

and positive sense, integrated into their social relationships with adults and peers and that morality is not solely or even primarily an external or unwanted imposition on them. Kohlberg had stressed children's constructions of moral judgments from social interactions. Following Piaget's formulations, Kohlberg proposed that emotions of sympathy for others, spontaneous interests in helping others, and respect were centrally involved in children's moral development, especially as part of the process of taking the perspective of others (Kohlberg, 1969, 1971, 1976).

All the changes in perspectives on moral development cannot be attributed solely to Kohlberg's influence. The issues noted are ones he addressed directly and for which he provided persuasive arguments. Nor do contemporary analyses of moral development exclude elements of the positions taken by behavioristic and psychoanalytic theorists. There are researchers concerned with the internalization of values, the ideas of conscience and self-control, and with emotions like anxiety, shame, and guilt. Nevertheless, the scope of inquiry has been broadened to include and emphasize positive emotions; the intricacies of moral, social, and personal judgments as part of individuals' relations with the social world; and social interactions contributing to development, including with parents, peers, schooling, and culture. Debates now center on the roles of emotions and judgments, on the individual and the collectivity, on the contributions of constructions of moral understandings and culturally based meanings, and on how to distinguish between universally applicable and locally based moralities.

## ISSUES, EMPHASES, AND THEORIES

Discussions of moral development seem to involve strongly held and conflicting positions. It is frequently asserted that positions held by others exclude a particular feature of central importance—usually the feature emphasized by those characterizing the other's approach. Portraying others as excluding a feature deemed of central importance extends well beyond debates over moral development. Probably the most common example is seen in the debates over the roles of biology and environment. Those debates seem to be everlasting and there is a recycling of the issues even though periodically there appears something of a consensus that such de-

bates are futile because both biology and environment contribute to psychological functioning and development. One reason for this state of affairs is that the question is usually mischaracterized as whether biology or environment is taken into account rather than *how* each feature is explained. An equally important reason for the continual reemergence of the debates is that these matters are not settled, yet researchers pursuing different and even opposite explanations tend to declare matters settled.

For example, consider assertions about supposedly new disciplines: One labeled cultural psychology (Shweder, 1990a; Shweder & Sullivan, 1993) and the other evolutionary psychology (Cosmides & Tooby, 1989; Tooby, 1987; Wright, 1994). Proponents of cultural psychology maintain that thoughts, meanings, emotions, and behaviors vary by culture. Consequently, they propose that there are no general psychological processes to be discovered: "[T]he mind . . . is content driven, domain specific, and constructively stimulus bound" (Shweder, 1990a, p. 87), with an emphasis on that which is local, contingent, and context-dependent. Cultural psychology is said to be a newly emerging discipline entailing "the study of the way cultural traditions and social practices regulate, express, and transform the human psyche, resulting less in psychic unity for humankind than in ethnic divergences in mind, self, and emotion" (Shweder, 1990a, p. 73).

By contrast, proponents of evolutionary psychology maintain that mind and behavior have a firm evolutionary basis, which makes for a "unity within the species" connecting the peoples of the world. According to evolutionary psychologists, social relationships, and especially relationships between the sexes, including and going well beyond reproductive functions, are highly influenced by evolutionary processes. Evolutionary processes extend to morality: "Altruism, compassion, empathy, love, conscience, the sense of justice—all these things, the things that hold society together, the things that allow our species to think so highly of itself, can now confidently be said to have a firm genetic basis" (Wright, 1994, p. 12). Confidence in a firm genetic basis brings with it confidence in uniformities among people of different cultures: "Evolutionary psychologists are pursuing what is known in the trade as 'the psychic unity of humankind'" (Wright, 1994, p. 26).

Along with the striking confidence expressed by cultural and evolutionary psychologists in discoveries

against and for the psychic unity of humankind, they make other parallel claims. They claim that the discipline has discovered knowledge contrary to the established perspective in psychology that will be resisted by those with vested interests in the old paradigm. Cultural psychologists argue that psychology and other social sciences have been dominated by those seeking psychic unity and proposing general psychological mechanisms. Evolutionary psychologists argue that psychology and other social sciences have been dominated by those seeking environmental and cultural explanations.

If the content were omitted, it would appear that cultural and evolutionary psychologists are in agreement about the past and future of psychology. Each asserts that there is a previously dominant paradigm about which its proponents are defensive and resistant to change but which is being displaced by a new paradigm. Yet, they hold contradictory views about which paradigm was previously dominant and which one is taking over. Not only are levels of the state of knowledge and documentation and verification for discoveries exaggerated so that matters are prematurely claimed to be settled, but also opposing positions are characterized as accounting for mainly one type of feature. This is an old story. Behaviorists made similar claims early in the twentieth century. Most notably, Watson (1924) proclaimed that behaviorism was the wave of the future that would replace the prescientific thinking of the mass of people and of psychologists through its experimental approach and the recognition of the ways environment shapes behavior (Turiel, 2004a).

Among theorists of moral development, there seems to be a greater recognition of the viability of competing points of view. However, it is not uncommon to find characterizations of others' explanations of moral development as excluding a feature judged to be of central importance. It is implied that the omission, in itself, invalidates the theoretical point of view. The most frequent examples of this revolve around whether theorists account for emotions or judgments, for social influences or the individual's logical operations, for parental influences or peer influences, and for cultural or individual constructions. There is a tendency to mischaracterize positions as failing to account for this or that instead of recognizing that differences in theoretical perspectives have more to do with how different features (e.g., emotions and judgments) are explained and emphasized. Even when a theorist excludes a particular component

regarded important by others, it is usually mistaken to say that there is a failure to account for the component. Often, the relevance of a component is explicitly excluded. An example is Skinner's (1971) arguments for the exclusion of moral judgments, along with cognition in general, as epiphenomena.

It is important, therefore, to consider how a theoretical perspective frames the relevant issues. In current theoretical perspectives and research programs, it is particularly important to consider how issues like emotion, culture, gender, judgment, social influences, and individual constructions are explained. Indeed, emphases placed on these issues serve to distinguish points of view on moral development. Whereas most explanations of moral development attempt to account for each of these issues, there are differences in the importance and roles given to them that result in varying explanations of morality and its development.

This chapter is organized around theoretical approaches to moral development, with the central issues emphasized. There is a tradition in which morality is defined as the possession of habits or virtues or traits of character, which are usually linked tightly with emotions. In recent years, psychologists have not emphasized habits or traits. Many have moved away from explanations of morality as the formation of internal traits or dispositions of personality. Nonetheless, there are sizable groups, including those concerned with moral education and certain sociologists and social commentators, who rely on the concept of character as linked more to emotions than to reasoning. Some of this literature—that on character and moral education (often referred to as character education)—will not be considered here, as it is the topic of the chapter by Narvaez and Lapsley, Chapter 7, this *Handbook*, Volume 4. Narvaez and Lapsley also consider propositions using the notions of character and moral identity as bridging moral judgments to moral actions (for a critique and alternative view, see Turiel, 2003a). However, I do discuss some views outside of psychology that are presented by social critics and sociologists who link emotions to the formation of character traits and/or habitual moral practices. Their positions have connections to psychological concepts and can be evaluated by psychological evidence. After discussing their positions, I consider, in greater detail, the concepts and research of developmental psychologists who emphasize emotions, influences of parental practices, and conscience. This is followed by

discussion of approaches that, though including emotions and judgments, emphasize the role of gender and gender-related experiences in moral development. Then, I consider approaches in which culture is regarded as central and in which fairly sharp distinctions are drawn among moral orientations in different cultures. Next, I discuss approaches emphasizing moral judgments and reciprocal interactions in development. Finally, a perspective is presented based on reciprocal interactions; the domains of personal, social, and moral judgments; and their interplay with cultural practices. I approach each of the positions, and associated research, from the perspectives of their conceptualizations of the moral realm, the theoretical constructs on development, and the ways development is influenced by biological and environmental features.

In the course of this chapter, I do not solely review the different positions on moral development. While presenting the different positions, I comment on and evaluate the positions. Those evaluations are connected to my own views and positions. In the latter parts of the chapter, I discuss my positions, which are shared by a number of colleagues and collaborators.

## **BUILDING CHARACTER AND STRENGTHENING COMMUNITIES**

Some philosophers who trace their roots to Aristotle have proposed explanations of morality as entailing virtues and character. Aristotelian and neo-Aristotelian accounts (e.g., MacIntyre, 1981) have included conceptions of morality as the good life, reflected in habitual practices and in living up to the virtues through action. Although Aristotle linked virtues to tradition, he also believed that traditions should not necessarily remain fixed or immune from criticism. According to Nussbaum (1989), Aristotle's position was "If we reason well we can make progress in lawmaking, just as we do in other arts and sciences" (p. 36). However, the sociologists and social critics who stress the concept of character have not carried over the philosophical substance of the Aristotelian and neo-Aristotelian propositions, at least as interpreted by Nussbaum. Instead, they have used the concepts of character as a means of commenting on the state of American society. It has been proposed that American children's acquisition of moral habits requires a renewed valuing of cultural traditions and commitment to a sense of community, along with a de-emphasis of individualism. Positions emphasizing

community have affinities to Durkheim's (1925/1961) proposition that morality involves a collective sense of solidarity, experienced by individuals as feelings of attachments to and respect for the moral authority embedded in society.

The common themes in these positions are that habits and character traits are at the core of morality and that American society is in moral crisis, decay, or serious decline. Myriad causes have been offered as bringing about the decline. These include the culture of the 1960s (Bloom, 1987); changes in the family (Bloom, 1987; Etzioni, 1993; Wilson, 1993); a failure to attend to traditions (Bennett, 1993; Etzioni, 1993; K. Ryan, 1989; Wynne, 1986, 1989); a failure to provide moral education (Bennett & Delattre, 1978); an onset of radical individualism (Bellah, Madsen, Sullivan, Swidler, & Tipton, 1985; Etzioni, 1993); the influences of feminism (Bloom, 1987); and the teachings of elites (intellectuals, scholars) who, in contradiction with the common sense or natural propensities of ordinary people, create theories hostile to virtues and character (Bennett, 1992; Bloom, 1987; Wilson, 1993).

## **Character Traits and Moral Sensibilities**

Some who lament the moral decline of American society propose that the remedy lies in promoting character in children through firm controls by adults in the family and schools. They find fault in programs of moral education (especially those based on Kohlberg's theories) whose pedagogical aims are to stimulate the development of moral judgments, reflection, or the consideration of alternative moral decisions (see Bennett & Delattre, 1978). Judgment is deemed largely tangential to morality, and its emphasis is said to divert children from learning to behave in habitual ways consistent with traditions and virtues.

It is argued that, instead, there should be an emphasis on the inculcation of traits in children, with a focus on influencing how they act and not on their states of mind (Wynne, 1986). The traits, which are based on traditions of the culture, are transmitted not only through rewards and punishments but also, especially, through the example provided by the consistent actions of adults practicing the values and in the telling and retelling of stories about people behaving in accord with those values. The fundamental traits of character include honesty, compassion, courage, responsibility, self-discipline, and loyalty.

The premise that traits of character are ingrained in cultural traditions and held in respect by the majority of Americans may appear contradictory with the proposition put forth by the same writers that American society has lost its moral compass and is experiencing moral decay (the latter premise suggests that Americans do not possess the necessary traits). This potential contradiction is explained as due to a discrepancy between the beliefs and values of the majority of Americans, who constitute the mainstream, and an apparently highly influential minority of “elites” who “have waged an all-out assault on common sense and the common values of the American people” (Bennett, 1992, p. 13). In ways unspecified, the presumed elites’ rejection of the idea of character, their antipathy to the culture, and their embrace of an ideology contrary to the beliefs of most Americans are said to have placed the country in moral crisis.

These propositions are at root paradoxical because if people acquire character and habits through the example of others and if the majority of mainstream Americans maintain the morally proper traits and beliefs, then it would be expected that there are many examples from which children would learn. Presumably, children are exposed to exemplary virtues in most families, schools, and elsewhere. A similar paradox is seen in the propositions of Wilson (1993), another social scientist who shares some of the emphasis on character, while attempting to account for evidence from psychology, anthropology, economics, and biology in formulating a theory of morality and its acquisition based on emotions and innate sociability. Wilson sees a loss of confidence in the use of the language of morality due to a prevailing moral skepticism perpetuated by “intellectuals” who question the scientific bases for morality and who further an ideology of individual autonomy and choice. At the same time, Wilson’s explanation of morality is founded on the proposition that a natural moral sense emerged in the process of evolution and that most people’s moral behaviors are determined largely by emotions and habits: “Much of the time our inclination toward fair play or our sympathy for the plight of others are immediate and instinctive, a reflex of our emotions more than an act of our intellect. . . . The feelings on which people act are often superior to the arguments that they employ” (Wilson, 1993, pp. 7–8).

In Wilson’s formulation, although reasoning, reflection, and deliberation may emerge later in life than the reflexive and habitual, they are less adaptive, from the

moral point of view, than the earlier emerging moral sensibilities. Such a reversal of often-held conceptions of development (where reasoning and reflection are advances built on earlier reflexive processes) is based on the idea that morality stems from natural emotions, whose emergence is best facilitated by early experiences in appropriate types of families (i.e., defined by Wilson as intact, heterosexual families where parents provide love, nurturance, and act authoritatively). Evolution, Wilson argues, has selected for attachment or affiliative behavior. In addition to natural selection for reproductive success, with a disposition toward self-interest, there is a biologically based disposition for bonding and attachment that takes the form of sociability. Innate sociability is the overriding component in producing four central “sentiments” that make up the moral life: *sympathy* (allowing people to be affected by the feelings and experiences of others), *fairness* (based on equity, reciprocity, and impartiality), *self-control* (a necessary sensibility because conflicts arise between self-interest and the moral sense), and *duty* or conscience (which dictates actions in the absence of sanctions).

In keeping with a de-emphasis of individuals’ reasoning and reflection, Wilson believes that morality is, in most instances, local and parochial. In simple agricultural communities, and in Western cultures prior to the Enlightenment, the moral sense applies to those who are similar and familiar to oneself (kin and the local community). The idea that moral considerations should be universalized is a Western concept stemming from the Enlightenment and the advent of individualism.

The idea that morality is constituted by moral sentiments guiding behavior in instinctive and reflexive ways is akin to the idea that morality comprises habitual behaviors reflecting traits or dispositions. Wilson goes beyond solely describing traits by attempting to explain the sources of moral sensibility in biologically based dispositions toward sociability and attachments. This type of link between emotions and habitual behaviors also has affinities with those who regard emotions as linked to habits based on commitments to community.

### Habits and the Communitarian Spirit

As noted, those who believe that individuals need to form tighter and better attachments to communities that transcend individual goals echo the theme of a moral decline in American society. Not surprisingly, the emphasis on community is evident in works of sociologists—

among the most visible are Etzioni's (1993) *The Spirit of Community* (also Etzioni, 1996) and Bellah et al.'s (1985) *Habits of the Heart*. With regard to the moral status of American society, Etzioni (1993) has asserted that because of a waning of traditional values, without an affirmation of new values, "we live in a state of everlasting moral confusion and social anarchy" (p. 12). Bellah et al. (1985) assert that American "individualism may have grown cancerous" (p. vii), and that "we seem to be hovering on the very brink of disaster . . . from the internal incoherence of society" (p. 284). They ask: "How can we reverse the slide toward the abyss?" (p. 284).

The call for a greater sense of community is necessary to reverse a supposed breakdown in society connected to a supposed overemphasis on personal goals and individual rights that is part of the cultural ethos. The cultural ethos of rights and individualism is seen as, in large measure, a contemporary phenomenon at odds with the traditions of social commitment and responsibility. To a good extent, a return to past practices is required. Much of the reason there is a need for a return to past practices and recommitment to moral values, restoration of law and order, and rebuilding of the foundation of society is that Americans have become overly concerned with rights (there has been an "explosion" of rights, and "incessant issuance of new rights") and a concomitant "elevation of the unbridled pursuit of self-interest and greed to the level of social virtue" (Etzioni, 1993, p. 24). However, the call is not for an elimination of all personal rights, but for a renewed balance of rights and responsibilities. To accomplish such a balance, Etzioni recommends a moratorium on virtually all new rights for a decade, a reaffirmation of responsibilities, and a restoration of communities. Essential to the renewal are changes in family structure—ranging from maintaining two-parent families (such as by legislating a lengthy waiting period for remarriage after divorce) to reinstating the ritual of the family meal.

Bellah et al.'s (1985) analyses of late-twentieth-century American culture adopt the idea of "national character"—the American character is firmly, and legitimately from the moral point of view, individualistic. In the past, American individualism was characterized by personal autonomy, self-reliance, and individual initiative, with beliefs in the dignity of the individual, a valuing of equality, and questioning of fixed social ranks and subjugation of persons.

In its traditional form, however, individualism was balanced with commitment to the moral order and at-

tachments to family, church, and community. American society is "hovering on the brink of disaster" and sliding "toward the abyss" because individualism is no longer balanced (Bellah et al., 1985, p. 284). There is now a radical individualism, characterized by isolation, separation, independence from the past (from a "community of memory"), with personal choice and individual fulfillment placed over attachment to family, social institutions (e.g., the church), and community. Moral goals have been transformed into ones of economic effectiveness, self-fulfillment, and personal satisfaction. The proposed solution—the way to avoid the abyss—is to achieve a balance by attenuating individualism and by restoring traditions, a sense of community, and concerns for the common good.

### Moral Appraisal and Moral Recommendations

The writings on character and the need for restoration of a sense of community have applied components because much of the focus is on changing society and people. However, the validity of the proposed social recommendations rest on assertions about the moral state of society in the present and past (i.e., moral crisis, decay now and a better moral state of affairs then); about the nature of individuals' morality in the past and present (i.e., firm character traits and commitment to virtues and community then but not now); and about the causes of moral problems in the present (i.e., selfishness, individualism, failures of commitment and community, and changes in family life). Those assertions are subject to social scientific analysis and imply assumptions about the process of successful moral development. It is assumed that in the past morality was acquired through training in character or commitment to family and community and that society was then more successful morally. On that basis, it is assumed that adequate moral development should proceed (and be facilitated) as it did in the past. These assumptions about the psychology of moral development, however, are not grounded on detailed psychological and developmental analyses or empirical evidence. Instead, the line of reasoning rests on certain key untested assumptions.

One is the repeatedly stated assumption of the moral downslide. The causes attributed to the moral decline of the society are quite varied, and many of those causes reflect disagreements about the events with others who would regard them as having promoted moral goals. As examples, many would regard as furthering moral ends events in the 1960s (especially the anti-Vietnam War

and civil rights movements), feminism, and the assertion of rights for groups faced with discrimination. Furthermore, the only evidence provided for the sweeping claims of moral decline is some data, open to varying interpretations, on increases (since the 1950s) of rates of suicide, homicide, and out-of-wedlock births (Wynne, 1986).

The vast societal changes over the past two centuries, however, make it very difficult to document whether there has been decay, improvement, or simply patterns of positive and negative changes associated with different realms of social life. To cite some salient examples of morally relevant (and often viewed as positive) societal shifts, there have been changes in (a) race relations and treatment of minority groups; (b) the roles, burdens, and privileges of women; (c) the treatment of children and the conditions of work for children; (d) the workforce and labor relations more generally; (e) the care of the elderly; (f) the levels of political representation of many groups (including women); (g) the numbers of people receiving higher levels of education; and (h) the power and authority relationships among those of higher and lower social classes.

No analyses have been provided of the ways all these changes might constitute some betterment of the lives of people or of how past practices may have produced harm. Even with regard to violence and homicide—for which there are statistics documenting its prevalence in contemporary society—there are good indications that they are traditional in American society and were prevalent in the past (Butterfield, 1995). Moreover, to the extent that there is documentation regarding levels of honesty, it reveals that even in the early part of the twentieth century children exhibited a fair amount of dishonesty in school activities and in experimental tasks (Hartshorne & May, 1928, 1929, 1930). And strikingly similar concerns with moral decay existed in Western countries. During the 1920s, much concern was expressed in the United States regarding the moral state of youth, cultural disintegration, and social chaos (see Fass, 1977). Similarly, in *fin-de-siècle* France (the late 1800s), there were widespread concerns with moral degeneration, national decline, the declining morality of youth (e.g., an explosion of juvenile crime rates), and calls for renewal of the society (see Norris, 1996). In each instance, similar claims were made about moral crisis and decay in society and about the “good old days” (see Turiel, 2002, for discussion of these issues).

These examples demonstrate the complexity of social and moral change through history and suggest that we are

seeing stereotypic impressions and speculations of the morality of the present, along with nostalgic views of the past (Turiel, 2002). Without solid evidence of negative changes in the morality of the society, it cannot be concluded that the ways morality was transmitted in the past are the most efficacious (similar considerations apply to claims that recent activities, such as of the 1960s or feminism, have caused moral decay). It may be that the proposed explanations of the process of moral development would hold for the past (and present) even in the absence of any considerations of moral decline. However, the assertions about how morality was transmitted or acquired in the past are themselves undocumented.

At best, the propositions regarding moral development as the acquisition of character traits or as commitment to community must be seen as standing alongside several other competing explanations. However, the basic concepts used still require research so as to know more about the parameters of the habitual, the criteria for an adequate commitment to community, and how these are acquired. Several of the psychological, social, and cultural issues raised by those lamenting the moral state of society arise in research on moral development. For instance, the propositions regarding the family as a central influence on moral development through parental example and training represents only one perspective on the family. Others have attempted to account for the effects of the structure (e.g., extent of a hierarchical structure) of the family, its particular practices in terms of their fairness and justice, and the content of communications and proclaimed ideology. Furthermore, many researchers have given a fair amount of emphasis to the influences of other social experiences (e.g., with peers, in school, or in relation to culture), to the ways children account for heterogeneity of social experiences, and to their ways of constructing judgments about those different dimensions of social experience.

## EMPHASIZING EMOTIONS

Emotions have been considered the basis for morality by some philosophers, and have been central in certain psychologists' formulations. As already noted, the Freudian and behavioristic conceptions relied heavily on emotions as the basis for the acquisition of morality—though in different ways from each other. However, both saw the acquisition of morally obligatory actions as a process by which aversive emotions are central to moral

learning and maintenance. Therefore, most emphasis was given to emotions of fear, anxiety, shame, and guilt in their explanations of moral acquisition. Aversive emotions were seen as forces that served to transform the individual's natural inclinations into needs and desires in a psychological make-up that included a "conscience" or behaviors consistent with societal norms or values. However, a major shift in thinking about emotions in the late 1970s and through the 1980s entailed a focus on attachment, bonding, love, sympathy, and empathy.

The emphasis on these emotions included continued concerns with the influences of the family (in keeping with Freudian and behavioristic accounts), the role of aversive emotions, and a renewed interest in the evolutionary sources of emotions. Research demonstrating that very young children display positive emotions and affiliate and bond with others was particularly influential in the shift (Dunn, 1987, 1988; Dunn, Brown, & Maguire, 1995; Hoffman, 1991a, 1991b; Kochanska, 1993, 1994). Another set of relevant findings show that young children are sensitive to the interests and well-being of others, producing actions of a prosocial or altruistic nature. That body of research is not reviewed in this chapter as it is the topic of the chapter by Eisenberg, Fabes, and Spinrad in Chapter 11, this *Handbook*, this volume, but the general pattern of findings is that young children engage in acts of sharing and helping or altruism. As put by Zahn-Waxler, Radke-Yarrow, Wagner, and Chapman (1992): "The evidence for early moral internalization, however, highlights the need to reformulate theories emphasizing the egocentrism and narcissism of young children" (p. 133). Studies conducted in the home show that even children under 2 years of age share possessions (e.g., toys) with others, help mothers with household tasks, cooperate in games, and respond to the emotional distress of others (Radke-Yarrow, Zahn-Waxler, & Chapman, 1983). Toddlers and young children, in addition, show comfort and engage in caregiving of others. It also appears that reactions of empathy emerge by age 3 (Lennon & Eisenberg, 1987; Zahn-Waxler et al., 1992). Moreover, distinctions drawn among reactions of empathy have a bearing on the relations of emotions to prosocial or altruistic behaviors (Carlo, 2006; Eisenberg & Fabes, 1990, 1991; Eisenberg, Spinrad, & Sadorsky, 2006).

Empathy, defined as an emotional response stemming from another's emotional state, can result in sympathy or "personal distress." Sympathy goes beyond solely experiencing an emotional reaction to another

similar to the other's feelings in that it entails an other-oriented response and concern for that person's well-being. Empathy can also result, by contrast, in personal distress, which entails a self-focused aversive reaction (e.g., anxiety, discomfort) to the distress of another; the motivation is to alleviate one's own aversive state (see Eisenberg & Fabes, 1990, 1991; Eisenberg, Fabes, & Spinrad in Chapter 11, this *Handbook*, this volume, for further discussion). There is also evidence that children's feelings of empathy are related to their prosocial actions (Eisenberg & Miller, 1987; Eisenberg & Strayer, 1987). In particular, measures of facial and psychological indexes of affect have shown that sympathy, and not personal distress, is positively related to prosocial actions motivated by concerns for the welfare of others (Eisenberg & Fabes, 1991).

The research findings on sympathy and prosocial actions are inconsistent with the idea that children, before they have internalized parental values, or societal standards, or have been taught to behave in socially sanctioned ways, will act solely in selfish and self-directed ways when they are not coerced or fearful of detection. It does not necessarily follow that sympathy and spontaneous prosocial behaviors at a very young age reflect innate dispositions or that morality is primarily based on emotions (to be discussed). Moreover, questions still exist regarding the validity of age-related findings in empathic responses, the need to draw further distinctions between closely aligned emotions, and the development of more adequate methods of measurement (Eisenberg & Fabes, 1991). The findings on sympathy and prosocial actions are not inconsistent with emotive positions on morality. In several formulations, it has been proposed that morality is directed more by emotions than reasoning (Dunn, 1987, 1988; Haidt, 2001; Hoffman, 1984, 1991b; Kagan, 1984; Kochanska, 1993, 1994).

### A Primacy for Empathy

Empathy has been considered primary in moral development by some who do not rely heavily on associations of unpleasant and pleasant affect with morality. Hoffman (1991a, 1991b, 2000) has put forth a formulation combining emotion due to evolution with internalization, in that "the society's moral norms and values [are made] part of the individual's personal motive system" (1991a, p. 106). In addition to emotion and internalization, this approach includes motives, cognition, moral principles of care and justice, and perspective taking.

Despite the attempt to incorporate all these features, it can be said that primacy is given to emotion because the linchpin is empathy.

Hoffman distinguishes his approach from those giving primacy to moral judgments in that he defines moral actions in motivational terms. A moral act is “a disposition to do something on behalf of another person, or to behave in accord with a moral norm or standard bearing on human welfare or justice” (Hoffman, 1991b, p. 276). The distinction between defining a moral act in terms of moral judgment or motives is not unambiguous (Blasi, 1993; Turiel, 2003a). It could be said that the moral judgments one makes—say that one should come to the aid of another in distress because it is wrong to allow suffering—motivates one to act. The key to the distinction is in the term *disposition* in the definition of a moral act—disposition referring to an emotional reaction that propels action. The main source of moral motives is the feeling of empathy, which is defined as an affective response that does not necessarily match another’s affective state. By putting the matter in affective-motivational terms, Hoffman poses the question, “Why act morally?” and answers in terms of feelings that need to be acted on.

Although empathy is regarded as a biological predisposition and a product of natural selection, it is characterized as developing through four stagelike manifestations that are partly determined by changing cognitive capabilities. The first of these stages is characterized simply by the “global” distress felt by infants (during the 1st year) entailing a confusion of the infant’s own feelings with those of another. At the second stage of “egocentric” empathy (age of 1 year), the onset of object permanence allows for an awareness that other people are physically distinct from the self and a concern (“sympathetic distress”) with another person who is in distress. However, children do not distinguish between their own or other’s internal states.

Hoffman further asserts that role taking emerges at about 2 or 3 years of age (this, however, is a controversial issue), allowing for a differentiation of the child’s own feelings from those of others. At the third stage, therefore, children are responsive to cues about the other person’s feelings and empathize with a range of emotions other than distress (e.g., disappointment, feelings of betrayal). Whereas the third stage is labeled “empathy for another’s feelings,” the fourth stage, emerging in late childhood is labeled “empathy for another’s life conditions.” The relevant social cognitions

for the fourth stage are children’s awareness of self and others with separate identities. These conceptions allow for awareness that others feel pleasure and pain in their general life experiences. At this stage, empathy is felt in particular situations, as well as for more general life circumstances of others or of groups of people (e.g., the poor or the oppressed).

Whether this sequence of stages is an accurate representation of how children develop is undetermined because the stages were not, for the most part, based on empirical evidence. There is some evidence that infants respond to the actual crying of other infants to a greater extent than to sounds resembling the crying of human infants (Sagi & Hoffman, 1976). However, it is not entirely clear that this type of response is a form of very early empathy. The other stages have not been tested empirically and, instead, rely on illustrations with the types of anecdotal examples previously mentioned. Research by Zahn-Waxler and her colleagues (Hastings, Zahn-Waxler, & McShane, 2006; Zahn-Waxler, Robinson, & Emde, 1992; Zahn-Waxler et al., 1992) does provide some evidence that young children show empathic reactions to the distress of others and attempt to understand the nature of the distress (see Eisenberg, Fabes, & Spinard, Chapter 11, this *Handbook*, this volume, for discussion of further distinctions in the general construct of empathy).

In later writings, Hoffman (2000) attempted to identify situations in which empathic reactions and moral actions occur. He labeled these moral encounters and proposed that five “encompass most of the prosocial domain” (Hoffman, 2000, p. 3). These include situations in which a person is an innocent bystander (witnessing someone in pain or distress), a transgressor (harming or about to harm someone), or a “virtual transgressor” (an imagined harmful act). The two others are situations in which there are “multiple moral claimants” (where a person has to make choices about who to help) and in which there is a clash between caring and justice (between considering others and abstract issues of rights, duty, and reciprocity). These categories are meant to capture the situations that evoke guilt and empathic responses. Empathy is also supposedly associated with a variety of moral reactions, including sympathy, aggression or anger at another who injures people, guilt, and feelings of injustice (empathy due to perceived unfairness of a situation). Indeed, in Hoffman’s perspective, moral principles of care and injustice are validated by emotions.

Hoffman invoked a distinction between “cool” and “hot” cognitions with regard to moral principles. Moral principles, in that view, can be so-called cool cognitions because they are detached from emotions. The association of empathy with principles renders them “hot”—morally meaningful and linked to action. At least as common, if not more common, a perspective, especially among philosophers (but also see Baldwin, 1896; Kohlberg, 1971; Piaget, 1932), is that to the extent that moral principles are understood by people in ways that are part of their belief systems and mental functioning, it is not necessary that they receive their force from other elements (like empathy) so as to render them meaningful. Instead, there is a synthesis between judgments and emotions, making it difficult to disentangle the two.

### Evolution and Internalization

The formulations of morality emphasizing emotions illustrate that, in many instances, asking whether theories are based on nature or nurture, or biology or environment, is not useful. These positions show a firm orientation to evolutionary-based biological processes and to influences of the family, historical contexts, and culture. Much of the research on the internalization side has focused on the family, examining the types of parental child-rearing practices producing more and stronger incorporations of moral standards by children. A large body of research (for reviews, see Eisenberg, Fabes, & Spinard, Chapter 11, this *Handbook*, this volume; Hoffman, 1970; Maccoby & Martin, 1983) has examined, mainly through self-reports, parental child-rearing practices, along with various measures of moral functioning. Three types of parental practices were identified. One is referred to as power assertion, mainly involving physical punishment, deprivation of goods or privileges, and threats of force. The second, love withdrawal, involves disapproval and other expressions of the removal of affection or emotional supports. The third type, referred to as induction, entails the communication of reasons or explanations for the prescribed behavior, including appeals for concerns with the welfare of others.

Parental reports of their use of these discipline techniques have been correlated with measures of children's guilt (e.g., children's tendencies to confession to misdeeds; projective measures of story completions), an external or internal orientation to moral stories (i.e., if they judge by fear of external sanctions or by an evaluation of the act's wrongness), and whether children resist

the temptation to engage in a prohibited act (e.g., often measured in experimental situations). A consistent finding from these studies is that parental practices of induction are the most successful method of discipline (Hoffman, 1970; Hoffman & Saltzstein, 1967; Maccoby & Martin, 1983). Measures reflecting moral development are correlated more with induction than love withdrawal or power assertion. For example, a moral orientation based on fear of sanctions is correlated with parental practices of physical punishment, whereas expressions of guilt and an internal orientation are correlated with parental practices that emphasize explaining reasons for avoiding or engaging in moral actions.

### Conscience and Internalization

By including natural or biological features, these perspectives go beyond earlier socialization perspectives by which it was assumed that morality could be adequately defined through consensual norms (Berkowitz, 1964; Maccoby, 1968; Skinner, 1971). However, some contemporary researchers have addressed hypotheses regarding moral internalization—defining morality through consensual norms—with the assumption that morality entails the acquisition of a conscience serving to internally regulate conduct consistent with societal values, norms, or rules (Kochanska, 1993, 1994; Thompson, Mayer, & McGinley, 2006). The concept of conscience, central to Freud's theory, was also central to behavioristic conceptions in which internalization was theorized to be acquired through the anxiety associated with punishments for transgressions (Aronfreed, 1968). Whether it be from a psychoanalytic or behavioristic perspective, the concept of conscience has been used to refer to a mechanism internalized by children for exerting control on needs that would otherwise be acted on: “Conscience is the term that has been used traditionally to refer to the cognitive and affective processes which constitute an internalized moral governor over an individual's conduct” (Aronfreed, 1968, p. 2).

In a contemporary formulation that has affinities with earlier positions on conscience and that includes elements of other socioemotional perspectives, Kochanska (1993, 1994) has examined conscience as regulation due to internalization marking successful socialization as “the gradual developmental shift from external to internal regulation that results in the child's ability to conform to societal standards of conduct and to restrain antisocial or destructive impulses, even in the absence of surveillance” (1993, pp. 325–326). Moreover, the for-

mation of conscience is functional from the societal perspective: "Without reliance on internalized consciences, societies would have to instill ever-present surveillance in all aspects of social life" (Kochanska, 1994, p. 20). This position includes a shift in balance away from natural moral propensities of concerns with the welfare of others back to more of an emphasis on the need to control antisocial and destructive tendencies. Ultimately, it is society that has to control the behavior of individuals, either by instilling control internally in children or through continual and all-encompassing ("in all aspects of social life") external control.

In keeping with the traditional conception of conscience, it was proposed that it is encompassed by "affective discomfort" or the various aversive emotional reactions to acts of transgression and "behavioral control." Reactions of sympathy and empathy contribute to the process of development, but they do so through the anxiety and distress they can arouse in a child. One focus is on anxiety, fear arousal, and discomfort in the process of internalizing moral prohibitions. A significant aspect of this process is that parental socialization contributes greatly through arousal of children's anxiety.

Kochanska and her colleagues have continued this line of research in a series of studies aimed at examining what they refer to as bidirectional models of mother-child relationships. In these cases, the bidirectional conceptualizations of relationships remain within the context of a conception of conscience or morality as the internalization of values, norms, and behaviors established by parents. Some of these studies, for example, were designed to examine the role of children's temperament in the formation of conscience (Kochanska, 1997; Kochanska, Gross, Linn, & Nichols, 2002; Kochanska, Murray, & Coy, 1997). Anxiety, fearfulness, and arousal (e.g., as found for shy children) underlie the affective component of conscience, and impulsivity and inhibition are related to behavioral control. Specifically, impulsive children are more likely to transgress and find it more difficult to internalize conscience than nonimpulsive children. Thus, parents' methods of socialization may work differently for children with different temperaments. The practice of induction (which involves explanations and reasoning) may be less effective with impulsive than nonimpulsive children.

In other aspects of the research program, the type of mother-child relationships was correlated with measures of conscience. In particular, measures were obtained of the extent to which mother-child relationships were mutually responsive (Kochanska & Murray, 2000)

and entailed secure attachments (Kochanska, Aksan, Knaack, & Rhines, 2004). Greater mutuality in the form of cooperation and shared positive affect was associated with the measures of conscience. Similarly, it has been found that more secure attachments at 14 months of age were correlated with measures of conscience. In this approach, the quality of the mother-child relationship is proposed to influence internalization of and compliance with parental standards. As put by Kochanska et al. (2004), "security may make the child eager to embrace parental demands. A secure child is cooperative and receptive to parental demands, emulates the parent and follows parental suggestions" (p. 1234).

### **Beyond Family and beyond Incorporation of Societal Standards**

Findings on temperament are not consistent. A longitudinal study by Dunn et al. (1995) showed, in contrast with the other studies, that shy children (i.e., inhibited, nonimpulsive, and anxious) scored lower on the same measures of moral orientation than children who were not shy. Dunn et al. also found that along with some positive correlations between nonpower-assertive parental practices and moral orientation, other factors were associated with moral orientation, including the quality of the child's relationships with older siblings (children who had friendlier, more positive relationships with siblings showed higher moral orientation scores) and the child's earlier level of understanding of emotions (children who had shown better emotional understandings at earlier ages scored higher on moral orientation at first grade). Moreover, Dunn et al. found differences among the stories used in the assessments. At kindergarten and first grade, children gave more empathic responses to a physical harm story than to a story dealing with cheating in a game. Correspondingly, more children gave guilt responses (i.e., reparative endings in the story completions) to the physical harm story than to the cheating story.

Findings in the Dunn et al. (1995) study, as well as from a study by Dunn, Cutting, and Demetriou (2000), suggest that influences on moral development extend beyond the practices of parents in disciplining children and that a child's reactions to transgressions are not uniform. Other research indicates that young children's development may proceed in several directions with regard to relationships with parents and in their orientations to morality. Along with an increased awareness of standards, at the age of 2 or 3 years, young children display

increased teasing of their mothers, more physical aggression and destruction of objects, and greater interest in what is socially prohibited (Dunn, 1987). Along with greater sympathy and empathy for others, with increasing age children may begin to understand how to manipulate situations and upset others. This increasing complexity of young children's social relationships is also evident by their abilities, by 18 to 36 months, to engage in arguments and counterarguments in disputes with mothers (Dunn & Munn, 1987). By 36 months, children also provide justifications for their positions in disputes with mothers and siblings (see also Kuczynski, Kochanska, Radke-Yarrow, & Girnius-Brown, 1987). Disputes occurred over issues such as rights and needs of persons, conventions (manners, etiquette), and destruction or aggression. Children's emotional reactions also varied by the different kinds of disputes; distress and anger were associated with disputes affecting children's rights and interests. These differentiations and extensions of the influences of social relationships are consistent with a reconceptualization of moral internalization presented by Grusec and Goodnow (1994), Grusec, Goodnow, and Kuczynski (2000), Kuczynski and Hildebrandt (1997), Grusec (2006), and Kuczynski and Navara (2006).

Grusec and Goodnow (1994) maintained that the traditional view of internalization as the process by which children take over the values of society has significant limitations and is not consistent with existing data. A better understanding of the process requires accounting for additional factors, including the nature of the act (the misdeed or transgression), characteristics of parents, the child's perspective on the position of parents, and the child's perceptions of the misdeed. Furthermore, they argue that it is necessary to consider the child's ability to "move beyond the parent's specific position to one of his or her own, a consideration that points to successful socialization as more than an unquestioning adoption of another's position" (Grusec & Goodnow, 1994, p. 4). As summarized by Grusec et al. (2000):

A significant shift is required to understand the process of socialization. This shift will be facilitated by an explicit interest in the agency of parents and children, that is, in the meanings they construct of each other's behavior, in their capacity for strategic action, and in their ability to behave "as if" the other is also an agent. (p. 205)

In essence, they call for a reorientation in research that would take seriously the idea of reciprocal interac-

tions in explanations of social development. There is evidence (some of which is reviewed by Grusec and Goodnow) that the effectiveness of particular parental practices are not uniform and that parents do not consistently use one type of discipline. Mothers use different reasons for different kinds of transgressions. Smetana (1989b) found that mothers of toddlers used explanations of needs and rights for acts entailing harm to others, whereas they used explanations pertaining to social order and conformity for violations of social conventions. It also appears that mothers vary their methods in accord with the types of standard violated. Working with families of children from 6 to 10 years of age, Chilamkurti and Milner (1993) found that mothers report using reasons or explanations mainly for moral transgressions and forceful verbal commands for conventional transgressions. Furthermore, parents use a combination of power assertion and reasoning in reaction to acts like lying and stealing, whereas reasoning is used in reaction to a child's failure to show concern for others (Grusec & Goodnow, 1994).

Other findings in accord with these propositions stem from studies of children's evaluations of parental discipline, as well as of correspondences between the judgments of children and adults (studies on parent-adolescent relationships are discussed later in the chapter). Catron and Masters (1993) showed that 10- to 12-year-old children and mothers endorsed corporal punishment (spanking) for prudential (i.e., acts harmful to the self, such as opening a bottle of poison) and moral transgressions to a greater extent than for transgressions of social conventions. These findings indicate both that mothers make discriminations in the ways discipline should be used and that by at least 10 years of age children make similar judgments about that type of discipline. Research by Saltzstein, Weiner, and Munk (1995) on judgments about moral intentionality and consequences shows that children evaluate the fairness of mothers' (in hypothetical situations) approval or disapproval of actions in accord with their own judgments regarding those actions. For example, children regard a mother who disapproves of a well-intentioned act resulting in a negative outcome more unfair than a mother who approves it. Moreover, children whose own judgments were based on the actor's intentions made greater distinctions in evaluations of mothers' approval or disapproval than children whose judgments were based on the consequences of the act. All these findings indicate that children apply their judgments to parental acts in ways that involve both acceptance and critical scrutiny.

It has also been found that children's own judgments about intentions and consequences are not concordant with the judgments they attribute to adults (Saltzstein et al., 1987). For acts with positive intentions and negative outcomes, children (incorrectly) believe adults' judgments of wrongness would be harsher than their own; whereas children judge by intentions, they believe that adults' judgments are mainly based on disobedience or rule violations.

These findings indicate that it is necessary to account for the child's perspective and, thereby, view the process of discipline as interactive. In particular, Grusec and colleagues maintained that because children's judgments differ for different types of misdeeds (e.g., moral as opposed to conventional transgressions; Turiel, 1983a), they would evaluate and judge the appropriateness of the reasons given by parents, or others, when disciplining the child. It has been found that children are more responsive to adults' directives when the adults use reasons that correspond to the ways children classify moral actions. For example, when teachers simply point to rule violations in discussing acts like stealing or hitting, children are less responsive than when teachers underscore the welfare of others or fairness (Killen, 1991; Nucci, 1984). It has also been found that children are more likely to share with others when given reasons based on empathy and concern for others than when to adhere to norms (Eisenberg-Berg & Geisheker, 1979).

Several other features of communications from parents to children bear on the effectiveness of discipline. These include verifiability of its truth value, the level of generality of reprimands, whether they are tangential or directly relevant to the misdeed, and whether statements are direct or indirect. Distinctions need to be made in discipline activities to understand how they are interpreted and how they might lead to changes in children's behaviors. Along those lines, it is proposed that characteristics of the parents and children would also make a difference in the ways discipline is interpreted and felt.

Unlike the traditional views of conscience or internalization, the model presented by Grusec and Goodnow includes the idea that internalization is not necessarily the sole desired goal of parents or the only positive outcome from the societal or individual perspectives. Parents may strive for flexibility and initiative on the part of the child rather than simply the adoption of parental standards. They may also be motivated by the goal that children acquire negotiation and thinking skills. Grusec and Goodnow raised the issue of noncompliance for positive goals and thereby raised the specter of social oppo-

sition and resistance. From the perspective of moral development as internalization of parental or societal norms, the good is defined as some form of compliance to the social environment. Social accommodation on the part of the child is thus regarded as the desirable end-state. In a later section, I consider research on opposition and resistance to social norms, societal arrangements, and cultural practices that stem from a moral standpoint.

## GENDER, EMOTIONS, AND MORAL JUDGMENTS

The major issues considered thus far—emotion, socialization, and interaction—also have received scrutiny in theory and research on gender differences in moral development. The question of gender differences has been posed regarding many aspects of development (Maccoby & Jacklin, 1974), but it has been of particular controversy in the moral realm because in the early part of the century it was asserted (most notably by Freud) that the morality of females is less developed than that of males, and then, in the latter part of the century, that the morality of females is qualitatively different from that of males (Gilligan, 1977, 1982; Gilligan & Wiggins, 1987). Gilligan and her colleagues maintained that two moral injunctions define two sequences of moral development—the injunction not to treat others unfairly (justice) and the injunction to not turn away from someone in need (care). Gilligan (1982) argued that a morality of care, mainly linked to females, had been overlooked in favor of analyses of justice because mainly males had formulated explanations of moral development. These assertions, however, have generated controversy among students of moral development, as well as in other social scientific disciplines (Abu-Lughod, 1991; Okin, 1989; Stack, 1990), within feminist scholarship (Faludi, 1991) and in journalistic accounts (Pollitt, 1992).

In a way, Gilligan accepts Freud's (1925/1959) contention that women "show less sense of justice than men." She does not accept Freud's contention that women show less moral sense than men because women show more of a sense of the alternative form of care. A morality of justice fails to account for women's moral orientation because it focuses on rules and rights. According to Gilligan (1982), justice links development to the logic of equality and reciprocity, which contrasts with "the logic underlying an ethic of care [which] is a

psychological logic of relationships" (p. 73). The morality of care is one of fulfillment of responsibility and avoidance of exploitation and hurt and is linked to concepts of self as attached to social networks, whereas the morality of justice is linked to concepts of self as autonomous and detached from social networks.

It would appear then that the formulation of a morality of care has affinities with those who emphasize emotions. Care entails avoidance of harm and concerns for the welfare of others (sympathy and empathy) and is applied mainly to those in close relationships. Although empathy and sympathy are relevant, this formulation differs in several respects from other perspectives emphasizing emotions. First, the central emotions for morality are defined differently from empathy, sympathy, shame, and guilt and are associated with a different set of experiences and mechanisms for the development of morality. Second, more emphasis is given to judgments in both moralities. And third, there is a sequence of development for the morality of care progressing toward increasing inclusiveness of moral judgments.

Very young children's relationships constitute the groundwork for the types of morality formed by individuals. Two dimensions of relationships are proposed as mechanisms for development at early ages, establishing long-term moral orientations. First, the experience of attachment, which produces awareness that one can affect others and be affected by them, results in discoveries of the ways people care for and hurt one another. Relying on neo-psychoanalytic accounts of identity formation (Chodorow, 1978), there is a basic difference in the social experiences of boys and girls that results, by an early age (3 or 4 years), in differences in their personality and identity. For girls, identity formation occurs in the context of a relationship with another female, the mother, which maintains continuity and in which mothers and daughters see themselves as alike. Most important, in forming her identity as a female, the young girl maintains an attachment with her mother, and thereby development progresses toward creating and sustaining relationships. Thus, the emotions associated with attachment and care are "co-feelings."

For young boys, identity formation occurs in the context of a sense of difference (in both mother and son), and in the process of forming a masculine identity there is separation from the mother and individuation. The consequence is an orientation to differentiations from others and independence on the part of boys. The second related dimension is the inequality that stems from the

child's awareness of being smaller, less powerful, and less competent than older children and adults (Gilligan & Wiggins, 1987). For girls, the experience of inequality is not as overwhelming as for boys because girls identify with the object of their attachment (mother). Because boys identify with their fathers without a strong attachment with him, they relate more to the father's authority and power. Inequality and authority are therefore salient for boys, resulting in strivings for equality (part of fairness) and regulation as moral ends.

Gilligan regards the care and justice orientations as systems of moral judgments. In fact, she considers the conception of justice and fairness as one of the two major types of morality and, at least implicitly, accepts the validity of the stages of moral judgment formulated by Kohlberg (1969). The morality of care, too, proceeds through a sequence of transformations culminating in a level of thinking based on universal principles encompassing self and others, with an understanding that self and other are interdependent, violence is destructive, and care benefits others and self. That level of moral judgment is preceded by two less advanced levels, and associated transitions, reflecting a conflict between self and other that constitutes the central moral problem for women. At the first level, there is a focus on caring for the self as a means of survival. At the second level, concepts of responsibility focus on care for dependent persons.

The sequence of women's conceptions of the morality of care was derived from interview studies. The main study entailed interviews of 29 pregnant women (ages 15 to 33 years) about their decision to have or not to have an abortion. Follow-up interviews were conducted with 21 of the women a year after they had made their choices. A necessary feature of this study, according to Gilligan (1982), is that the interviews were about situations faced in the women's own lives. This is because women's moral judgments are tied more closely to contexts than men's. Interviews about hypothetical situations, in her view, are likely to provide misleading information since women attempt to reframe hypothetical situations into real, contextualized ones. Gilligan also asserted that interviews about hypothetical situations are more likely to elicit justice concerns than would interviews about real-life situations. Nevertheless, hypothetical situations (along with judgments about situations generated by participants) have been used to study levels of development of judgments about care (Skoe & Gooden, 1993; Skoe et al., 1999). Those studies indicate that levels of

care reasoning are associated with age and that there are some variations by nation in the levels attained by females and males (i.e., Canadian and U. S. females score higher than males, but no gender differences were obtained among Norwegians). Skoe, Eisenberg, and Cumberland (2002) found that self-reports of sympathy by adults are associated with care reasoning.

Gilligan (1982) has argued that the study of the judgments of females serves to correct biases in influential theories of moral development put forth by males who largely overlooked females or who, when they addressed the issue, superficially relegated females' morality of care to a "lesser" form. Freud, for example, included women in his observations and case studies but misinterpreted their care orientation simply as a concern with approval. Gilligan also contends that others, such as Piaget (1932) and Kohlberg (1963), constructed their theories through research with samples of males and then studied females from the inappropriate perspective of male-based theories.

In considering Piaget's ideas, Gilligan imposes certainty where ambiguity exists. Piaget did maintain that girls are less interested than boys with "legal elaboration" and that "the legal sense is far less developed in little girls than in boys" (Piaget, 1932, pp. 69, 75, and quoted in Gilligan, 1977, and Gilligan & Wiggins, 1987). As noted earlier, however, in Piaget's view, the developmentally advanced level of autonomous morality was organized by concerns with mutuality, reciprocity, and cooperation. Piaget saw a strict legal sense for fixed rules that left little room for innovation and tolerance as part of the less advanced form of heteronomous morality. Thus, it is not at all clear that Piaget regarded girls to be less advanced than boys because he thought that girls were oriented to tolerance, innovation with rules, and cooperation. Aside from his studies of children's practices with game rules, Piaget's research was not conducted only with males. Piaget supported his interpretations with many interview excerpts (he did not report statistical analyses) that included both boys and girls.

In contrast, Kohlberg's (1963) original formulation of stages of the development of moral judgments was based on interviews with males only. The first studies assessing Kohlberg's stages that included females showed college-age and adult women scoring at Stage 3 (entailing judgments of morality focused on interpersonal considerations) more than men, and men scoring at higher stages (mainly Stage 4, which entails judgments of morality focused on maintenance of rules, authority,

and social order) more than women (Kohlberg & Kramer, 1969). Briefly speculating on these results, Kohlberg and Kramer (1969) suggested that Stage 3 moral thinking might be functional for the roles of housewives and mothers. The generalizability of this finding, with regard to the stages formulated by Kohlberg, was accepted by Gilligan, but she was critical of the idea that Stage 3 was functional for the roles of housewives or mothers and proposed that instead women's reasoning proceeds through the sequence of the morality of care.

However, the conclusion that women score lower on Kohlberg's stages (as drawn by Kohlberg and Kramer and reaffirmed by Gilligan) has not been supported empirically. Walker (1984, 1991) presented extensive reviews of 80 studies, which included assessments of males and females on Kohlberg's stages. Those analyses reveal little in the way of sex differences on this dimension. In most studies (86% of the samples), no differences were obtained. In some samples (9%), males scored higher than females, but in other samples (6%), it was the reverse. Walker also found that when researchers controlled for educational and occupational levels, no sex differences were observed.

Furthermore, it is not generally accepted that Kohlberg's concept of morality at the most advanced stages actually fails to account for judgments about interdependence and concerns with welfare (Gilligan construed Kohlberg's formulation as focusing on rights, rules, and separation). It has been argued that embedded in Kohlberg's formulations of justice and fairness are considerations of respect for others and ways of maintaining social relationships that are nonexploitive, non-harmful, and that promote the welfare of persons (see Boyd, 1983; Habermas, 1990b; Kohlberg, Levine, & Hewer, 1983; Nunner-Winkler, 1984; Walker, 1991).

### Care and Justice as Moral Orientations

Gilligan's propositions have received a good deal of attention, with some providing positive evaluations (Haste, 1993; Shweder & Haidt, 1993), and others pointing to inadequacies in sampling, procedures, research designs, and data analyses (see Colby & Damon, 1983; Greeno & Maccoby, 1986; Luria, 1986; Mednick, 1989). Gilligan's formulation was not based on extensive research but initially on a combination of (a) the argument that a conception of morality as justice did not adequately characterize the moral judgments of females

because they were usually assessed in stages lower than males (a conclusion that, as already discussed, does not hold), and (b) subjectively analyzed excerpts from a limited number of boys and girls responding to moral dilemmas in Kohlberg's interview (Gilligan, 1982, Chapter 2).

The construct of a morality of care was also based on the studies of women discussing abortion and of interviews of college students. Those studies were limited in that the samples were small and restricted to either pregnant women discussing one particular contested issue (abortion) or students in elite universities. Perhaps most important, the analyses of interview responses were neither based on systematic coding schemes nor analyzed statistically in any extensive ways (Colby & Damon, 1983; Greeno & Maccoby, 1986; Luria, 1986). Furthermore, the propositions regarding the origins of moral concepts in early relationships entailing inequalities, detachments, and attachments have not been subjected to empirical study.

In subsequent research, a more circumscribed approach was taken, with a focus on defining the proposed orientations of care and justice and on coding (Lyons, 1983) the extent to which males and females use one or the other or combine the two. Studies assessing the distribution of care and justice orientations included male and female adolescents and adults responding to questions about moral conflicts in their lives (Gilligan & Attanucci, 1988). Varying results were obtained. Lyons (1983), for example, found that the majority of females (75%) judged by a care orientation, whereas the majority of males (79%) judged by a rights orientation. Other studies, with more refined analyses, indicated that only a minority of people exclusively use either care or justice orientation and that most use both in one fashion or another (Gilligan & Attanucci, 1988). Those studies also suggested that the justice orientation was used more frequently than care but with a tendency for females to use care more than males and males to use justice more than females. Research with preschoolers revealed no gender differences in care or justice orientations (Cassidy, Chu, & Dahlsgaard, 1997).

These types of studies (see Gilligan, Ward, Taylor, & Bardige, 1988, for reports of additional research) have provided some evidence that care and justice tend to be associated with gender. However, the patterns are not clear-cut because studies also show shifts by context (Johnston, 1988). Perhaps because of the combinations of care and justice found in the reasoning of males and

females, Gilligan and her colleagues appear, in later writings, to be inconsistent or ambiguous about sex differences, asserting that care and justice are concerns that can be part of the thinking of males or females. The conclusion drawn from a meta-analysis of research on care and justice orientations was that neither is used predominantly by women or men, though there is a tendency for females to use more care related reasoning than males (Jaffee & Hyde, 2000).

### **Moral Judgments, Orientations, and Social Contexts**

The ambiguities in the interpretations of gender differences may very well stem from contextual variations in individuals' judgments. Issues of context are considered in propositions regarding justice and care, but in a limited way. In the first place, a broad contextual distinction was drawn through the proposition that the life circumstances of girls and women usually differ from those of boys and men. Especially for females, judgments in the context of a hypothetical situation may differ from judgments in the context of real-life situations (Gilligan, 1982). The inclination to be distant from hypothetical situations may be related to another proposed feature of the psychology of those with a care orientation—that they are more attuned to contextual features than those with a justice orientation. Those with a justice orientation are more likely to abstract from a situation (i.e., decontextualize it) in ways that generate judgments of likeness with other situations.

Because those formulations essentially propose group differences in the ways people approach morality, a more fundamental issue regarding social contexts is unaddressed: People may apply their moral judgments in sufficiently flexible ways to take features of situations into account in coming to decisions. In that case, moral judgments would not be of one type for females or males. Females and males may hold both concepts of justice and concepts regarding the network of social relationships. Individuals may be oriented both to independence and interdependence. How individuals apply these different judgments might depend on the situation. Because of the different roles and status in social networks and hierarchies of women and men, it may also be that they would apply justice and care considerations differently. In some situations, men may even apply considerations regarding social networks and interdependence more than women (e.g., situations in which men

wish to maintain the existing network of unequal relationships and role obligations), whereas in some situations women may apply justice considerations more than men (e.g., situations in which women are more sensitive to the injustices of the existing inequalities, networks of role obligations, and interdependence; see Abu-Lughod, 1993; Turiel & Wainryb, 1998; Wainryb & Turiel, 1994). Gilligan treats different moral and personal orientations as general characteristics of individuals.

These multifaceted concerns are not unrelated to the types of childhood experiences proposed to be sources of the different orientations. It was proposed that attachments and detachments are the central social experiences for girls, while inequalities and power are central for boys (Gilligan & Wiggins, 1987). This is surely a one-sided characterization. In certain respects, issues of equalities, inequalities, and power relationships are at least as salient for girls as for boys. Perhaps starting in the family (Okin, 1989), and then in school (Ornstein, 1994) and the wider society, girls confront unequal treatment in more poignant ways than boys. Women, too, experience inequalities and unjust treatment in ways that permeate their family and work experiences (Hochschild, 1989; Nussbaum, 1999, 2000; Okin, 1989; Turiel, 2002). Conversely, issues of attachment and detachment may be salient in the experiences of boys. The prominence of groups, cliques, team sports, and gangs are evidence of the pull for cooperation, attachments, and solidarity pervasive in their experiences. This is not to say that researchers should simply reverse the ways the proposed moral orientations have been linked to gender, but that concerns with justice, fairness, individuation, care, solidarity, and interdependence are all important coexisting aspects of children's social experiences and developing judgments.

A number of studies on how care and justice orientations are used in different hypothetical and real-life situations show that situational contexts affect whether a justice or care orientation is used. A study by Rothbart, Hanley, and Albert (1986) found that more reasoning about rights was used in one of Kohlberg's hypothetical dilemmas (a husband is faced with deciding whether to steal a drug to save his dying wife) than in the real-life situations, but real-life situations produced more reasoning about rights than a Kohlberg hypothetical situation pertaining to physical intimacy.

Therefore, the substance of the situations (e.g., physical intimacy or saving a life), and not only whether they are hypothetical or real-life, has a bearing on people's

judgments. Other studies (Walker, 1991; Walker, de Vries, & Trevethan, 1987) have shown that only a minority makes consistent judgments across the hypothetical and real-life situations, and that about 50% of them showed consistency among the real-life situations. Whereas no sex differences were obtained in children's or adolescents' use of the care orientations on the real-life situations, adult women showed more use of care than men (60% versus 37%). In addition, the real-life conflicts were divided as to whether they involved a specific person or group with whom the subject had or did not have a relationship (labeled personal and impersonal, respectively). Both female and male adults used the care orientation more on personal than impersonal conflicts. Whereas this shows that type of conflict can predict moral orientation better than gender (Walker, 1991), overall the adult women showed more care responses than men. This means that women generated more personal conflicts than men. Therefore, type of orientation is related to the content of the situation (reflecting contextual variations), but women are more likely than men to use the care orientation if they are more likely to perceive moral conflicts as personal rather than impersonal. These findings are generally consistent with findings from other studies (Jaffee & Hyde, 2000; Pratt, Diessner, Hunsberger, Pancer, & Savoy, 1991; Smetana, Killen, & Turiel, 1991).

The findings of these studies indicate that concerns with fairness and with the maintenance of interpersonal relationships do not represent individual differences in moral orientations. Furthermore, numerous studies on the development of moral judgments, considered in subsequent sections, have included females and males in the initial investigations (theory building). Little in the way of sex difference has been obtained in all that research. Some studies are worth noting at this juncture because of their focus on judgments about positive actions toward others. Using stories that pose conflicts between close friendship considerations, personal interests, and the interests of nonclose friendships, Keller and Edelstein (1990, 1993) longitudinally studied the interpersonal concepts of children and adolescents (7 to 15 years). Along with understandings of friendship relationships, there are age-related shifts, but no gender differences, in moral commitments based on obligations, intimacy, and mutuality in relationships. Kahn (1992) put forth a similar proposition on the basis of his findings on children's judgments about positive moral actions (i.e., whether to give money for food to hungry

persons). Females were no more likely than males to judge that people should give to, or care for, hungry persons. Moreover, the reasons for these evaluations were mainly consideration of the welfare of others and issues of justice. Whereas younger children emphasized welfare, older girls and boys embedded welfare into concepts of justice.

### **Politics, Economics, Social Structure, and Women's Perspectives**

The proposition that care and justice tend to be organized differently in males and females as a consequence of differences in childhood relationships carries a host of problems, including scientific verification, stereotyping of moral orientations, and the role of politics, economics, and social structure in possible inequalities and power relationships between men and women. Issues pertaining to scientific verification are raised by the assertion that male psychologists have imposed male-oriented formulations of moral development that overlook a major strand of development associated with females. This, however, is a criticism that turns on itself as a vicious cycle. It could be said, for example, that Gilligan's perspective is a consequence of various biases. It could be said that her ideas are colored by her status as a female of a rather advantaged position writing from the perspective of her memberships in a male-dominated field and in a highly elitist, well-endowed, and powerful male-dominated educational institution. The myriad ways that such contexts can determine one point of view or another should be evident if too much credence is given to the ways an individual's characteristics and place color scientific or scholarly analyses. The alternative is to evaluate the arguments and the evidence on their own merits.

A related point made by Gilligan, closer to issues of evidence, is that some researchers (e.g., Kohlberg, 1969) used data from males only to build theory. An analogous criticism applies to the data used by Gilligan to build her theory because her initial findings came from samples of largely White middle-class and upper-middle-class women, most of whom were undergraduates at Harvard and Radcliffe (Pollitt, 1992; Stack, 1990). Gilligan's (1977) focus has been on women's status in society, which is that they are usually in subordinate and vulnerable positions relative to men (see also Nussbaum, 1999, 2000; Okin, 1989, 1996; Turiel, 1996, 2002; Wainryb & Turiel, 1994). However, working-class and racial minority groups are also in vulnerable positions relative to

middle- and upper-class groups. The hierarchical relationships between White middle-class women or men in relation to working-class or minority racial groups pose interesting questions that have not been much investigated. One such question bears on the racial and economic injustices experienced by children in those groups, and its effects on their sensitivity to the issues.

This question was addressed in a study by Stack (1990) of the moral thinking of African American adolescents and adults who were return migrants from the north to rural, southern home places in the United States. She interviewed the participants in the study about dilemmas relevant to their lives and found no differences between responses of the adolescent girls and boys or between adult females and males, all of whom gave more justice than care responses. Stack proposed that African American boys and girls are aware, from an early age, of social and economic injustices. Men and women experience a good deal of injustice in the workplace and other settings and are committed to combating it. Simultaneously, males and females are embedded in extended families, concerning themselves with their own aspirations and the needs of their kin. Stack's findings and theoretical analyses suggest that broader life experiences than identifications, attachments, and separations are central to the development of moral concepts.

Another potential methodological problem in Gilligan's (1982) research is that much of the data used to formulate the levels of care reasoning were derived from interviews about abortion, which is an issue with some unique features that may not generalize to other moral issues. Other research has shown people are divided as to whether abortion should be classified as a moral issue, and those divisions are associated with assumptions people make about the fetus as a person and as constituting a life (Smetana, 1982; Turiel, Hildebrandt, & Wainryb, 1991). Whereas those who assume that the fetus is a life with attributes of personhood judge abortion as morally wrong, those who do not hold to that assumption judge abortion as mainly a decision of personal choice. Moreover, many individuals' assumptions about the status of the fetus as a life include ambiguities and uncertainties resulting in conflicting and contradictory judgments about abortion not evident in the same individuals' judgments about welfare, harm, and life in other contexts (Turiel et al., 1991).

Finally, in contrast with the way the issue has sometimes been couched, women have been involved in the construction of theoretical approaches at variance with the proposition that there are sex differences in moral

orientations. Many women, including those writing from a feminist perspective, have taken issue with the proposition that women's morality is mainly one of care and interdependence (e.g., Abu-Lughod, 1991; Colby & Damon, 1983; Mednick, 1989; Nussbaum, 1999; Okin, 1989; Pollitt, 1992; Stack, 1990). These critiques have highlighted the stereotypical nature of gender-linked distinctions, the significance of justice and fairness in women's judgments and life circumstances, how men's concepts of nurturance and interdependence serve to maintain those circumstances, and how economics and social structural arrangements bear on the moral judgments of females and males. Writing from her perspective as a journalist and feminist, Pollitt (1992) has critiqued characterizations of women as nurturing, caring individuals whose concerns are with relationships but not justice, rationality, or logic. Not that Pollitt would exclude nurturing and caring from the purview of women by any means. Rather, it is that women neither have a monopoly on caring nor are they solely caring nurturers of others. Women are caring, cooperative, competitive, assertive of independence, and committed to rights and justice.

The characterization of women as caring and nurturing, according to Pollitt, stereotypes them in traditional and restrictive ways. It is restrictive because it limits real concern with justice, rights, and independence—just as it is restrictive to attribute characteristics of males solely to justice, rights, and autonomy. This stereotyping serves several ends for females and males. The positive end is that it provides women with an equal moral status to men and challenges the division of men as rational and women as irrational. Women are said to develop a type of rationality by which their morality is different and equal to that of men. Despite the greater concern with equality in moral orientations, Pollitt argues that the formulation constitutes a stereotype serving also to reinforce a status quo in which women retain positions subordinate to men. Men encourage the idea that women are concerned with care because men are, in addition to children, the main beneficiaries of women's nurturance.

Pollitt also argues that propositions regarding the sources of women's judgments in early identifications (Chodorow, 1978) overlook the important contributions of their roles in the economic and social structure. Along with its positive aspects, caring is a consequence of economic dependence and subordination in the family. The role of caretaker and nurturer is, in part, imposed by a power structure in which men are in positions

of influence and economic independence (at least middle-class men). Pollitt's argument, it should be stressed, is not that caring and interdependence are negative and independence is positive. Rather, it is that women, too, can appropriately function independently, claiming rights. In particular, the workplace in capitalist society entails autonomy, concerns with personal advancement and rights, along with caring and justice. Women appear less autonomous in the workplace as a consequence of discrimination serving ends of men in positions of power and influence.

The justice of distribution of resources, privileges, and burdens in the family, especially as it affects women, has been analyzed in depth by Okin (1989, 1996). She argues that moral philosophers and social scientists have either ignored the justice of gender relationships or accepted the legitimacy of unequal distributions and unjust treatment by relegating women to traditional roles. In that context, she also maintains that (a) justice and rights are spheres relevant to women's thinking, (b) there is no evidence that women are more inclined to contextualism than universalism, and (c) the idea that women are oriented to care and not universally applicable concepts of rights and justice reinforces traditional stereotypes. In Okin's (1989) view, the distinction between care and justice has been overdrawn:

The best theorizing about justice, I argue, has integral to it the notions of care and empathy, of thinking of the interests and well-being of others who may be very different from ourselves. It is, therefore, misleading to draw a dichotomy as though they were two contrasting ethics. The best theorizing about justice is not some abstract "view from nowhere," but results from the carefully attentive consideration of *everyone's* point of view [emphasis in original]. (p. 15)

An implication of Okin's contention is that justice needs to be inclusive. Those emphasizing emotions argue, as noted, that an inclusive or universal conception of morality is a Western one, largely promulgated by intellectuals. In other cultures, and perhaps for ordinary people in Western cultures, morality is applied in a local and parochial fashion. A similar position has been taken by those who propose that integrated cultural patterns are central in the development of morality.

## EMPHASIZING CULTURE

The idea of cultures forming integrated cohesive patterns diverging from each other goes back at least to the

formulations of cultural anthropologists of the early part of the twentieth century. One of the most influential proponents of the idea that cultures form integrated patterns was Ruth Benedict (1934), who proclaimed that “the diversity of cultures can be endlessly documented” (p. 45). Cultural anthropologists of the time also wrote about morality, often taking positions of cultural relativism, in reaction to predominant late-nineteenth-century anthropological assumptions that cultures could be classified in a hierarchy of lower to higher. Usually, Western cultures were placed at the apex of the hierarchy. Cultural anthropologists argued that the classifications of cultures in a hierarchy of progress or development were due to bias in favor of Western cultural values and to intolerance and lack of respect for the equally valid values of other cultures. Along with relativism, therefore, it was asserted that cultures should be treated as different and equal, and each accepted as functioning on its own moral standards with moral ends endemic to its system. Some critics of cultural relativism (e.g., Hatch, 1983) have pointed out that the position actually includes nonrelativistic moral prescriptions. In particular, relativists espouse the values of tolerance (that the validity of other cultures’ values and perspectives should be accepted), freedom (that a culture should not be obstructed from following its moral standards), and equality (that a culture’s moral standards should be regarded as of equal validity as those of any other).

Benedict (1934) sharply characterized the proposed variations among cultures through an example that many would consider to epitomize moral concerns, transcending time and place, and pertaining to justice, rights, empathy, sympathy, and care:

We might suppose that in the matter of taking life all peoples would agree in condemnation. On the contrary, in a matter of homicide, it may be held that one is blameless if diplomatic relations have been severed between neighboring countries, or that one kills by custom his first two children, or that a husband has right of life and death over his wife, or that it is the duty of the child to kill his parents before they are old. It may be that those are killed who steal a fowl, or who cut their upper teeth first, or who are born on a Wednesday. (p. 46)

In this way, Benedict encompassed several cultural practices commonly used to illustrate variations in moral codes: parricide, infanticide, and family relationships of deep inequalities. Observations of variations in

social practices, thus, were used to argue for the incomparability of the moralities of different cultures, and in that sense empirical observations were used for propositions about the nature of morality (i.e., to define it as local and entailing an acquisition of the standards of the culture). The core of these propositions is that variations in social practices stem from differences in the ways cultures are integrated (Benedict, 1934, p. 46): “A culture, like an individual, is a more or less consistent pattern of thought and action.”

In contemporary views of human development, the role of culture has once again been emphasized (Bruner, 1990; Shweder, 1990a; Shweder & Sullivan, 1993) and has become increasingly part of research on moral development. As already seen, those emphasizing emotions include cultural influences as a part of moral acquisition, along with the idea that morality is highly influenced by biologically based propensities. Others assert that culture must be given center stage (Markus & Kitayama, 1991; Miller & Bersoff, 1995; Shweder, 1990a; Shweder, Mahapatra, & Miller, 1987; Shweder, Much, Mahapatra, & Park, 1997; Triandis, 1990). In giving culture center stage, sharp distinctions are drawn between Western and non-Western cultures in morality and concepts of self. Westerners are said to place an emphasis on abstractions, justice, and the autonomy of individuals, whereas non-Westerners are said to place emphasis on concrete contexts, duties, and interdependence. Yet, when discussing Western cultures in the context of critiques of some explanations of moral development, such as Kohlberg’s, culturalists end up portraying people in Western cultures as holding both types of orientations (Shweder, 1982; Simpson, 1973).

Shweder (1982), for instance, asserted that Kohlberg’s highest stages (Stages 5 and 6), which include the ideas of “society as a social contract” and the “individual as possessing natural and inalienable rights prior to or outside society” (p. 424), are culture specific. However, he also stated that these ideas are the domain of a small segment of Western culture: “If they are advocated at all, and they rarely are, it is among Western educated middle-class adults” (p. 425). The majority of people (nonintellectuals in Western culture and those in non-Western cultures), therefore, hold views that do not revolve around individual autonomy and separateness from society: “Moral exegesis seems to stabilize around the not unreasonable ideas that social roles carry with them an obligation to behave in a certain way, that society is not of our own making, and that

self and society are somehow intimately linked (Stages 3 and 4)" (p. 425).

Most often, Shweder's (1986) position is that a variety of systems of rationality exist that are framed by culture. Western cultures have an individualistic orientation (in contrast with the collectivistic orientations of non-Western cultures) focusing on rights and autonomy. Therefore, while asserting that individualism is the central ethos of Western cultures, it is argued that concepts of freedom, contract, and rights are ways of thinking espoused mainly by intellectual elites and not others in the West. Furthermore, whereas these writers often emphasize the role of the elites in Western culture and draw differences in the thinking of elites and laypersons, they seldom do so with non-Western cultures. Because there is mention of elites or leaders in non-Western cultures, it is on the premise that there is consistency in their thinking with that of ordinary people (Shweder, 1986).

### Social Communication and Cultural Coherence

Like Benedict, contemporary researchers point to many areas of *moral* diversity that are said to be well documented by anthropologists and historians:

On the basis of the historical and ethnographic record we know that different people in different times and places have found it quite natural to be spontaneously appalled, outraged, indignant, proud, disgusted, guilty and ashamed by all sorts of things: masturbation, homosexuality, sexual abstinence, polygamy, abortion, circumcision, corporal punishment, capital punishment, Islam, Christianity, Judaism, capitalism, democracy, flag burning, miniskirts, long hair, no hair, alcohol consumption, meat eating, medical inoculations, atheism, idol worship, divorce, widow remarriage, arranged marriage, romantic love marriage, parents and children sleeping in the same bed, parents and children not sleeping in the same bed, women being allowed to work, women not being allowed to work. (Shweder, 1994, p. 26)

The sweep of this statement is breathtaking. Being appalled, outraged, indignant, proud, disgusted, guilty and ashamed are all seen as moral reactions. Most positive and negative reactions are regarded to have a moral component. Moreover, as evident in the long list given of "all sorts of things," many different behaviors can be and have been part of the moral domain. Little is exempt, given that sexuality, hairstyle, clothing style,

love, marriage, sleeping patterns, and work are all included. Despite appearances, it would not be correct to say that these researchers endorse moral relativism (although questions can be raised about this) nor that they regard the reactions to social practices (e.g., women being allowed to work or women not being allowed to work) as arbitrary or fortuitous. This is because particular social practices are proposed to be part of sets of "moral qualities" entailing rights, autonomy, duty, interdependence, and sanctity. In turn, moral qualities are connected to more general patterns that make up cultural communities. Cultures do not simply provide a series of isolated standards, values or codes. Some worlds of moral meaning emphasize rights and justice, others emphasize duties and obligations, each part of general orientations to individualistic (read Western cultures) and collectivistic (read non-Western cultures) conceptions of self, others, and society.

The proposed contrast between individualistic and collectivistic cultural orientations is related to moral conceptions, practices, and appraisals. However, these orientations encompass much more; they are the bases for cultural constructions of how persons are defined, how they interact with each other, how society is defined, and how the goals of persons and the group are established and met (e.g., Geertz, 1984; Markus & Kitayama, 1991; Shweder & Bourne, 1982; Triandis, 1990). As put by Markus and Kitayama (1991): "In many Western cultures there is a faith in the coherent separateness of distinct persons. . . . Achieving the cultural goal of independence requires construing oneself as an individual whose behavior is organized and made meaningful primarily by reference to one's own internal repertoire of thought, feelings, and action" (p. 225). And in the contrasting construal of interdependence "many non-Western cultures insist . . . on the fundamental connectedness of human beings to each other. A normative imperative of these cultures is to maintain this interdependence among individuals" (p. 227).

In these formulations, the United States is often identified as the quintessential individualistic society (also by Bellah et al., 1985), but individualism is also prevalent in other countries such as Australia, Canada, England, and New Zealand (Triandis, 1990). Prototypical collectivistic cultures are found in Japan, India, China, and the Middle East, as well as in Africa, Latin America, and southern Europe (Markus & Kitayama, 1991). The person conceived as an autonomous agent, with personal goals, is central in the individualistic frame,

whereas the group as an interconnected and interdependent network of relationships is central in the collectivistic frame. A core feature of individualistic cultures is that the highest value is accorded to the person as *detached* from others and as independent of the social order. People are, therefore, oriented to self-sufficiency, self-reliance, independence, and resistance to social pressure for conformity or obedience to authority. Collectivistic cultures, by contrast, are oriented to tradition, duty, obedience to authority, interdependence, and social harmony (for a general review of evidence, see Oyserman, Coon, & Kemmelmeier, 2002; for conceptual analyses, see Mascolo & Li, 2004).

A significant component of cultural meanings is the kind of moral orientation communicated to children and reproduced by them as they grow into adulthood. Shweder et al. (1987) proposed a distinction between “rights-based” and “duty-based” moralities in their comparisons between the United States and India. In Western cultures, moral authority resides in individuals who voluntarily enter into contracts and promises, with the idea of rights as fundamental (hence a “rights-based” morality). In a contrasting duty-based morality, the social order is the organizing feature of moral rationality. Customary social practices are viewed as part of the natural moral order, so that social practices are seen neither as within individual discretion nor as a function of social consensus (thus the concept of conventionality as agreement in a group is largely absent). The social order dictates specified duties based on roles and status in the social structure, “while the individual per se and his various interior states, preferences, appetites, intentions, or motives are of little interest or concern” (Shweder et al., 1987, pp. 20–21). Moreover, Shweder et al. asserted that in a duty-based culture, individuals are not free to deviate from rules and that there is little conception of a natural right (such as free speech) that might lead to advocating deviation from the socially defined good.

### Social Practices and Cultural Coherence

Propositions regarding cultural divergence in “moral rationality” were examined in a study conducted with samples of secular middle- and upper-middle-class children and adults from the United States (Hyde Park in Chicago), and samples of “untouchables” and Brahmans living in the old temple town of Bhubaneswar, Orissa, in India (for research in Brazil, see Haidt, Koller, & Dias,

1993; and in Israel, see Nissan, 1987). In large measure, the research aimed at ascertaining whether a distinction could be drawn across the two cultures between morality, as based on concepts of justice, rights, and welfare, and conventionality, as based on context-specific uniformities serving goals of social coordination—a distinction that had been addressed by others and is considered further in subsequent sections of this chapter (e.g., Nucci, 1981; Smetana, 1981, 1984; Tisak, 1986; Turiel, 1979, 1983a).

Shweder et al. (1987) hypothesized that a distinction between morality and convention is particular to cultures which structure social relationships through the concept of autonomous individuals free to choose by consensus. Accordingly, they included topics of consensual choice in Western cultures such as issues about food, dress, and terms of address. Whereas some items were straightforward (e.g., a son addressing his father by his first name) others included religious and metaphysical considerations for Indians because of their connections to ideas about an afterlife (e.g., a widow wearing jewelry and bright-colored clothing 6 months after the death of her husband, a widow eating fish 2 or 3 times a week). Also many of the items entailed acts on the part of women that might contradict the power and desires of men (e.g., a woman wanting to eat with her husband and elder brother, a son claiming an inheritance over his sister). Shweder et al. (1987) included items reflecting concepts they consider candidates for moral universals (e.g., a father breaking a promise to his son, cutting in line, refusing to treat an injured person) that dealt with justice, harm, reciprocity, theft, arbitrary assault, and discrimination. Still other issues dealt with family practices that might vary by culture, including those bearing on personal liberty, privacy, and equality (considered central themes for Americans), and sanctity, chastity, and respect for status (considered central themes for Indians).

The assessments were adapted, in modified form, from previous research on morality and convention (Turiel, 1983a). Shweder et al. (1987) found that Americans and Indians rank the seriousness of transgressions in very different ways, such that there are high correlations among Americans and among Indians but little correlation between Americans and Indians. There was agreement in judgments about some moral issues between Indians and Americans and a good deal of disagreement on issues pertaining to conventions, liberty, equality, sanctity, chastity, and status. The findings of

variations in judgments, aside from the few issues dealing with harm, promises, assault, and so on, led Shweder et al. (1987) to conclude that “many things viewed as wrong on one side of the Atlantic are not viewed as wrong on the other side” (p. 51).

On the side of India, according to the findings, more things are regarded as wrong than on the side of the United States. In particular, Indians regarded many breaches pertaining to food, dress, terms of address, and sex roles as wrong, as unalterable, and in some cases as universal. Shweder et al. (1987) maintained that conventional thinking “is almost a nonexistent form of thought in our Indian data” (p. 52). Although convention was existent in the American data, it was much less prevalent than found in many other studies conducted in the United States. It was also found that with increasing age Americans judged the issues in more relativistic ways (i.e., judging that the practices are acceptable for other people or in other countries) and were more likely to take situational features into account. By contrast, with increasing age, Indians judged the prohibitions as applicable universally and across varying contexts. On the basis of these findings, Damon (1988) has suggested “that moral maturity in some parts of the world implies an ever-expanding tendency to universalize one’s moral beliefs, whereas in other parts of the world moral maturity means applying one’s beliefs flexibly to an array of changing situations” (p. 109). Because it is Indians, in contrast to Americans, who universalize moral judgments, Damon’s suggestion is in direct opposition to presumptions that moral universality is a post-Enlightenment Western idea.

In addition to differences in judgments between the two cultural groups, on issues related to food, dress, terms of address, and sex roles, Shweder et al. (1987) found that a number of issues were judged as wrong by both Indians and Americans (these are the candidates for moral universals). Agreement occurred on issues pertaining to harm (e.g., hospital workers ignoring an accident victim, destroying another child’s picture, kicking a harmless animal), injustice (e.g., cutting in line, discriminating against invalids), breaking promises, and incest. However, not all issues bearing on discrimination or harm were judged as wrong by Indians and Americans. Three issues, in particular, were judged as right by Indians and wrong by Americans. One of these depicted a father who canes his son for a misdeed. Two others pertained to gender relationships. One depicted a husband who beats his wife “black and blue”

after she disobeys him by going to a movie alone without his permission, and a son who claims most of his deceased father’s property, not allowing his sister to obtain much inheritance. As put by Shweder et al. (1987):

Oriya Brahmins do not view beating an errant wife as an instance of arbitrary assault, and they do not believe it is unfair to choose the son over the daughter in matters of life and inheritance. . . . [T]hey believe, that beating a wife who goes to the movies without permission is roughly equivalent to corporal punishment for a private in the army who leaves the military base without permission. For Oriyas there are rationally appealing analogical mappings between the family unit and military units (differentiated roles and status obligations in the service of the whole, hierarchical control, drafting and induction, etc.). One thing the family is not, for Oriyas, is a voluntary association among equal individuals. (p. 71)

The overarching principle applied in the analyses of responses to these items is cultural meaning in a moral system. Not considered is that different and varying agendas may be at work in addition to “moral duties.” For example, Indians may judge caning a son as right because of their psychological assumptions regarding the effectiveness of physical punishment on learning (see Wainryb, 1991). Also, exerting power and asserting personal entitlements may account for the acceptability, among Indians, of husbands beating their wives and sons claiming an inheritance over their sisters. The analogy between the family and military units ignores some possibly important differences. Is it permissible for a private in the army to be “beaten black and blue”? What about an officer who leaves the base without permission? Is he not accountable for his actions, as opposed to a husband in the family situation? In that sense, there may be more accountability and reciprocity between people in different ranks in the military than husband and wife in the family. When a husband beats his wife, is it “in the service of the whole” or in the service of the husband’s personal interests?

Nevertheless, the examples and analogy point to some hierarchical social relationships, entailing dominance and subordination. Additional items used by Shweder et al. (1987) illustrate hierarchy in the family. Indians judged that it is wrong for a woman to eat with her husband’s elder brother, that it is wrong for a husband to massage the legs of his wife, and that it is wrong for a husband to cook dinner for his wife. Intimacy should not exist among certain family members, such as between a

woman and her husband's elder brother. A husband must not give his wife a massage or cook for her because "The wife is the servant of the husband. The servant should do her work" (Shweder et al., 1997, p. 137).

Another area where hierarchical relationships exist in a traditional culture like India is among people of different castes. Shweder et al. (1987) also propose that the morality of Indians includes the idea of "purity," communicating to children that they should avoid sources of impurity and uncleanness, and one such source of pollution is contact with people of a lower caste: "Just as the pure must be protected from the impure, the higher status and the lower status must be kept at a distance . . . the culture is providing the child with a practical moral commentary in which one of the many messages is ultimately that menstrual blood, feces, and lower status go together" (pp. 74–75). Again, these practices are attributed to cultural meanings around duties, without consideration of the possibility that they reflect the creation of distance in social relationships that benefit those in positions of power (in a culture that is supposed to be collectivistic and to stress interdependence).

### **Emotional Forms, Intuitions, and Rapid Processing**

The emphasis on the dictates of roles, status, and hierarchy appears to leave little room for the types of moral concerns with justice, harm, and even rights (e.g., that it is wrong to discriminate against invalids) apparent in some of the findings of the Shweder et al. (1987) research. Recognizing that such judgments are made in that non-Western, "sociocentric" culture (as in their own findings and as in interpretations by Turiel, Killen, & Helwig, 1987), Shweder and his colleagues (1990b; Shweder et al., 1997) attenuated somewhat the proposition regarding the separation of a rights-based morality and a duty-based morality and elaborated on it. One elaboration is the proposition that three "ethics" are found the world over: the ethics of autonomy, community, and divinity. Although the inclusion of three ethics broadens the scope of the analyses beyond the dichotomy of rights and duties, it is still presumed that the social order determines the interplay of different types of "goods" in a worldview. Thus, in India, community and divinity are dominant, whereas in the United States autonomy prevails (Shweder et al., 1997). In Indian society, the ethics of autonomy, based on justice, harm, and rights, is subordinated to and in the service of the ethics

of community, which refers to status, hierarchy, and social order, and the ethics of divinity based on concepts of sin, sanctity, duty, and natural order. In the United States, by contrast, there is a "specialization" in the ethics of autonomy, with community, and divinity in even smaller part, providing a background. Reminiscent of Etzioni's (1993) position, Shweder et al. (1997) are of the opinion that the "expertise" in the ethics of autonomy in the United States has led to a wide extension of the concept of rights (e.g., to children or animals), to the desire to be protected from "every imaginable harm" (e.g., from secondary cigarette smoke or psychologically offensive work environments), and to an enlargement of the idea of harm (to include "all-embracing notions as 'harassment,' 'abuse,' 'exploitation,'" p. 142). Shweder et al. (1997) view these extensions as distortions, just as other distortions may occur through the extensions of concepts of community and divinity in Indian culture.

In India, the ethics of autonomy is linked to the idea of a soul, which obligates respect (souls include human and nonhuman animals). More dominant, however, is the ethic of community, in which a person's identity is associated with status and relationships to others to a much greater extent than individuality. Relationships are part of hierarchical orderings in which people in subordinate and dominant positions are obligated to protect and look after each other's interests (e.g., wives should be obedient to husbands and husbands should be responsive to the needs and desires of wives). Shweder et al. (1997) regard this as analogous to feudal ethics, where the feudal lord does for others as much as they do for him (an asymmetrical reciprocity because one person is in a position of dominance and control).

Along with the three types of morality, another set of modifications and extensions of the theory is that cultural content is communicated to individuals who are prepared by evolution with deep emotions to receive and rapidly process the content, making decisions intuitively (Shweder, 1994; Shweder & Haidt, 1993). Moreover, emotions are regarded as "the gatekeeper of the moral world," revealing features of social reality.

The proposition that emotions are linked to intuitions has been extended by Haidt (2001) in ways that render rationality and reasoning largely irrelevant in moral evaluations and decisions (which contrasts with Shweder's, 1986, proposition that people in different cultures maintain different types of rationality). In Haidt's view, immediate, reflexive reactions, such as revulsion, disgust, and sympathy, trigger moral reactions.

Judging acts as wrong involves immediate “gut” reactions of intuitive kinds that do not involve reasoning. For Haidt, the defining feature of “intuitions” is quantitative: They occur rapidly, without effort, automatically, and without intentionality. Haidt proposes that intuitions are due to evolutionary adaptations shaped by culture. Culture provides a context for the expression (referred to as externalization) of built-in moral intuitions. The outcome in children and among adults is a morality that is unique to their culture or group and often includes asymmetrical reciprocity with acceptance of dominance and subordination.

In Haidt’s view, humans are reasoning beings only in secondary ways. Reasoning contrasts with intuitions in that it is slow, requires effort, and makes use of evidence. Moral reasoning is used mainly after the fact to justify to self and others why an act is intuitively grasped as wrong “when faced with a social demand for a verbal justification one becomes a lawyer building a case rather than a judge searching for the truth” (Haidt, 2001, p. 814). Moral reasoning is also used to persuade and to rationalize but does not involve choices, rationality, deliberation, or use of evidence. According to Haidt, most people are not concerned with reflection on moral matters. It is philosophers and those with a “high need” for cognition who engage in private or personal reflection.

To the extent that evidence is provided for the proposition that moral evaluations are intuitive, it is from research in nonmoral realms. Haidt cites a number of studies from social psychology that appear to support the idea that people are biased, emotive, intuitive, and unconcerned with evidence. Moreover, Haidt proclaims that research on moral reasoning only reveals what people do in the way of justification to convince others or to rationalize, in a post hoc way, positions they hold for other reasons. However, he does not provide evidence as to how the moral reasoning investigated in so many studies fails to account for moral evaluations or how it is that such reasoning is mainly used for purposes of persuasion and rationalization. A good part of Haidt’s argument is based on a few examples. One that he seems to regard as prototypical is that of incest—an example that could be viewed as shared within cultures, yet applicable across cultures, and an evolutionary adaptation. Incest is an act, even when it is specified that it is consensual and there is no risk of pregnancy occurring, to which people react immediately with a gut reaction that it is wrong and are unable to explain why. The specific ex-

ample provided is of a brother and sister who go on vacation and, with all precautions, decide to make love. The act is intuitively grasped as wrong because most people say something like “I don’t know, I can’t explain it. I just know it’s wrong.”

A key question is the generality of this type of example (or examples like people judging it wrong to eat dogs, etc.) and whether it applies to people’s moral lives more generally and meaningfully. The research discussed in subsequent sections provides a good deal of evidence that children, adolescents, and adults explain many of their moral evaluations in ways that are very different from the way they approach an issue like incest. A number of features in social situations are taken into account, including what has been referred to as informational assumptions or assumptions about reality (see the discussion that follows; for a critique of the emotivist-intuitionist position, see Turiel, 2006).

### Justice and Interpersonal Responsibilities

The position taken by Shweder and his colleagues (Shweder, 1986, 2002; Shweder et al., 1987; Shweder et al., 1997) gives more emphasis to systems of rationality in moral judgments than is evident in the proposition that morality is based on intuitions given expression by cultural practices. Moral systems of rationality, as already noted, vary by cultural orientations to self, other, roles, and duties. Social hierarchy is seen to be central in the morality of Hindu Indians, as exemplified by Shweder’s view that their morality includes treating the family unit like a military unit and acceptance of the legitimacy of a husband beating his wife “black and blue” when she is disobedient. Another aspect of hierarchy, in this moral orientation, is the necessity of members of the higher caste to avoid contact with members of lower castes (to avoid pollution). Although social hierarchy is portrayed as entailing asymmetrical reciprocity, it also makes for a good deal of distance and separation between males and females and among social classes. Shweder et al.’s (1987) depiction of the family unit as akin to a military unit implies formality and dependence of women (like privates) on men (like commissioned officers). The distance between members of different castes due to the need to avoid pollution makes for very little interdependence or care and concern for the welfare of those of lower castes. These conclusions are at odds with the portrayal of non-Western cultures as oriented to interdependence and social harmony.

Another series of studies comparing Americans and Indians on their judgments about helping others, interpersonal obligations, and justice was based on the proposed cultural distinction between independence and interdependence (Bersoff & Miller, 1993; Miller & Bersoff, 1992, 1995; Miller, Bersoff, & Hardwood, 1990; Miller & Luthar, 1989). In contrast to Gilligan (1982), Miller and her colleagues proposed that variations in judgments about interpersonal obligations and justice reflect cultural, and not gender, differences. Miller and Bersoff (1995) maintained that Gilligan takes a narrow approach to culture by failing to consider differences in cultural meanings that affect individuals' concepts of self and morality. They believe Gilligan's ideas lead to implausible predictions—that concepts of self and morality would be more similar among individuals of the same gender from different cultures (e.g., a secular American woman versus a traditional Hindu Indian woman) than individuals of different genders from similar cultures (e.g., a traditional Hindu Indian man versus a traditional Hindu Indian woman). Miller and Bersoff (1995) further argue that in Gilligan's propositions regarding the influences of early childhood experience there is a failure to consider how they are related to cultural meanings.

Miller and Bersoff (1995) proposed that American women, too, are influenced by the individualistic views of self in their culture and that Indian men are influenced by the relational or interdependent views of the self in their culture. As a consequence, Americans have a "minimalist" view of interpersonal moral obligations that contrasts with the maximalist views of Indians. The thinking of Indians is contextual because self is conceptualized as part of the social order so that duty is not in contradiction with individual desires.

In a study (Miller & Luthar, 1989) comparing Indians and Americans, adults were presented with a set of scenarios depicting transgressions of role-related interpersonal obligations (e.g., a son refusing to care for his elderly parents, a man leaving his wife and children for another woman), and justice (e.g., a college student cheating on a final exam because family responsibilities do not allow time for study, a man leaving the city without paying back a personal loan). It was found that both groups evaluated the justice issues as wrong, but Indians were more likely than Americans to evaluate the interpersonal transgressions as wrong. Correspondingly, each group classified the justice transgressions mainly in moral terms. There was a greater tendency for Indi-

ans to classify the interpersonal transgressions as moral rather than as matters of personal choice and the reverse for Americans.

In addition, a study by Miller et al. (1990) showed that a large majority of Indians judged as wrong actors who, for selfish reasons, failed to help persons in extreme, moderate, or minor need. This was true for relationships between parent and child, best friends, and strangers. The same judgment was made by the large majority of Americans regarding situations of extreme need and situations of moderate need involving parents and children. With regard to the situations of minor need with parents, and moderate need in relationships of friends and strangers, Americans (especially among the oldest groups) were less likely to see helping as an obligation.

Miller and Bersoff (1995) also proposed that selflessness is consistent with a duty-oriented culture and that providing psychological support is consistent with a cultural orientation to voluntary, personal decisions in interpersonal relationships. More generally, for Americans, because of their orientation to individualism, interpersonal relationships are not strictly moral obligations but are seen as either matters of personal choice or as involving a combination of the moral and personal. For Indians, interpersonal relationships are seen as moral obligations that can be given priority over matters of justice or rights.

However, the proposed commitment of Indians to interpersonal obligations is discrepant with the findings of Shweder et al. (1987) showing detachment between castes and among family members. Other aspects of the research conducted by Miller and her colleagues are discrepant with findings obtained by Shweder et al. (1987). In the first place, they (Bersoff & Miller, 1993; Miller & Bersoff, 1992) found that Indians do think in terms of social conventions. Both Indians and Americans judged a violation of a dress code (not related to religious obligations) in social conventional and not moral terms, and these judgments differed from judgments about theft (which was judged in moral terms). Other research (Madden, 1992) conducted in the temple town of Bhubaneswar also showed that there was conventional thinking about nonreligious issues, which was distinct from moral thinking.

Additionally, Miller contends that Indians take contextual features into account to a greater extent than Americans. Evidence for this proposition comes from studies of person descriptions and social explanations

indicating that Americans tend to explain behaviors with trait attributions, whereas Indians tend to do so with references to context (Miller, 1984, 1986). Evidence also comes from studies indicating that Indians are less likely than Americans to hold individuals accountable for violations of moral codes, attributing the causes of behavior to contextual features (Bersoff & Miller, 1993; Miller & Luthar, 1989). These propositions about the contextual dependence of duty appear to be in opposition to the Shweder et al. (1987) findings that with age Americans become more relativistic and flexible in their moral judgments and that Indians become more universalistic, applying moral injunctions across contexts. Miller's propositions regarding moral accountability also appear to be different from the view of Shweder et al. (1997) that karma institutionalizes human tendencies to attribute consequences to personal responsibility. "It is a great irony of Western understanding that karma is often misinterpreted as a description of how Indians excuse themselves from responsibility by describing themselves as passive objects of the force of their past actions (p. 152)." According to Shweder et al., some Indians do use an interpretation of karma to account for failures of responsibility, but other Indians are critical of such thinking.

### **EMPHASIZING JUDGMENT AND RECIPROCAL SOCIAL INTERACTIONS**

In several approaches considered thus far, it is, for the most part, proposed that children acquire morality from the family and/or the culture, and that this occurs very early in life. It is presumed that the necessary components of morality emerge very early in life—infants and very young children show positive social behaviors, react with positive emotions to others, and form attachments with them. This presumption, in turn, is linked to the propositions that much of it is naturally derived (through evolution), that much of it is acquired from parents because most of the child's early social experiences are in the family, and that much of it is reflexive and habitual.

The findings that young children show positive moral emotions and actions toward others indicate that the foundations of morality are established in early childhood and do not solely entail the control and inhibition of children's tendencies toward gratifying needs or drives or acting on impulses. However, that the foundations of positive morality are established in early child-

hood does not necessarily establish that significant aspects of development do not occur beyond early childhood; that judgments, deliberations, and reflections are unimportant; or that many experiences, in addition to parental practices, do not contribute. As noted earlier, the theories and research of Piaget and Kohlberg have had much to do with the shift away from conceptualizing morality as entailing self-control over impulses through their demonstrations that children think about the social world, attempt to understand social relationships, form judgments of right and wrong, and thereby engage in reciprocal interactions with others. However, Piaget and Kohlberg thought that extrinsic features, such as basing right and wrong on obedience and sanctions, structure young children's moral judgments. As is discussed, it appears that Piaget and Kohlberg failed to uncover not only the positive nature of young children's moral feelings but also that young children form relatively complex judgments that are not based on extrinsic features.

Moral reasoning is multifaceted and can entail ambiguities and uncertainties, certainties and unreflective apprehension, as well as deliberation and reflection. Whether moral evaluations and judgments are processed very quickly or slowly, with certainty or given pause, with an apparent lack of self-awareness or with reflection and deliberation, depends on the individual's development, the situation or problem confronted, and the points of view of other people. First, how well a concept is understood has a bearing on the rapidity of a moral evaluation. A well-understood concept that is perceived as readily applicable to a particular situation may well be used in rapid fashion and give a false appearance to the outside observer that it is "intuitive" or a habitual practice. The same concept for that individual at an earlier time may have been applied with more uncertainty and less of a sense of being evidently true. That does not mean that a concept, once formed and accepted, will be produced rapidly and without self-awareness in all situations. Ambiguities in a situation, as well as awareness that others take a different point of view, can produce deliberation, awareness of ambiguities, and argumentation.

It will be recalled that Haidt (2001) used the quantitative dimension of rapidity and lack of effort as criteria for designating responses as intuitive and habitual. He referred to social psychological research in nonmoral realms to support the propositions that people's thinking is intuitive, unreflective, and that they do not concern themselves with evidence. However, there is a large

body of evidence from developmental and cognitive psychology in realms like number, mathematical reasoning, classification, understandings of space and physics more generally, causality, intentionality, and theories of mind showing that people make judgments that are not necessarily immediate, rapid, and categorical and that can be intentional, deliberative, and reflective. People do reason and are not intuitive in many realms of knowledge. The research also shows that such reasoning can become immediate and rapid. Conceptualizations of, for example, number and arithmetic may be acquired laboriously over time but, once acquired, are applied in rapid fashion (for further discussion, see Turiel, 2006).

Research on young children's psychological understandings also demonstrates that the quantitative dimension of rapidity of response is inadequate as a means for ascertaining whether reasoning is at work. Many studies of children's understandings of others' minds (see Flavell & Miller, 1998) show that cognitive processes of a slow and rapid nature are at work between 3 and 5 years of age. As the research clearly shows, 5-year-old children have an understanding of others' mental states, including beliefs, desires, and intentions. For instance, 5-year-olds readily understand that another person may hold a "false" belief about, for example, the contents of a crayon box that actually contains candy. For adults, this is rapidly understood and readily applied—and it appears to be so also for 5-year-olds. Yet, processes of development and thought are involved in these understandings given that 3-year-olds generally do not answer correctly on tasks assessing false beliefs (or other assessments of understandings of mental states). The rapidity of the cognitive processing of 5- or 6-year-old children can mask the uncertainties and ambiguities in younger children's judgments, as well as the processes of reasoning in the older children. Furthermore, the development of psychological understandings does not stop there. Even adults can face difficulties and ambiguities in understanding the psychological states and behaviors of persons (Ross & Nisbett, 1991).

Research on the moral decisions of people identified by Colby and Damon (1992) as moral exemplars indicated that judgments could include convictions, certainty, *and* openness to new ways of thinking. The search for "truth" and openness to change in thinking do not reflect automatic, reflexive, or intuitively evident truths immediately apparent to an individual. However, the certainty in the thinking of these individuals also leads them to make decisions that much of the time does not require belabored weighing of alternatives. It might

be said that the "moral exemplars" studied by Colby and Damon are among those with more philosophical orientations or a "high need" for cognition. In a later section, however, research is discussed on how reflection and social critique are part of most people's social lives (Turiel, 2003b; Turiel & Perkins, 2004).

Studies of moral development, including several of the ones already considered, suggest alternatives to the propositions that emotions are primary in morality, that moral acquisition is mainly due to effects of parental practices on children, or that morality largely reflects the acquisition of societal standards. Dunn et al. (1995) found differences in the two types of situations they assessed (physical harm and cheating) and documented that relationships with siblings influence development. By 2 or 3 years of age, children display a fair amount of teasing of mothers, physical aggression, destruction of objects, and an increasing ability to engage in arguments and disputes with mothers (Dunn, 1987; Dunn & Munn, 1987). This increasing variety in young children's social relationships is consistent with the findings reviewed by Grusec and Goodnow (1994) showing that parental practices are related to type of misdeed (e.g., moral or conventional), children judge the appropriateness of reasons given by parents when communicating with them, and parents may encourage ways of behaving that differ from those they engage in themselves.

An interactional perspective on parent-child relationships casts a different light on the types of child-rearing practices studied in research on moral development (Turiel, 1983a, 1983b). In addition to how particular practices shape children's behaviors (the focus of much of the research), it is necessary to consider how these very practices constitute forms of social communication. Among the types of child-rearing practices, the most effective (the so-called induction method) entails explanation of reasons for the required behaviors (Hoffman, 1970; Maccoby & Martin, 1983). That explicit communications of this sort are more effective than practices like physical punishment and love-withdrawal suggests that parents and children engage in reciprocal interactions. Another body of findings on parental practices has shown that "authoritative" forms of parenting are more effective than either "authoritarian" or "permissive" forms (Baumrind, 1973, 1989; Maccoby & Martin, 1983; see also Collins & Steinberg, Chapter 16, this *Handbook*, this volume; Parke & Buriel, Chapter 8, this *Handbook*, this volume). One of the features distinguishing authoritative parenting from the others is an emphasis on discussion, communication, and explana-

tion. It is also likely that the types of parental practices that do not emphasize communications entail implicit communications. As implicit communications, the messages are less clear and more open to children's own interpretations. Perhaps this accounts for the findings that the use of physical punishment is connected with greater aggressiveness on the part of children (Hoffman, 1970; Maccoby & Martin, 1983). Physical punishment may convey the implicit message that inflicting physical harm and using a form of aggression is acceptable.

It is also likely that family influences on children's moral development go beyond the effects of parental discipline practices. The structure of family interactions is another important influence, especially as it relates to fairness in arrangements among males and females (Hochschild, 1989; Okin, 1989, 1996). In most families, there exist gender-related inequalities in the distribution of power, the ways goods and privileges are allocated, and the work opportunities encouraged or discouraged. Such structural arrangements and practices may well have an effect on children's development, but this is an area largely neglected in research on family influences.

An interactional perspective, therefore, needs to account for many aspects of family life and social life in addition to family experiences (Turiel, 2004b). One of these that has received some attention from researchers is interaction among peers. Some have followed Piaget's (1932) lead in proposing that peer interactions are important to children's moral development (Damon, 1981, 1988; Youniss, 1980). Piaget maintained that relationships of young children with adults were ones of constraint, whereas relationships with peers are more likely to be ones of cooperation. According to Piaget, because peers are perceived more or less as equals, children are more likely to take their perspectives and see themselves as responsible partners in social interchanges.

Without necessarily presuming that interactions with peers are more conducive than interactions with adults to the development of moral judgments, several researchers have examined the influences of children's relationships with each other. Damon (1981, 1984, 1988) and Youniss (1980) propose that the effects of peer interactions are a consequence of "the coordinating of one's perspective and actions with those of another, rather than through the transmission of information and ideas" (Damon, 1981, p. 165). Furthermore, Damon maintains that important aspects of morality are first learned through play with friends, including norms that may be discrepant with societal standards espoused by adults.

Even norms consistent with those of adults are "discovered" by children through their interactions with friends.

Damon (1988) identified as primary to childhood relationships reciprocity of a symmetrical kind, which is more likely to occur among children than between adults and children because children perceive each other as equals in status and power. Moreover, the mutuality and intimacy that develop among children entail close collaboration and communication and are more likely to foster decisions based on consensual agreements. Children, thereby, come to understand that social rules can be based on cooperation among equals in creating and applying them and not solely on the authority of others. Children, through interactions involving give-and-take, collaborations, the sharing of ideas, openness to new insights, and compromise "co-construct" knowledge and ways of thinking. Co-construction involves children together discovering solutions to problems and encouraging creative thinking.

In the context of research on the development of concepts of distributive justice, experimental work has shown that children change more as a consequence of discussions with peers than with adults (Damon, 1981). Other studies on the influences of peer discussion among college students were conducted in the context of Kohlberg's stages of moral judgments. In these studies, students were paired for discussions about moral dilemmas so as to create disparities in their previously assessed levels of moral judgment. It was found that discussions between those whose levels were only slightly different served to stimulate change (Berkowitz, Gibbs, & Broughton, 1980) and that the most effective types of discussions entailed efforts at transforming each other's meanings into comprehensible forms (Berkowitz & Gibbs, 1983).

Another source of development related to peer interactions occurs through social conflicts (Berkowitz & Gibbs, 1985; Killen & Nucci, 1995), which are common among children, and can stimulate them to take different points of view to restore balance to social situations, to produce ideas as to how to coordinate the needs of others and self, and to consider the rights of others—especially claims of ownership or possession of objects (see Killen & Nucci, 1995, for more extensive discussion). Research by Killen and her colleagues (Killen, 1989; Killen & Naigles, 1995; Killen & Nucci, 1995; Killen & Sueyoshi, 1995; Rende & Killen, 1992) has also demonstrated that in the absence of adult intervention, young children are quite capable of addressing social conflicts and producing resolutions that take the

needs and interests of others into account. In another study (Eisenberg, Lundy, Shell, & Roth, 1985), it was found that preschool children justified meeting the requests of peers with references to the needs of others and to their relationships with others (requests of adults, by contrast, were justified with references to authority and punishment).

### **The Construction of Moral Judgments through Social Interactions**

Conflicts, disputes, argumentation, and discussion are all part of social interactions. For many who emphasize the role of judgments in morality, such social interactions are involved in the individual's constructions of moral judgments that are not solely local or derived primarily from parental teachings or from an integrated, consistent cultural pattern. In these positions, generalizable, nonlocal moral judgments are not innately based but constructions through social interactions. A significant aspect of approaches emphasizing judgments is to have an epistemological grounding with regard to the nature of the realm of morality. For a number of researchers, such grounding is provided by philosophical traditions that, as put by Nussbaum (1999), presume that "human beings are above all reasoning beings." Nussbaum has summarized such traditions going back to Immanuel Kant and John Stuart Mill and including contemporary philosophers like Rawls (1971, 1993), Dworkin (1977), Gewirth (1978), and Habermas (1990a, 1990b, 1993) as follows:

At the heart of this tradition is a twofold intuition about human beings: namely, that all, just by being human, are of equal dignity and worth, no matter where they are situated in society, and that the primary source of this worth is a power of moral choice within them, a power that consists in the ability to plan a life in accordance with one's own evaluations of ends . . . the moral equality of persons gives them a fair claim to certain types of treatment at the hands of society and politics. What this treatment is will be a subject of debate within the tradition, but the shared starting point is that this treatment must do two closely related things. It must respect and promote the liberty of choice, and it must respect and promote the equal worth of persons as choosers. (p. 54)

Nussbaum adds that a basic moral premise in these approaches is that each person be treated as an end and not as a means to other goals. She maintains that emotions are intertwined with moral reasoning. In this view,

morality is not primarily driven by emotions. Emotions involve evaluative appraisals so that "the entire distinction between reason and emotions begins to be called into question, and one can no longer assume that a thinker who focuses on reason is excluding emotion" (Nussbaum, 1999, p. 72). From the psychological perspective, emotional experiences inform the development of thought and, reciprocally, thinking informs the development and maintenance of emotions.

In line with Nussbaum's propositions, the approaches to moral judgments linked to Piaget (1932) and Kohlberg (1963) have considered emotional appraisals important to both the formation of morality and its applications. However, aversive emotions are not the basis of moral judgments. Rather, emotions of sympathy, empathy, and especially respect are central. In Piaget's view, combinations of in-born or very early emerging emotions of fear, affection, and sympathy, as well as vindictiveness and compassion, help form the basis for the development of morality. He regarded instinctive tendencies as "a necessary but not a sufficient condition for the formation of morality" (Piaget, 1932, p. 344), and maintained that "the child's behavior toward persons shows signs from the first of those sympathetic tendencies and affective reactions in which one can easily see the raw material of all subsequent moral behavior. But an intelligent act can only be called logical and a good-hearted impulse moral from the moment that certain norms impress a given structure and rules of equilibrium upon this material" (p. 405). It is especially the combination of fear, affection, and sympathy in relation to adults that are intertwined with social interactions and processes of reasoning that make for the emergence of heteronomy—which includes "unilateral respect" for those in authority. The transformation of unilateral respect into feelings of mutual respect is essential for the emergence of autonomous moral judgments about welfare and justice.

From philosophical perspectives, as well as psychological ones, propositions regarding universalizable moral reasoning are consistent with the idea that morality stems from social experiences and social constructions. One of the most extensive philosophical formulations of the social sources of moral reasoning can be seen in the "neo-Kantian" propositions of Habermas (1993), based on his theory of communicative action and discourse ethics, that morality entails concepts of justice, rights, and welfare (of others and the general welfare). Habermas bridges important distinctions: one between justification and application of moral norms,

the other between individual autonomy and social solidarity. Whereas moral principles are justified or grounded in criteria of universalizability and impartiality, situational features are taken into account in their application to concrete instances. Consequently, the way moral principles are understood is a necessary component, as is an understanding of the features of the context. As put by Habermas (1993):

The principle of universalization that regulates discourses of justification does not exhaust the normative sense of the impartiality of a just judgment. A further principle must be adduced to guarantee the correctness of singular judgments. An impartial judge must assess which of the competing norms of action—whose validity has been established in advance—is most appropriate to a given concrete case once all the relevant features of the given constellation of circumstances have been accorded due weight in the situational description. Thus, principles of appropriateness and the exhaustion of all relevant contextual features come into play here. (p. 129)

Habermas maintained that both autonomy and social solidarity are essential features for those participating in a network of reciprocal expectations. Discourse, communication, and argumentation are the means by which individuals function in a moral world. This places individuals in a collectivity, attempting to maintain social solidarity by submitting their moral principles for verification by others in moral dialogue, reflective discussion, and argumentation. In the process, individuals take positions based on moral concepts but through consensus attempt to achieve resolutions that account for the general welfare and maintenance of solidarity.

Habermas also incorporated developmental research into his philosophical formulations, relying on his revised form of the progression of moral judgments formulated by Kohlberg (the general outline of the stage progression was provided earlier). Like Kohlberg (1976), Habermas regarded stages of perspective taking (Selman, 1980) as part of the process of the formation of moral judgments. However, Habermas's theory of discourse ethics is not dependent on Kohlberg's particular formulation. It would be consistent with psychological formulations that postulate that individuals make moral judgments of a generalizable kind.

Kohlberg's formulations are not further reviewed here, as they have been discussed extensively in previous editions of this *Handbook* (see Hoffman, 1970, and, especially, Rest, 1983). Several researchers, however, have pursued hypotheses based on the stages proposed by

Kohlberg. This includes research conducted by Kohlberg and his colleagues tracing developmental changes longitudinally (Colby, Kohlberg, Gibbs, & Lieberman, 1983) and reformulating the specific descriptions of the stages (Colby & Kohlberg, 1987a; Kohlberg, 1984; Kohlberg, Levine, & Hewer, 1983). Other researchers have used Kohlberg's formulations to examine relationships between perspective taking and moral development (e.g., Keller & Edelstein, 1991; Selman, 1980; Walker, 1980), hypotheses regarding the invariance of the stages (Walker, 1982; Walker, de Vries, & Bichard, 1984), and processes by which changes occur (Berkowitz & Gibbs, 1983; Walker & Taylor, 1991).

Some studies have examined family variables and moral judgment, including correspondence between parents' and children's levels (e.g., Hart, 1988b; Walker & Taylor, 1991). Other studies (Hart, 1988a; Hart & Chmiel, 1992) have related personality measures and defense mechanisms to stages of moral judgment. There have also been theoretical formulations aimed at combining aspects of Kohlberg's stage sequence with other variables, such as affect, coping, and stress, to explain unusual moral commitments on the part of individuals (Haste, 1990). Still other research has attempted to extend the analyses to the adult life span, including among the elderly (Pratt, Golding, & Hunter, 1983; Pratt, Golding, Hunter, & Norris, 1988).

Studies were conducted on the influences of attending college on the development of moral judgments (e.g., Rest & Narvaez, 1991). These studies deviate from Kohlberg's procedures in that assessments were made using a paper and pencil questionnaire requesting individuals to rate and rank a series of solutions to moral dilemmas corresponding to the six stages—in contrast with Kohlberg's semistructured clinical interview aimed at ascertaining individuals' ways of thinking (see Rest, 1979, for details on the standardized assessment; see Damon, 1977, Piaget, 1929; Turiel, 1983a, for discussions of the aims and value of the clinical interview method). The research conducted by Rest is also linked to what he refers to as a "Four Component Model" of moral development, including judgment, "sensitivity," motivation, and ego strength (it is detailed in a previous edition of this *Handbook*; Rest, 1983; see also Rest, Narvaez, & Thoma, 1999).

### Moral Judgments in Early Childhood and Beyond

Kohlberg's stage formulation, in which young children's moral judgments are based on obedience and sanctions,

was derived from responses to complex situations in which competing and conflicting issues are depicted. As an example, the often-cited situation of a man who must decide whether to steal an overpriced drug that might save his wife's life includes considerations of the value of life, property rights, violating the law, interpersonal obligations, and personal responsibilities to each of these. In that sense, Kohlberg was attempting to study judgments in contexts. He constructed hypothetical situations in which the use of readily conceived values (e.g., it is wrong to steal; it is wrong to allow someone to die) would be complicated by situational circumstances (e.g., if you do not steal, you sacrifice a life; if you try to save a life, you violate another's property rights). These situations, however, presented multifaceted problems requiring children to weigh and coordinate competing moral considerations and nonmoral considerations (Turiel, 1978a, 1978b, 1983a, in press-a). The complexity of the judgments required by those situations led to the appearance that young children's moral judgments are contingent on sanctions, are not based on understandings of morality as generalizable, and it is not until after progressing to the fourth stage (usually not until at least adolescence) that morality is distinguished from nonmoral issues (Turiel & Davidson, 1986). Research into several aspects of moral judgments indicates that starting at a young age children make moral judgments that are not based on extrinsic features like obedience and sanctions. These include judgments about distributive justice, social justice in institutional settings, and prosocial actions.

### **Concepts of Distributive Justice and Fairness of Social Practices**

In accord with long-standing presumptions among philosophers (e.g., Aristotle, 1947; Mill, 1863/1963; Rawls, 1971), Damon (1988, p. 31) has placed issues of distributive justice at the forefront of moral concerns. His research on children's concepts of sharing and distribution revealed a developmental progression of moral judgments (Damon, 1975, 1977, 1980, 1988), with indications that very young children are somewhat attuned to sharing. In their 2nd year, children take turns in playing with objects and show awareness that food or candy can be divided. Information regarding how children 4 to 5 years of age and older conceptualize sharing comes from research on children's judgments about hypothetical and real-life situations entailing the distribution of

goods (Damon, 1977, 1980). For example, in one situation, children in a class that made paintings to sell at a school fair must decide how to distribute the proceeds. Children were asked to respond to examples of ways of distributing the money (e.g., on the basis of merit, need, equality, and sex of the children) and to give their ideas on how the money should be distributed. The children were presented with examples of ways of distribution so as to elicit reactions to three categories considered basic in the literature on moral philosophy: equality, merit, and benevolence.

It was found that children's thinking about distributive justice progresses through four levels encompassing equality, merit, and benevolence (though not at the first level). At the first level, concepts of distribution initially are tied to the child's own desires and perspectives. After these initial judgments, children begin to bring in external criteria (such as size or ability). Although these external features ultimately are used to justify a person's desires and goals, this way of thinking leads to other-oriented concepts based on equality, merit, and benevolence. Elementary school-aged children, at the next level, base their judgments on equality; everyone should be given the same amount and receive the same treatment, regardless of merit or need. Next comes a shift to considerations of merit and reciprocity; distribution is based on the need to acknowledge good deeds, hard work, or personal attributes like intelligence. The next shift includes judgments that take benevolence into account, with greater awareness of competing claims and an understanding of the need for compromises to resolve claims in a fair manner. Therefore, by the ages of 10 or 11 years, children take into account merit (hard work, talent), advantages and disadvantages, and other factors (e.g., investment, inheritance).

This developmental sequence was supported by longitudinal findings (see Damon, 1977, 1980). Furthermore, similar patterns of judgment were obtained in studies of behavioral situations in experimental contexts (Gerson & Damon, 1978). Judgments on the "real-life" situations (elicited individually and in group discussions) were highly correlated with judgments on the hypothetical situations, and the same age trends were evidenced. It was also found, however, that personal concerns were coordinated with judgments about distribution to a greater extent in the real-life than the hypothetical situations. For example, children who showed an understanding of merit as a basis for fairness were

most likely to apply that understanding when they were themselves in a meritorious position than when they were not. In ways consistent with these findings, Blasi (1993) proposed that an integration of concepts of self and identity contributes to how individuals act on their moral judgments.

An age-related sequence generally corresponding to the levels of concepts of distributive justice has been observed by Thorkildsen (1989a, 1989b, 1991) in children's judgments about the fairness of classroom practices pertaining to "educational goods" (e.g., ways of fostering learning, contests, and testing situations). In one study (Thorkildsen, 1989a), children and adolescents judged the fairness of several different teaching practices as to how faster workers would proceed, relative to slower workers, in a class assignment (e.g., after finishing, faster workers tutor slower ones; faster workers move on to other learning experiences). It was found that younger children focus on equality and older ones on equity. In the focus on equality, there are also shifts with age in the goods considered relevant. The youngest children judged as fair attainment of an equality of rewards, whereas somewhat older children consider as fair those practices that result in equality in schoolwork completed. This is followed by an emphasis on learning as the relevant good where practices that foster equality in learning are judged as fair. Finally, equity in learning is judged as the basis for fairness; it is fair that those capable of learning more than others do so.

Thorkildsen, in other research (1989b), has linked judgments of fair practices to individuals' situational definitions. What is considered a fair classroom practice in the context of a learning activity differed from what is considered fair in a testing situation (e.g., helping slower workers to learn was judged as more fair than helping them on a test). These findings indicate that children coordinate their understandings of the goals of events (e.g., to learn or to demonstrate what one knows), participants' perspectives on those events, and what would constitute a breach of just expectations. Thorkildsen (1989b, 1991) interprets these results as showing that concepts of justice vary in accord with "spheres" of activities (e.g., justice is one thing in economics, another in the family).

### Prosocial Moral Judgments

Children's judgments about sharing or distribution pertain to actions beneficial to others and possibly entail

sacrifice of self-interests. These are not the only types of positive social actions experienced by children. The term *prosocial* moral reasoning has been used (Eisenberg-Berg, 1979) with reference to judgments about positive social actions (e.g., helping, giving) serving to benefit others in contexts in which a person's actions are not based on rules, laws, or the dictates of authorities. Children were presented with hypothetical situations posing conflicts between the needs and desires of different actors and questioned about whether it would be right to help, give, or share with others at the expense of their own goals (Eisenberg-Berg, 1979). One situation depicted people faced with deciding whether to help feed those of another town who had lost their food in a flood; doing so would present a hardship to them. Other situations included donating blood, helping another who is being mugged or bullied, and helping physically disabled children.

A sequence of five age-related levels in judgments about prosocial actions were identified—a sequence proposed to reflect developmental advances in "capabilities for complex perspective taking and for understanding abstract concepts" (Eisenberg, Miller, Shell, McNalley, & Shea, 1991, p. 849). It was also proposed that the levels do not constitute hierarchical, integrated structures, and that the sequence is not entirely invariant nor necessarily universal (i.e., Eisenberg indicates that some aspects of the levels likely are invariant due to developmental changes in perspective-taking skills and abstract reasoning and that the early levels are more likely to be universal than later ones; Eisenberg, 1986). This implies that an individual's reasoning can be spread over the different types and that the sequence may vary by situations and life circumstances. At the first level, judgments are based on a "hedonistic," self-focused orientation (personal gain is linked to reciprocity with others, based in identification and relationship with another, or liking for the other), whereas at the next level there is an orientation to the needs of others. This is followed by judgments based on stereotypes of good or bad persons, along with concerns with the approval or disapproval of others. The fourth level is characterized by a self-reflective and empathetic orientation, including sympathetic concern and caring for others, and taking the perspective of others. At the fifth level, there is an internalization of affect linked to self-respect and an internalization of laws, norms, duties, and responsibilities, as well as abstract types of reasoning about society, rights, justice, and equality.

A series of longitudinal assessments were conducted following children from preschool to ages 19 to 20 years (Eisenberg, Carlo, Murphy, & Van Court, 1995; Eisenberg, Lennon, & Roth, 1983; Eisenberg et al., 1987, 1991; Eisenberg-Berg & Roth, 1980; Valiente et al., 2003). The longitudinal findings yielded a heterogeneous pattern of changes in prosocial judgments. In broad terms, there was advance on the levels with increasing age and decreased use of the lowest levels. However, along with increased use of the higher levels with age, there were renewed uses of aspects of lower levels. Hedonistic reasoning decreased in mid-adolescence, but in late adolescence, along with increases in self-reflection and empathy, there was some increase in hedonistic reasoning (i.e., in situations where costs of helping were high). The patterns obtained in the longitudinal studies indicate, again, an interaction of different ways of thinking with situational contexts, as do studies in Brazil (Carlo, Koller, Eisenberg, DaSilva, & Frolich, 1996) and on relations of prosocial reasoning to emotions (Miller, Eisenberg, Fabes, & Shell, 1996; for further discussion of this extensive body of research, see Eisenberg, Fabes, & Spinard, Chapter 11, this *Handbook*, this volume).

### DOMAIN SPECIFICITY: EMPHASIZING DISTINCTIONS IN JUDGMENTS

Concepts of welfare and justice emerge as central in the development of morality across the diversity of theoretical approaches. Several theorists pursued hypotheses regarding other issues, but their research findings have pointed to welfare and justice as ubiquitous components of moral judgments. Gilligan's (1982) initial emphasis on the division of gender more or less along a care or justice orientation has been largely transformed into the proposition that the two orientations coexist in most individuals, including a substantive concern with justice on the part of females. The proposition that cultures divide more or less on the basis of an orientation to the individual as an autonomous agent with rights or an orientation to the duties of the social order has also been transformed. The research by Miller and her colleagues consistently demonstrated that Indians maintain concepts of justice and welfare (in this regard, little difference was obtained between cultures).

Philosophers, dating back to the formulations of Aristotle, have considered concepts of justice and welfare

central to morality. Aristotle, like many philosophers after him (e.g., Dworkin, 1977; Gewirth, 1978, 1982; Habermas, 1990b; Rawls, 1971), considered justice as "other-regarding," impartial, and as characterized by universality (see Helwig, Turiel, & Nucci, 1996, for further discussion). As already indicated, Piaget's research was consistent with moral epistemologies of this type. However, Piaget proposed that understandings of welfare, justice, and rights did not emerge until after a period in which right and wrong are judged by the word of authorities and the necessity of adhering to their rules. Such "unilateral respect," according to Piaget, reflected young children's heteronomous thinking in which undifferentiated concepts of authority are based on adults' size, power, and knowledge. In this way of thinking, justice is subordinated to obeying rules and authority: "if distributive justice is brought into conflict with adult authority, the youngest subjects will believe authority right and justice wrong" (Piaget, 1932, p. 304). However, several studies conducted in the United States (Braine, Pomerantz, Lorber, & Krantz, 1991; Damon, 1977; Laupa, 1991, 1994; Laupa & Turiel, 1986, 1993; Tisak, 1986) and Korea (Kim, 1998; Kim & Turiel, 1996) have yielded a different portrayal of young children's understandings of authority relations and moral judgments (see Helwig, in press; Turiel & Smetana, 1998, for a discussion of problems in Piaget's propositions regarding young children's moral thinking).

These studies have shown that young children, in evaluating commands by either adults or peers in positions of authority, account for the type of act commanded and the boundaries of the authority's jurisdiction in a social context. Damon (1977) found that young children do not accept the legitimacy of a parent's directive to engage in acts judged to violate moral injunctions such as directives to steal or cause another harm. Other studies (Kim, 1998; Kim & Turiel, 1996; Laupa, 1991, 1994; Laupa & Turiel, 1986, 1993) examined how children account for the type of act commanded and the attributes of persons giving commands (i.e., adult or peer, social position in a school, and attributes like possessing knowledge about rules or an event). With acts entailing theft or physical harm to persons, young children (4 to 6 years) give priority to the act itself rather than the status of the person as in a position of authority. For example, whether they hold positions of authority, commands from peers or adults that children stop fighting were judged as legitimate. Moreover, commands from peers (with or without positions

of authority in a school) that children stop fighting were judged as more legitimate than a conflicting command from an adult authority (e.g., a teacher) that children be allowed to continue fighting. By contrast, children do give priority to adult authority over children or other adults who are not in positions of authority for acts like turn-taking and interpretations of game rules.

Children's judgments are not based on respect or reverence for adult authority but on an act's harmful consequences to persons (for a more general discussion of concepts of authority, see Laupa, Turiel, & Cowan, 1995). Children's judgments about harmful consequences emerge early in life along with emotions of sympathy, empathy, and respect (Baldwin, 1896; Piaget, 1932; Turiel, in press-a); at young ages children go well beyond social impulses and the habitual or reflexive, attempting to understand emotions, other persons, the self, and interrelationships (Arsenio, 1988; Arsenio & Lemerise, 2004; Nucci, 1981; Nunner-Winkler & Sodian, 1988; Turiel, 1983a, in press-b). A great deal of research has demonstrated that young children make moral judgments about harm, welfare, justice, and rights, which are different from their judgments about other social domains.

### Domains of Social Judgment

Distinguishing morality from other domains presupposes that individuals think about social relationships, emotions, social practices, and social order. It presupposes that thinking about morality has features distinctive from thinking about other aspects of the social world (hence the idea of domain specificity). It also presupposes that individuals' judgments about the social world include domains of importance, which need to be distinguished from morality. Individuals form judgments in the "personal" domain that pertain to actions considered outside the jurisdiction of moral concern or social regulation and legitimately in the jurisdiction of personal choice (Nucci, 1996, 2001; Nucci & Lee, 1993). Individuals also form judgments about social systems, social organization, and the conventions that further the coordination of social interactions in social systems. As summarized in Turiel et al. (1987):

Conventions are part of constitutive systems and are shared behaviors (uniformities, rules) whose meanings are defined by the constituted system in which they are embedded. Adherence to conventional acts is contingent on

the force obtained from socially constructed and institutionally embedded meanings. Conventions are thus context-dependent and their content may vary by socially constructed meanings. (pp. 169–170)

Morality, too, applies to social systems, but the contrast with convention is that it is not constitutive or defined by existing social arrangements. In this perspective on morality, prescriptions are characterized as obligatory, generalizable, and impersonal to the extent that they stem from concepts of welfare, justice, and rights (Turiel et al., 1987). This type of definition of morality is, in part, derived from criteria given in philosophical analyses where concepts of welfare, justice, and rights are not seen as solely determined by consensus, agreement, or received wisdom. In his *Nicomachean Ethics*, Aristotle drew a distinction of this type, although he couched it as two forms of justice:

There are two forms of justice, the natural and the conventional. It is natural when it has the same validity everywhere and is unaffected by any view we may take of the justice of it. It is conventional when there is no original reason why it should take one form rather than another and the rule it imposes is reached by agreement after which it holds good. Some philosophers are of the opinion that justice is conventional in all its branches, arguing that a law of nature admits no variation and operates in exactly the same way everywhere—thus fire burns here and in Persia—while rules of justice keep changing before our eyes. It is not obvious what rules of justice are natural and what are legal and conventional, in cases where variation is possible. Yet it remains true that there is such a thing as natural, as well as conventional, justice. (as cited in Winch, 1972, p. 50)

Although Aristotle considered other aspects of morality, including happiness and the good life, which differed from the approaches of philosophers like Dworkin (1977), Gewirth (1978), Habermas (1990a, 1990b), and Rawls (1971), there is overlap among all of them in the propositions that justice is universal (it has the same validity everywhere), it is not legitimated by agreement (as opposed to convention), and it is impartial (not based on personal preference or individual inclinations).

These features of morality are not solely the products of philosophical conceptions but apply also to laypersons' ways of thinking. As noted earlier, children and adolescents in India make judgments about welfare and justice that differ from their judgments about social convention (Bersoff & Miller, 1993; Madden, 1992;

Miller & Bersoff, 1992). Similar findings have been obtained in several other non-Western cultures, including Korea (Song, Smetana, & Kim, 1987), Hong Kong (Yau & Smetana, 2003), Indonesia (Carey & Ford, 1983), Nigeria (Hollos, Leis, & Turiel, 1986), Zambia (Zimba, 1987), Brazil (Nucci, Camino, & Milnitsky-Sapiro, 1996), and Colombia (Ardila-Rey & Killen, 2001). A greater number of studies have evidenced that domain distinctions are made by children and adolescents in Western cultures. Well over 100 studies have examined and supported the validity of the domain distinctions (for comprehensive reviews, see Helwig, Tisak, & Turiel, 1990; Killen, McGlothlin, & Lee-Kim, 2002; Nucci, 2001; Smetana, 1995b, 2006; Tisak, 1995; Turiel, 2002).

One direction of early research on domains was to examine how children make judgments about moral, conventional, and personal issues (e.g., Davidson, Turiel, & Black, 1983; Nucci, 1981; Smetana, 1981; Tisak, 1986; Tisak & Tisak, 1990; Tisak & Turiel, 1984, 1988; Turiel, 1978b, 1983a; Weston & Turiel, 1980). Children were typically presented with a series of social acts or transgressions classified in accord with the distinctions among the domains. Thus, moral actions pertained to physical harm (e.g., hitting others or pushing them down), psychological harm (e.g., teasing, name-calling, or hurting feelings), and fairness or justice (e.g., failing to share, stealing, or destroying others' property). These acts were depicted as intentional and as resulting in negative consequences to others (a few studies also included prosocial actions—Kahn, 1992; Smetana, Bridgeman, & Turiel, 1983). Recent research has also examined in more detail issues of psychological harm (Helwig, Hildebrandt, & Turiel, 1995; Helwig, Zelazo, & Wilson, 2001) and fairness with regard to social exclusion (Killen, Lee-Kim, McGlothlin, & Stagnor, 2002; McGlothlin, Killen, & Edmonds, 2005). By contrast, conventional issues pertained to uniformities or regulations serving functions of social coordination (e.g., pertaining to modes of dress, forms of address, table manners, or forms of greeting). Actions that do not entail inflicting harm or violating fairness or rights and that are not regulated formally or informally are consistent with the definition of the personal domain (these issues, in Western culture, include choices of friends, the content of personal correspondence, and recreational activities).

Two dimensions, in particular, have been examined. One pertains to the criteria by which thinking in do-

main is identified (referred to as *criterion judgments*); the second pertains to the ways individuals reason about courses of action (referred to as *justifications*). Assessments of criterion judgments have included questions as to whether the actions would be right or wrong in the absence of a rule or law, if the act would be all right if permitted by a person in authority (e.g., a teacher in a school context), whether an act would be all right if there were general agreement as to its acceptability, and whether the act would be all right if it were accepted in another group or culture. These studies consistently show that children and adolescents judge that moral issues are obligatory; that they are not contingent on authority dictates, rules or consensus (e.g., that the acts would be wrong even if no rule or law exists about it); or on accepted practices in a group or culture (e.g., the act is wrong even if it were an acceptable practice in another culture). Judgments about moral issues, based on these criteria, are structured by concepts of welfare, justice, and rights. Justifications for these judgments entail preventing harm and promoting welfare, fairness, and rights (Turiel, 1983a, 2002).

However, all social actions and regulations are not judged in these ways. Conventional issues are conceptualized as linked to existing social arrangements and contingent on rules, authority, and existing social or cultural practices. Justifications for judgments about conventional issues are based on understandings of social organization, including the role of authority, custom, and social coordination. Even when conventional transgressions are deemed very important, children still judge them by conventional criteria and justifications (Tisak & Turiel, 1988). Furthermore, nonmoral actions that are not part of the conventionally regulated system are judged to be part of the realm of personal jurisdiction, which defines the bounds of individual authority and establishes distinctions between the self and group (Nucci, 1996, 2001).

The research has focused more on the distinctions among moral, conventional, and personal judgments, as well as ways the domains are manifested in varying aspects of social interactions, and much less on changes in the domains. However, the findings on domain distinctions have far-reaching developmental implications. Because the domains are differentiated at fairly early ages and continue to be so into adulthood, development is not adequately characterized as entailing differentiations between domains. In addition, the domains provide the context for the study of developmental

transformations. At least two types of analyses need to be drawn to better understand developmental changes. One would entail analyses of changes in judgments within domains and the other analyses of how the different domains are coordinated.

Research has been done on levels of thinking within the conventional domain (Turiel, 1983a) and the personal domain (Nucci, 2001). Thus far, analyses of changes in thinking within the moral domain are limited. Levels of thinking about distributive justice identified by Damon (1977, 1980) have already been discussed. Other research indicates that young children's moral judgments are grounded in concepts of physical harm and welfare and that older children form greater understandings of psychological harm, fairness, justice, and equal treatment (Davidson et al., 1983; Kahn, 1992; Turiel & Smetana, 1998). In early adolescence, there is also a greater concern with equity as part of fair treatment (Damon, 1977) and efforts to coordinate the fairness of equality and equity. (See Nucci, 2001, chap. 4, for a more extensive discussion of ways of characterizing developmental transformations in the moral domain.)

The research on domains shows that individuals' social judgments are multifaceted, including understandings of right and wrong based on concerns with welfare, justice, and rights that are not simply based on acceptance of societal values, along with understandings of the conventional system of social regulation and coordination judged as relative and context-specific. Starting in early childhood, differentiations are made among moral, conventional, and personal concepts whose origins appear to be based in early social experiences (for more detailed discussions of methods, types of studies, and numbers of studies documenting domain distinctions in criterion judgments and justifications, see Helwig et al., 1990; Smetana, 1995b; Tisak, 1995; Turiel, 1983a).

Several studies were conducted with young children. In one type of study, criterion judgments were assessed among children ranging from about 2 years to about 5 years (Crane & Tisak, 1995a; Nucci & Turiel, 1978; Siegal & Storey, 1985; Smetana, 1981, 1985; Smetana & Braeges, 1990; Smetana, Schlagman, & Adams, 1993; Smetana et al., 1999; Tisak, 1993; Yau & Smetana, 2003). These studies show that a distinction between moral and conventional transgressions becomes more consistent and focused by about the ages of 4 or 5 years. Whereas 2-year-olds do not distinguish the domains,

during their 3rd year children judge moral transgressions to be generally wrong to a greater extent than conventional transgressions. By the end of the 3rd year, children also judge moral transgressions independently of rules or authority (Smetana, 1995b; Smetana & Braeges, 1990). Although 6- or 7-year-old children generally make the distinction on several dimensions, it has been found that they apply it readily to familiar but not unfamiliar issues (Davidson et al., 1983). By the ages of 9 or 10 years, children apply the distinction to both familiar and unfamiliar issues.

### Social Judgments and Social Experiences

Just as children's judgments are multifaceted, their social experiences are varied. Some of those variations have already been considered—experiences with parents, siblings, and peers. Children also experience the substance of people's (adults' or children's) reactions to the events around them, including emotional responses to social interactions. An important part of all this is communications among persons, and as already considered, how explicit communications (induction or explanations) may be more effective than implicit communications between parent and child. Among young children's experiences are interactions that differ in the context of dealing with moral, conventional, or personal issues. A series of observational studies in schools, playgrounds, and homes (ages ranging from 2 and 3 years to late childhood) has shown that communications between adults and children, as well as other types of social interactions, are not uniform (Nucci & Nucci, 1982a, 1982b; Nucci & Turiel, 1978; Nucci, Turiel, & Encarnacion-Gawrych, 1983; Nucci & Weber, 1995; Smetana, 1984, 1989b; Tisak, Nucci, Baskind, & Lamplig, 1991).

To summarize the findings, children's experiences around moral transgressions (e.g., when one child hits another, a failure to share, or taking another's objects) usually entail communications about the effects of acts on others, the welfare or expectations of others, and attention to the perspectives and needs of others. At an early age, children respond to moral transgressions and focus on the consequences of actions, the pain and injuries experienced, and emotions felt. The observational studies generally show that young children do not respond to conventional transgressions to the extent they respond to moral transgressions. However, adults' responses to conventional transgressions focus on issues

of disorder, rule maintenance, authority, and more generally on social organization.

Much more than exposure to directives about rules, standards, or norms is involved in children's social experiences. At the least, social interactions and social communications differ in accord with domains. Furthermore, the distinction between morality and social conventions applies to situations actually experienced (Smetana et al., 1999; Turiel, 2002). The most extensive study showing that this is the case was conducted in the context of social interactions in elementary and junior high schools, where observations were made in classrooms, periods of recess, during lunch, and during transitions from one activity to another (reported in Turiel, 2002, chap. 6). The detailed recording of observations included events or incidents entailing moral or conventional issues and events that involved combinations of the two domains.

The majority of observed events involved transgressions (e.g., around physical harm, issues of fairness, and psychological harm), but some also involved efforts at preventing moral or conventional transgressions. As in prior observational studies, social interactions and communications were, in important respects, different for the moral and conventional events. In reaction to moral events, participants responded with statements about the injurious effects on others, the unfairness of actions, and at times with physical or verbal retaliation. By contrast, reactions to the conventional events focused on rules, sanctions, and commands to refrain from the acts. In this research, unlike most of the prior studies, participants' judgments about the events were assessed shortly after the events had occurred. For the most part, participants negatively evaluated the moral and conventional transgressions and accepted as valid the rules prohibiting the actions. Nevertheless, judgments about the actual moral events differed from judgments about the actual conventional events in ways consistent with previous findings in studies conducted in nonbehavioral contexts. Acts in the moral domain, in contrast with acts in the conventional domain, were judged independently of rules, institutional context, or authority dictates. As examples, generally it was judged that moral acts should be regulated, and that moral acts would be wrong even if a rule did not exist in the school or in a school in another city. It was judged that conventional acts were acceptable if rules did not exist. It was also found that transgressions in the moral domain, in contrast with conventional transgressions, would be wrong even if the

teacher dictates that they are acceptable. In turn, justifications for judgments about moral events were mainly based on welfare and justice, whereas for conventional events, justifications were mainly based on considerations of social organization, rules, authority, and tradition. Moreover, these participants made similar judgments and justifications when responding to situations put to them in hypothetical terms.

### Social Judgments and Family Interactions

Differences among the domains of social judgment also have a bearing on social interactions in families. In addition to moral and conventional issues, the domain of personal jurisdiction is a salient aspect of social interactions across different age periods. As shown in a study (Nucci & Weber, 1995) of social interactions in the home between children (3 to 4 years of age) and mothers, children are given a fair amount of freedom and discretion with regard to aspects of behavior revolving around personal issues. Mothers allow their children choices in activities, show a willingness to negotiate, and accept challenges from them. Other studies have shown that mothers in the United States (Nucci & Smetana, 1996) and Japan (Yamada, 2004) believe that there are areas of personal jurisdiction to be granted to young children (e.g., clothes, recreational activities, or choices of playmates). American and Japanese mothers also believe that control should be exercised over children's activities that have moral implications, that involve social conventions, and that might be unsafe (see also Killen & Smetana, 1999, on judgments of teachers in the United States). The mothers reported that conflicts occurred with their children over issues of safety and prudence. In the observational studies, as well as the studies of mothers' beliefs, it was found that most allow choice on certain activities, but interact differently with their children over moral, social-conventional, and prudential issues, often placing restrictions on them. Therefore, the discretion mothers allow in the personal domain does not simply reflect a general permissive orientation.

The observational study by Nucci and Weber (1995), along with the research by Dunn and her colleagues (e.g., Dunn & Munn, 1987), show that relationships between parents and children, early on, include conflict and harmony, as well as domain differences in the extent to which parents are directive. This pattern of heterogeneity of social relationships is not, by any means, re-

stricted to early childhood. It is generally accepted that conflicts occur between parents and adolescents (Collins & Laursen, 1992; Smetana, 1995a). Adolescence is a period in which parents have multiple goals for their children and in which personal decisions become more salient. The ways parents and adolescents think about moral, social-conventional, and personal issues in family interactions have been part of an extensive program of research by Smetana and her colleagues (see Smetana, 1995b, 1997, 2002, for reviews). This body of work has included European American and African American working-class and middle-class families and working-class families in Hong Kong. The studies included divorced and two-parent families.

These studies consistently showed that morality is judged to be legitimately regulated and enforced by parents (Smetana, 1988, 1995a, 2000, 2002; Smetana & Daddis, 2002). There is acceptance of parental authority over moral issues by adolescents of varying ages and by their parents in nondivorced and divorced families (Smetana, 1988, 1993, 2000; Smetana & Asquith, 1994; Smetana, Yau, Restrepo, & Braeges, 1991), and with regard to both hypothetical and actual conflicts (Smetana, 1989a; Smetana, Braeges, & Yau, 1991). Smetana (1995a) reports that moral issues are not a frequent source of conflict between parents and adolescents. Adolescents also accept parental regulation over conventions, so that there is a good deal of agreement on those issues as well (Smetana, 1988, 2000; Smetana & Asquith, 1994; Tisak, 1986). Nevertheless, there is greater acceptance on the part of adolescents of parental authority over moral than conventional issues. It is issues in the personal domain, as well as those entailing a combination of personal and conventional considerations, which produce disagreements and conflicts (Smetana, 1988, 1993; Smetana & Asquith, 1994). As with younger children, adolescents identify issues they consider part of personal jurisdiction (some of the issues examined in these studies include spending decisions, appearances, and friendship preferences). European American parents tend to believe that they should have authority to control these activities (judging the activities as part of social convention), whereas adolescents believe that the activities are not legitimately regulated and are part of the realm of personal choice. Moreover, from early to late adolescence, there is an increase in judgments (by both parents and adolescents) that parents do not have authority over personal issues (Smetana, 1988; Smetana & Asquith, 1994). Another

type of disagreement occurs when parents judge a set of activities to be part of the personal realm but believe that their child is not old enough to make those choices. Parents accept that the acts can be freely chosen by older people and by their child at an older age. Conflicts occur when adolescents maintain that they should be free to engage in the activities (especially actions involving risks, such as smoking, drinking, and sex). An even sharper sort of disagreement occurs over issues combining conventional and personal considerations (e.g., disputes over order in an adolescent's room because it can be seen as both personal and shared space in the home; see Smetana, 1995a). Typically, clashes between adolescents and parents actually entail different interpretations of the issues. Parents focus on components pertaining to conventional regulations, whereas adolescents focus on personal components.

These patterns of findings hold for African American families, with some differences. As one example, parents in African American families were more likely than European American families to insist on some degree of involvement in the decisions of adolescents as they grew older (Smetana, 2000; Smetana & Gaines, 1999). There also appears to be more concern among the middle-class African American parents with pragmatic and prudential issues (and less with conventional issues). More generally, African American parents are more restrictive of adolescents' freedoms of choices over personal issues and issues that involve conventional and personal matters. Nevertheless, African American adolescents do assert their personal choices and oppose parents. According to Smetana (2006, p. 140), the greater restrictions imposed by African American parents are linked "to their concerns for their children's well-being in an environment where racism and prejudice remain pervasive and where too-early autonomy may carry substantial risks for their children's safety."

The research by Smetana and her colleagues provides evidence that synchrony does not always exist in the ways parents and their children interpret and evaluate social events. Although parents and children alike identify the different domains of judgment, they differ regarding the legitimacy of parental authority over some of the issues. They also differ in their interpretations of events with mixtures of personal and conventional considerations. Adolescents agree with parents in the ways they judge moral events and attribute legitimacy to parental authority. However, children and adolescents do not accept the legitimacy of parental authority with

regard to parental directives to engage in acts considered morally wrong (Laupa et al., 1995).

### Emotional Attributions and Social Judgments

Observational studies also show that conflicts among siblings usually occur over morally relevant issues, such as possessions, rights, physical harm, and unkindness (Dunn & Munn, 1987). These interactions include feedback from siblings, which reveal negative reactions and feelings, as well as communications, especially from parents, about reasons as to why acts are wrong (Smetana, 1995a). The observational studies suggest that the emotions surrounding moral transgressions may differ from those around conventional transgressions and that social events entail emotional reactions (Arsenio & Lover, 1995). Studies by Arsenio and his colleagues (Arsenio, 1988; Arsenio & Fleiss, 1996; Arsenio & Ford, 1985) have demonstrated that children associate different types of emotional outcomes with different types of social events.

In one study (Arsenio, 1988), children from 5 to 12 years of age, who were presented with descriptions of several different types of acts, gave their assessments of the emotions that would be experienced by different participants (actors, recipients, and observers). For events entailing positive moral actions, such as helping and sharing, children generally attributed positive emotions, like happiness, to the actors. For conventional transgressions, children attributed neutral or somewhat negative emotions (sadness, anger) to the participants. In the case of moral transgressions entailing one person victimizing another (e.g., a child stealing a toy from another), children attributed very negative emotions to the recipients and observers, and attributed somewhat positive emotions to the perpetrators of the acts. The research also showed children could use information about emotional responses to infer the types of experiences that would lead to the emotional reactions. Children, who were presented with descriptions of the emotional reactions of actors and alternative events that may have elicited the emotions, associated different emotions to the different actions; older children were able to do this more accurately than younger ones.

Children's reasons for characters in the events experiencing the emotions attributed to them, too, varied by domain of event and role of participants (Arsenio & Fleiss, 1996). The negative emotions expected of victims of moral transgressions were thought to occur be-

cause of the harm, loss, or injury resulting from the acts. For victimizers, however, it was thought that the material gains obtained by them would result in some feelings of happiness. With regard to conventional transgressions, it was thought that negative emotions would be felt by those in authority who tend not to want rules violated (also see Arsenio, Berlin, & O'Desky, 1989).

Thus, children differentiate among the emotions attributed to people in different roles in an event. In particular, they attribute different emotions to victims and those who do the victimizing. The youngest children assumed that those engaging in a transgression would feel positive emotions and the victims would feel negative emotions. The finding that positive emotions are attributed to victimizers is consistent with Nunner-Winkler and Sodian's (1988) finding that the younger children focused on the material outcomes for victimizers. Arsenio's research (e.g., Arsenio & Kramer, 1992) extends those findings by showing that attributions to victims and victimizers are very different, and that young children do not minimize the negative emotions that might be experienced by victims. Also, older children tended to attribute mixed emotions to victimizers, expecting that in addition to positive emotions for a desired outcome, there may be negative feelings due to the effects of their acts on others. Because even among the younger children, the moral transgressions were evaluated as wrong, it would appear that their attributions of positive emotional outcomes to victimizers do not determine their moral judgments about the acts. Instead, with regard to moral evaluations, the victims' reactions seem to be what is taken into account. It also appears that older children give priority to the victim in their moral judgments and understand that a victim's reactions can feed back on the victimizer and produce a mixture of positive and negative reactions (for more extensive discussion, including similar findings of a study conducted in Korea, see Arsenio & Lover, 1995).

Children's understandings of people's emotional reactions to moral and social transgressions bring to bear different realms of understanding. When young children state that a person who engages in a moral transgression feels happy and that the victim feels sad, it is likely that they are making psychological attributions. When older children state that a victimizer may experience a mixture of positive and negative emotions, they may also be making psychological attributions, with awareness that people can simultaneously experience more than one emotion. These interpretations are supported by a study

with children (ages 5 to 8 years) from Portugal and Germany (Keller, Lourenco, Malti, & Saalbach, 2003). Assessments were made of children's judgments of right and wrong about acts of stealing and breaking a promise, attributions of emotions to the victimizers, and whether the victimizers should feel a certain way (e.g., happy). Many of the younger children, especially the ones from Portugal, thought that the victimizer would feel happy. Nevertheless, they judged the acts to be wrong and tended to say that it was wrong for the victimizer to feel happy. Older children made the same moral evaluations, but attributed negative emotions to the victimizer. These findings demonstrate that children make psychological attributions that may be less or more coordinated with their moral judgments.

### Ambiguities, Uncertainties, and Deliberations

Despite the complexities in understandings of the psychological features of emotions, children do assume that victims of moral transgressions react negatively and they evaluate those transgressions as wrong using the previously mentioned criteria and justifications. The moral reasoning reflected in criterion judgments and justifications includes relatively complex components. Nevertheless, because young children (3- and 4-year-olds) make moral judgments about many situations, such as harming another person for reasons of self-interest or stealing another's property (situations referred to as "prototypical," see Turiel et al., 1987), in an unambiguous way and with certainty, it is said by some (e.g., Haidt, 2001) that their moral responses are easily derived and reflexive, and, in turn, that the judgments are intuitive or naturally given. As pointed out by Piaget (1932) many years ago, however, those presumptions ignore that 3- and 4-year-olds have experienced a fair amount of social interaction as infants and toddlers, and that they have already undergone some development. Piaget was responding to propositions put forth by Antipoff (H. Antipoff, *Observations sur la compassion et le sens de la justice chez l'enfant, Archives de Psychologie*, XXI, 1928), that a sense of justice involved "an innate and instinctive moral manifestation, which in order to develop really requires neither preliminary experience nor socialization amongst other children. . . . We have an inclusive affective perception, an elementary moral 'structure' which the child seems to possess very easily and which enables him to grasp simultaneously evil and its cause, innocence and guilt. We may say that

what we have here is an *affective perception of justice*" (quoted in Piaget, 1932, p. 228). Piaget noted that because Antipoff observed children who were between the ages of 3 and 9 years her research did not demonstrate innateness. By the age of 3, children would have experienced social interactions, including influences from adults. In addition, moral judgments give the appearance that they are readily derived and reflexive if we consider only their application once they have been constructed, and then only for judgments about relatively straightforward situations in the case of most children.

For some children, the application of their moral judgments to particular kinds of situations can be problematic. Astor (1994) investigated the reasoning of children with histories of violent actions, pursuing the propositions that they had formed moral judgments regarding harm and welfare but, nevertheless, would judge actions in response to various kinds of provocations differently from children who do not engage in violence. Children with or without histories of violent activities evaluated unprovoked acts of violence (e.g., a boy who is mad because he fell down hits his brother) as wrong, and justified their evaluations with moral reasons. Differences between the two groups emerged with regard to acts of violence after provocation (e.g., a boy hits his brother after being teased and called names by him). The group of children without a history of violence evaluated those acts as wrong on the grounds that physically harming another is worse than the provoking acts. By contrast, the group with a history of violence accepted the legitimacy of hitting in those situations on the grounds that it is fair retribution for an unjust action. For those children, therefore, the application of their moral judgments in situations perceived as entailing provocations differed from those who do not often engage in acts of violence (see Butterfield, 1995, for a historical and contemporary analysis of the role of provocation in individuals who have engaged in extremely violent acts).

Another difference from judgments about straightforward situations is seen in judgments about situations that include components from more than one domain (Helwig & Turiel, 2003; Smetana & Turiel, 2003; Turiel, 1989; Turiel & Davidson, 1986). In such situations, the application of moral and social judgments is not entirely straightforward, entailing ambiguities, uncertainties, contradictions, and a good deal of disagreement. Many situations, studied naturalistically (Kelman & Hamilton, 1989) and experimentally (Haney, Banks,

& Zimbardo, 1973; Milgram, 1974), pose conflicts between issues of harm and issues of authority, status, and social organization. Milgram's experiments on obedience to authority, which posed individuals with choices between avoiding harm and adhering to conventional authority-relations, have shown that moral and social decisions can entail uncertainties, emotional and cognitive conflicts, and belabored decision making (Turiel & Smetana, 1984).

Judgments about situations with salient features from more than one domain have been examined in several studies. A study by Killen (1990) presented children with both prototypical situations (e.g., one child hitting another) and "mixed-domain" situations (e.g., choosing between preventing harm or continuing a task to maintain a group activity). Whereas judgments about prototypical events were similar among children, there were differences as to whether children gave priority to the moral or nonmoral features in the mixed-domain situations. Moreover, decisions in the mixed situations involved consideration of the different components, with expressions of conflict (see also Smetana, 1985; Tisak & Tisak, 1990; Turiel, 1983a). It has also been found that older children are better able to coordinate varying components than younger children (Crane & Tisak, 1995b).

The coordination of different domains applies to evaluations and decisions about social inclusion and exclusion (Horn, 2003; Killen, Piscane, Lee-Kim, & Ardila-Rey, 2001; Killen & Stagnor, 2001; Killen, Lee-Kim, et al., 2002; Theimer, Killen, & Stagnor, 2001). Some studies, conducted with preschoolers, children, and adolescents, examined judgments about social exclusion and gender stereotypes (e.g., in doll play or truck play) and racial stereotypes (e.g., in a basketball team or in a math club). The studies examined judgments about straightforward exclusion; these were situations in which a child is excluded because of gender or race. The studies also examined contextualized situations that depicted additional social or group considerations: information was provided about children's past experiences with the activity (child fitting the stereotype has more experience) or their qualifications (equally qualified or the child fitting the stereotype is better qualified). These assessments were made with regard to exclusion in friendships, peer groups, and school contexts.

A central finding is that gender and racial exclusion were judged as wrong in straightforward situations. The judgments were based on moral reasons of fairness and equality. There was a greater tendency to accept exclusion in the contextualized situations. Moreover, these judg-

ments included reasons based on conventional expectations and the need to maintain the goals of a social group (e.g., perform well in a basketball game or math competition). The force of morality in children's thinking about stereotypes and exclusion was also evidenced by effective persuasion of moral reasons influencing changes toward greater inclusion. By contrast, conventional reasons were not effective in changing judgments to an acceptance of exclusion (Killen, Lee-Kim, et al., 2001).

Killen et al. (2002) found that at varying ages exclusion of girls or Black children is judged as wrong on moral grounds and that there are contextual variations in these judgments. For instance, exclusion in friendships was more acceptable than in the other situations. An intriguing finding is that older adolescents were more likely to accept exclusion in friendships and peer groups than younger adolescents.

### **Information, Assumptions about Reality, and Moral Decisions**

The research discussed thus far indicates that there is a good deal of uniformity within and between cultures in the ways certain issues are morally evaluated. However, as is generally known and amply documented by many polls and surveys, sharp differences among people exist in positions taken on issues like abortion, homosexuality, and pornography (Smetana, 1982; Turiel et al., 1991). Research into the judgments of adolescents and adults also shows that individuals display inconsistencies and ambiguities. People differ in their judgments about these issues (and not about issues like killing or rape), in large measure, as a consequence of differences in assumptions about reality or aspects of nature. With regard to abortion, for example, differences were associated with assumptions about the origins of life, with those who assumed the fetus to be a life evaluating abortion as wrong. Those assumptions, however, contained ambiguities in thinking, such that evaluations about abortion were inconsistent across situations and patterns of judgment differed from those usually found with regard to prototypical moral issues (e.g., abortion is wrong but should not be legally restricted because it is a personal decision).

Assumptions of an informational kind about persons, psychological states, biology, and nature represent an additional component to be added to the mix in analyses of social decision making. Wainryb (1991, 1993) has shown that individuals may hold similar concepts about welfare, fairness, and rights but come to different decisions in sit-

uations where they apply different informational assumptions. An example is that assumptions about the effectiveness of parental punishment bears on evaluations of physical harm in the context of a parent disciplining a child, whereas, in other contexts, parents inflicting harm on children is commonly judged as unacceptable.

Possible variations in informational assumptions, especially those entailing assumptions about the natural and an afterlife, bear on cultural variations in moral decisions. It has been noted, not infrequently, that differences in such assumptions give the appearance of radical differences in moral concepts, when moral judgments or principles themselves may actually not vary (Asch, 1952; Duncker, 1939; Hatch, 1983). Asch (1952) pointed out that beliefs about an afterlife bear on cultural practices (such as the social practices listed by Benedict, 1934, as evidence of variability in cultural patterns). An example is the cultural practice of putting one's elderly parents to death because "there prevails the belief that people continue into the next world the same existence as in the present and that they maintain the same condition of health and vigor at the time of death" (Asch, 1952, p. 377). According to Asch, a concern with the welfare of one's parents underlies the practice. A similar view was proposed by Hatch (1983): "Judgments of value are always made against a background of existential beliefs and assumptions, consequently what appears to be a radical difference in values between societies may actually reflect different judgments of reality" (p. 67).

Most analyses of culture and morality, however, have not seriously considered the role of judgments of reality. Through consideration of such judgments the findings of Shweder et al. (1987) were reinterpreted by Turiel et al. (1987). In their comparative research of judgments about morality and convention in India and the United States, Shweder et al. presented individuals with some issues pertaining to matters like dress and eating (practices such as a son avoids eating chicken or getting a haircut the day after his father's death or a widow does not eat fish). These issues were supposedly conventional by U.S. standards, given their content, but treated as moral by Indians. Indians treat these as moral issues because of their assumptions about reality—especially about an after-life. As detailed elsewhere (Turiel et al., 1987), classifying acts solely on the basis of whether they involve matters like dress or food entails an overly literal interpretation of how to classify issues in domains (moral or otherwise) that fails to account for the intentions and goals of actors, the surrounding context of

the actions, and informational assumptions. This literal interpretation would be akin to classifying any act that causes physical damage or pain to another person as a moral transgression. By that standard, a surgeon's thrust of the knife would be classified a moral transgression, as would the spanking of a child by a parent. Wainryb (1991) has shown that acts of hitting with the intent to harm are judged as morally wrong, whereas spanking is not judged as wrong because it is assumed that the actor's intent is to correct and guide a child's behavior and that he or she believes that spanking is effective.

For several "conventional" issues studied by Shweder et al. (1987), a different picture of their domain status emerges by considering the assumptions of reality surrounding the events. Those assumptions concern beliefs about an afterlife and actions on earth that can adversely affect unobservable entities such as souls and deceased ancestors. Using ethnographic material (presented by Shweder et al., 1987, and Shweder & Miller, 1985), further analyses of the issues were made by Turiel et al. (1987) to account for assumptions about reality. Consider some examples. The practice that a son not eat chicken the day after his father's death is connected to the belief that doing so would result in a failure of the father's soul to receive salvation (Shweder & Miller, 1985, p. 48). It is believed that if a widow were to eat fish regularly, it would cause her great suffering and offend her husband's spirit. If a menstruating woman were to enter the kitchen it would result in great misfortune for the family because the deceased ancestors would leave the household for several generations.

Because in these examples events on earth affect unobserved unearthly occurrences and beings, they illustrate how assumptions about an afterlife contextualize some issues to include potential harm. The cultural differences may thus reflect existential beliefs and not moral principles. The Turiel et al. (1987) reanalysis showed that many issues of this kind pertaining to dress, food, and the like resulted in different judgments between Indians and Americans. By contrast, issues that directly depicted consequences of harm or unfairness to people on earth were judged in the same ways by individuals in both cultures. These reanalyses are consistent with the findings of conventional judgments by Indians.

In the Shweder et al. (1987) American sample, "conventional" issues were more often judged by moral criteria than had been typically found in other studies. In part, this is because many of the issues pertained to practices that restrict the activities of one group and not another (usually restrictions on females and not males).

Americans were simply presented with a description of an act like “a widow eats fish two or three times a week” and asked to evaluate it. Other research with Americans (Vail & Turiel, 1995) has demonstrated that if children are given a little context regarding such practices, and if they are not couched in terms that can be perceived as discriminatory practices, the issues are judged differently. When American children were presented with the issues as cultural practices that apply to everyone (not just one group) they generally judged them by conventional criteria rather than moral criteria.

Informational assumptions also provide people with contexts for their acceptance and tolerance of beliefs that differ from their own. People take into account the informational assumptions held by others when evaluating their actions. For the most part, different moral beliefs are judged as wrong, in nonrelativistic ways, and are not treated with tolerance (Wainryb, 1993; Wainryb & Ford, 1998; Wainryb, Shaw, Langley, Cottam, & Lewis, 2004; Wainryb, Shaw, Laupa, & Smith, 2001). In contrast, beliefs about conventions, tastes of a personal nature, and psychological attributes are judged as acceptable and with tolerance. However, additional findings from these studies show that attitudes toward the beliefs of others are influenced by the informational assumptions held by others. For instance, beliefs with moral implications (e.g., it is alright for parents to hit children) were presented (i.e., for other individuals or in other cultures) as due to the view that such acts are all right or due to particular informational assumptions (e.g., that children who misbehave are possessed by evil spirits that can only be removed by beating the child). The pattern of findings is that such beliefs are judged more tolerantly when they are based on divergent informational assumptions, especially when there is agreement about the informational assumptions in a group or culture (Shaw & Wainryb, 1999; Wainryb et al., 2001). Therefore, informational assumptions and their implications for an actor’s intentions contribute to the ways context of events are construed.

### The Personal and the Social

Most of the research comparing moral and conventional judgments with judgments in the personal domain has been conducted in Western cultures. From the viewpoint of the proposition that cultures can be divided according to orientations to collectivism and individualism, it would be expected that concepts of personal agency and

jurisdiction are mainly part of Western individualism and not of non-Western collectivism. However, the findings from several studies (Ardila-Rey & Killen, 2001; Miller, Bersoff, & Harwood, 1990; Nucci et al., 1996; Yau & Smetana, 1996, 2003) in non-Western cultures showing that they distinguish areas of personal jurisdiction from moral and conventional regulations are consistent with fundamental propositions in the social theories and philosophical views of James (1890), Dewey (A. Ryan, 1995), and Habermas (1990b, 1993). Each of these writers argued that personal agency and individual freedom cannot be offset from collectivism or social solidarity. They held that the self and the social, individual growth and social engagement, and personhood and social solidarity are not opposing orientations restricted to particular societies.

The development of personal boundaries and their connections to moral development have been elaborated by several researchers (Helwig, 1995a; Nucci, 1996, 2001; Nucci & Lee, 1993; Nucci & Turiel, 2000; Turiel & Wainryb, 1994; Wainryb & Turiel, 1994). Beyond the identification of issues that individuals judge as part of personal jurisdiction, Nucci (2001) maintains that children attempt to establish boundaries between self and other, and that establishing such boundaries facilitates mutual respect and cooperation. Moreover, the process of coming to understand personal boundaries is social and includes interpersonal negotiations primarily around personal and not moral issues (Nucci & Weber, 1995). At a young age, children challenge parental authority to a greater extent in the personal than the moral realm. Interviews with Americans (Nucci & Smetana, 1996), Brazilians (Nucci et al., 1996), and Japanese (Yamada, 2004) further demonstrated that mothers believe children should be allowed discretion over certain activities to encourage a sense of autonomy and personal agency. (For a discussion of the psychological functions of the establishment of personal boundaries, see Nucci, 1996. For a discussion of the negative psychological consequences of over control of personal jurisdiction in U.S. and Japanese adolescents, see Hasebe, Nucci, & Nucci, 2004).

Along with conceptions of philosophers (e.g., Dworkin, 1977), Nucci sees necessary links between the development of a personal sphere and concepts of rights. Concepts of the agency of self and others constitute the locus of the application of freedoms and rights. Indeed, if concepts of personal agency did not develop because persons were defined mainly through connections with

the group and embeddedness in the collectivity (as in, e.g., Markus & Kitayama, 1991; Shweder & Bourne, 1982), it would follow that moral concepts of rights and freedoms would not apply.

Although many philosophers have regarded rights as universally significant, little research was conducted on the development of concepts of rights until recently (Clémence, Doise, de Rosa, & Gonzales, 1995; Doise, Clémence, & Spini, 1996; Helwig, 1995a, 1995b, 1997, 1998; Ruck, Abromovitch, & Keating, 1998). Helwig's research examined the judgments of American and Canadian children, adolescents, and adults about freedoms of speech and religion and about a series of situations entailing conflicts between the freedoms and other moral considerations. In response to general questions (e.g., Should people be allowed to express their views or engage in their religious practices? Would it be right or wrong for the government to institute laws restricting the freedoms?), most endorsed the freedoms and judged them as moral rights independent of existing laws that are generalizable to other cultural contexts. They based these judgments on psychological needs (e.g., self-expression, identity, and autonomy), social utility, and democratic principles. Along with the general judgments, however, individuals accepted restrictions on the freedoms when in conflict with other moral considerations (i.e., physical harm, psychological harm, or equality of opportunity). At younger ages, however, there was more likelihood of acceptance of restrictions than at older ages.

In other studies, Helwig (1997, 1998) found that in late adolescence and early adulthood there are also distinctions drawn among contexts in which people in authority can legitimately restrict freedoms (e.g., parents can legitimately restrict children's practice of religion but school or governmental authorities cannot). It has also been found that children of about 6 years of age reason about civil liberties on the basis of needs for personal choices and individual expression, whereas by about 8 years of age they start to consider the societal and democratic aspects of rights (Helwig & Turiel, 2002; Neff & Helwig, 2002; see Helwig, 1998, 2006; Helwig & Kim, 1999, for discussion of changes in children's conceptions of government and democracy). The pattern of the application of rights by contexts is also found in Costa Rica, France, Italy, and Switzerland (Clémence et al., 1995; Doise et al., 1996).

The findings on rights, based on in-depth interviews, are consistent with findings of large-scale surveys of the

attitudes of American adults toward civil liberties (McClosky & Brill, 1983; Stouffer, 1955). The surveys tapped the attitudes of large samples (in some cases over 3,000 adults) toward several freedoms (speech, press, assembly, religion privacy, dissent, and divergent lifestyles). When questions of freedoms and rights were put generally or in the abstract (e.g., a belief in freedom of speech for everyone) they were endorsed by large majorities of respondents. However, the surveys also tapped attitudes toward the freedoms in conflict with other moral considerations, such as when they may result in harm to others or may be detrimental to the general welfare. Also assessed were conflicts of freedoms with traditions, community standards, and the maintenance of social order. The results were striking for the ways majorities fail to uphold freedoms and rights in most of those situations. Most Americans do not endorse the very freedoms and rights highlighted in public discourse, evident in public documents (e.g., the United States Constitution and the Bill of Rights), and central to depictions of American culture as individualistic and perhaps overly oriented to rights (as maintained by Bellah et al., 1985; Etzioni, 1993).

The coexistence of concerns with the freedoms and rights of individuals and the welfare of the community supports the contentions of Dewey and Habermas that personal agency and social solidarity go together. Additional research, on the concepts of freedoms and rights of Druze Arabs living in northern Israel (Turiel & Wainryb, 1998), supports Habermas's (1993) view that the coexistence of personal agency and collectivism is not applicable "for Americans alone," and that it extends beyond those who are "heirs to the political thought of a Thomas Paine and a Thomas Jefferson" (p. 114).

The Druze community is tightly knit, living in large measure separately from the rest of the nation of Israel. They constitute a traditional hierarchical society, with strong sanctions for violations of societal norms—especially as applied to women because it is a patriarchal society (Turiel & Wainryb, 1994). Three types of freedoms were studied with adolescents and adults: speech, religion, and reproduction (i.e., freedom to bear the number of children desired). The Druze clearly judge, when put in general terms, that individuals should have noncontingent rights to each freedom.

Individuals were also presented with conflicts depicting freedoms producing physical or psychological harm or having negative effects on community interests. Conflict situations also depicted ways that in the family the

exercise of the freedoms by a son, daughter, or wife was in contradiction with the desires and directives of father or husband. The findings from the conflict situations showed that the Druze also think that freedoms should be, in certain situations, subordinated to other concerns, such as when they could cause harm to others. Similarly, in some situations (but not all) it is thought that considerations of community interest should take precedence over the right to exercise the freedoms.

For the most part, however, freedoms and rights of sons, daughters, and wives were not subordinated to the authority of the father or husband. Particularly for religion and reproduction, most upheld the rights and negatively evaluated the father's or husband's efforts to restrict the freedoms. The Druze were more willing to allow restrictions on the freedoms of females (wives and daughters) than males (sons) and, thereby, granted greater authority to men over their wives and daughters.

Concepts of rights, democracy, and political organization appear to extend beyond the heirs of Paine and Jefferson to people in China (Helwig, Arnold, Tan, & Boyd, 2003a). The judgments of adolescents from rural and urban settings regarding democratic and authority-based decision making in peer groups, families, and schools again showed contextual variations. Adolescents understood and supported democratic decision making, with endorsements of children's autonomy and their right to participate in certain decisions. For instance, there was greater support for children's participation in family decisions than in those about a school's curriculum. Similarly, Chinese adolescents expressed preferences for democratic systems of majority rule over nondemocratic systems of meritocracy (Helwig, Arnold, Tan, & Boyd, 2003b). As in studies with Canadians, there was an increase with age in understandings of political participation, the will of the majority, and the protection of minorities.

## CULTURE AND CONTEXT REVISITED

The research with the Druze and in China, along with the other research in non-Western cultures, indicates that concepts of rights, welfare, and justice are found across cultures. In the context of these similarities among cultures, however, there are also differences. In addition to differences in assumptions about reality,

there are differences in the degree of hierarchically based distinctions in relationships between males and females and those of different social castes and classes. Many analyses of culture have focused on differences between cultures on these dimensions, interpreting them in accord with the proposition that cultures form integrated patterns represented either by an individualistic or collectivistic orientation. The hierarchical distinctions in gender or castes are said to be connected with the role designations of persons, through which persons are submerged in the group.

It is not at all clear, however, that the presumption of coherent, integrated cultural patterns and associated consistencies in individuals' judgments and actions are in line with other formulations central to the propositions of those emphasizing culture. In particular, the idea of coherence and consistency conflicts with the call for pluralism, and with the core ideas of cultural psychology that the mind is context-dependent, domain-specific, and local. With regard to pluralism, those emphasizing culture often have voiced that there be acceptance of a variety of moral perspectives. Shweder and Haidt (1993) asserted that Gilligan "won the argument for pluralism" (p. 362) by augmenting the traditional views on justice with the care orientation. They also argue that Gilligan's proposition does not go far enough in the quest for pluralism because it does not account for further variations among cultures.

These kinds of arguments are contradictory because descriptions of cultural orientations actually frame most of the elements in Gilligan's formulation of justice as part of Western (or individualistic) morality and most of the elements of the care orientation as part of non-Western (or collectivistic) morality (see Miller & Bersoff, 1995). By describing cultures with integrated patterns of thought, a rather limited form of pluralism or heterogeneity is seen to be in differences between cultures while a unitary or homogeneous orientation (with a lack of pluralism) is imposed within cultures and for individuals. The evidence actually points in the other direction—that there is coexistence, not only within cultures but also for individuals, of care, interdependence, justice, and autonomy. As detailed earlier, the research assessing those dimensions through Gilligan's formulations has shown that care (or collectivistic) and justice (or individualistic) judgments vary by context for females and males. The evidence suggests that the types of contextual distinctions drawn by Gilligan between fe-

males' and males' life circumstances are too broad and require further distinctions within each context.

Those emphasizing culture also have maintained that general, "abstract," universal moral principles are inadequate because they fail to account for variations among cultures. However, by locating contextual variations at the cultural level little consideration is given to variations that may be associated with contextual differences within cultures. For a given culture, therefore, constructs like individualism and collectivism end up functioning as general, abstract orientations that apply across contexts and fail to account for domain specificity. Distinctions in judgments by domain mean that individuals have heterogeneous orientations in social thought.

The coexistence of domains stems from a process of development that is not restricted to circumscribed experiences characterized by the family or parental child-rearing practices, more narrowly, or by culture, more broadly. As shown by much of the research considered thus far, social experiences influencing development are varied (with parents, siblings, peers, or social institutions). Through reciprocal interactions, children are engaged in communications, negotiations, compromises, disputes, and conflicts. The research has also shown that the diversity of children's social interactions includes concerns with the desires, goals, and interests of persons (self and others), as well as with the welfare of others and the group.

### **Culture as Context or Context as Context?**

Children's social interactions involve a dynamic interplay of personal goals and social goals, as well as interplay among different social goals. Reciprocity of social interactions means that individuals both participate in cultural practices and can stand apart from culture and take a critical approach to social practices. Typically, there are elements both of harmony and tension or conflict. Moreover, through the development of different domains of judgment, individuals deal with social situations from more than one perspective, taking into account varying features of situations and contexts.

The diversity in judgments of individuals includes domain specificity in people's thinking and contextual variations in the ways judgments are applied. As seen from the research on concepts of freedoms and rights, people in so-called individualistic cultures have multiple social orientations, including concerns with social

duties, the collective community, and interdependence, as well as independence, rights, freedoms, and equality. People in so-called traditional, collectivistic cultures endorse traditions, status, and role distinctions, but they also endorse individual freedoms and rights even when in contradiction with status and hierarchy.

Another issue of importance to moral and social functioning that involves contextual variations in judgments and actions is that of honesty. Honesty is often regarded as one of those moral matters that once acquired by the individual will be and should be applied consistently. In some analyses, honesty is a virtue or trait of character that children must be taught to always follow (Bennett, 1993; K. Ryan, 1989; Wynne, 1986). In other perspectives, honesty is linked to the need to maintain trust in social relationships.

Most research has looked at whether children act honestly or in self-serving ways. Dishonest acts are taken to reflect deficiencies in character or the failure to internalize norms of truthfulness (Grinder, 1964; Hartshorne & May, 1928, 1929, 1930). Dishonest behavior can be self-serving and motivated for personal gain; however, issues of honesty are more complicated and are often weighed against other considerations so that there is much variability in the ways people act. For instance, honesty can be in conflict with desires to prevent harm to another. Some researchers who have recognized this type of conflict looked at so-called white lies—lies aimed at sparing the feelings of others (Lewis, 1993). There is only a little research on judgments about conflicts between honesty and preventing more serious harm. An example of how deception has been used to prevent harm is that during World War II many lied and engaged in elaborate deceptions to save people from Nazi concentration camps. No doubt, they gave greater priority to preventing harm and deaths than to honesty.

Recent research that has begun to address these issues shows that people systematically evaluate the consequences of telling the truth or engaging in deception in relation to furthering the welfare of persons, achieving justice, and promoting individual autonomy when it is perceived to be unfairly restricted. One study of this kind looked at, in hypothetical situations, how physicians evaluate deception of insurance companies when it is the only way to obtain approval for treatments or diagnostic procedures for medical conditions of different degrees of severity (Freeman, Rathore, Weinfurt, Schulman, & Sulmasy, 1999). In the two most severe

conditions (life-threatening ones), the majority thought that the doctor was justified in engaging in deception. In other conditions, the percentages accepting deception were considerably lower, with the fewest (only 3%) judging that deception was legitimate for purposes of cosmetic surgery. Moreover, there is evidence that physicians actually do engage in deception of insurance companies (Wynia, Cummins, VanGeest, & Wilson, 2000).

Other research has shown a corresponding pattern of contextual differences in judgments of college undergraduates and adults about deception between husbands and wives (Turiel & Perkins, 2004). Participants were presented with several situations entailing deception. One depicted a spouse who tightly controls the family finances, and the other maintains a secret bank account. Other situations involved secretly seeing a friend disliked by the spouse, shopping for clothes, and attending meetings of a support group for a drinking problem (the meetings are kept secret because a spouse does not want the other to attend). These acts were depicted as situations where only a husband works outside the home, with a wife engaging in deception; and the reverse, where only a wife works, with a husband engaging in deception.

Most participants judged deception to be legitimate in some situations. The large majority judged deception by wife or husband acceptable to attend meetings of a support group for a drinking problem. Most also judged it acceptable for the wife to maintain a secret bank account, but fewer judged it acceptable for a husband to engage in such deception even though it is the wife who works and controls the finances. It seems that the more general structure of power in society is taken into account in making these decisions. Males are accorded greater power and control over females, and family relationships are frequently based on the type of injustice that grants greater privileges and entitlements to men over women (Hochschild, 1989; Nussbaum, 1999, 2000; Okin, 1989). Similar patterns were found for situations that involved friendships and shopping (but the differences between judgments about the activities of husbands and wives were not statistically significant).

Another study (Perkins, 2003; see also Turiel & Perkins, 2004) assessed judgments of adolescents who deceive parents or friends. The situations involved parents or peers telling an adolescent to act in ways that might be considered morally wrong (i.e., not to befriend another of a different race; to physically confront another who is teasing him or her); giving directives about

issues of personal choice (not to date someone the parents or peers do not like; not to join a club because they think it is a waste of time); and directives about personal issues with prudential or pragmatic considerations (completing homework; not riding a motorcycle).

Most of the adolescents judged it acceptable to deceive parents about the demands considered morally wrong, viewing it necessary to prevent injustice or harm. The majority also thought that deception was justified when parents interfered with personal choices but that deception was not justified with regard to the prudential matters on the grounds that it is legitimate for parents to concern themselves with the welfare of their children (most thought the restrictions were not legitimate in the case of the moral and personal matters). Fewer judged deception of peers acceptable than deception of parents for the morally relevant and personal issues. Although the adolescents thought that the restrictions directed by peers were not legitimate, they were less likely to accept deception of peers than of parents because friends are in relationships of equality and mutuality and can confront each other about these matters without resorting to deception.

For these adolescents, honesty in social relationships is not a straightforward matter but they do not devalue honesty. Most said, in response to a general question, that lying is wrong, and the large majority thought that it is not justifiable to lie to parents or peers to cover up damage to property. As with the physicians, there are situations in which they believe honesty needs to be subordinated to other considerations. A consistent finding across these studies is that deception and lying are judged wrong, but honesty is nevertheless evaluated in relation to competing moral claims. Social psychological experiments of morally relevant behaviors demonstrate the same phenomenon of variations by contexts. Although these experiments are well-known for their findings of group influences (Latanée & Darley, 1970), conformity (Asch, 1956), obedience (Milgram, 1974), and adherence to roles in social hierarchy (Haney et al., 1973), they actually show that individuals respond in several ways, often with conflict, and that different domains of judgment are used in interpreting the parameters of situations (Turiel, 2002; Turiel & Wainryb, 1994). In each of these types of experiment, behaviors varied by context. In some experimental conditions, people generally obeyed an authority's directives to act in ways that caused physical pain to others (by adminis-

tering electric shocks), but in other experimental conditions people generally defied the authority's directives to engage in similar acts (Milgram, 1974). Other experiments showed that individuals are influenced by group decisions as to whether to help someone in distress, helping in some situations but not in others (Latanée & Darley, 1970). Similarly, individuals "conform" to the judgments of a group in some situations but contradict the group in others (Asch, 1956).

The behaviors tapped in the experiments are not readily classified as independent and interdependent because of the interweaving of both types of judgment. Consider the research on whether bystanders intervene to help others in distress. An individual is more likely to intervene to help others when alone than when in the presence of others who do not intervene (Latanée & Darley, 1970). Thus, people seem to act in independent ways and take personal initiative when alone, but do so in the service of interdependence because the act furthers the welfare of others. Conversely, when in the presence of others, people are influenced socially in failing to intervene. This social influence, however, simultaneously works against interdependence in the sense that it is at the expense of the welfare of others. A similar analysis applies to experiments on obedience to an authority's commands to inflict pain on another person (Milgram, 1974). To the extent that participants in the experiments adhered to their assigned roles and accepted the authority's status and commands, they acted in ways consistent with a collectivistic orientation. In doing so, however, they acted against an interdependent concern with the welfare of the victim. To the extent that people defied the experimenter, and in that sense acted independently, they were acting in the service of the nonindividualistic goal of promoting the welfare of the victim. The overarching observation is that individuals do not simply obey or disobey nor act as conformists or nonconformists. Rather, they make judgments about the actions of others, social organizational features, and right and wrong (see Ross & Nisbett, 1991, for an analysis of social construal and psychological attributions in these situations).

Asch (1952, 1956) has provided an incisive analysis of the process of social construal. In the experiments on conformity, some participants were asked to judge the length of lines in group settings, where the other participants were confederates of the experimenters who at predetermined times gave incorrect judgments. In

Asch's view, those who gave incorrect perceptual judgments consistent with those of the group were not simply "going along" with others so as to fit into the group but were instead attempting to make sense of a perplexing situation. One component of reality about which people were making judgments was the straightforward physical event regarding the relative lengths of lines. A second component was the actions of other people. Especially once the rest of the group began to give opposing judgments about the length of lines, participants had to make judgments about others' reactions to the physical event. Because the judgments about the lengths of lines were unambiguous and they could see no apparent reason for the others' judgments, they were led to question their own perceptions, perceive a conflict, and give credence to the group judgment. Asch proposed that individuals made a judgment about the total context experienced so that variations in situational features make for differences in the actual "objects of judgment."

Research by Ross, Bierbrauer, and Hoffman (1976) supported Asch's interpretation, through the finding that when participants could attribute the actions of the others in the group to motivation by extrinsic goals (e.g., attaining a material payoff) there was much less conformity than when no motives were specified. If individuals were acting so as to fit into the group, they should have conformed to an equal extent regardless of the perceived motivations of others.

Although it has been recognized that behaviors vary by situations (especially Mischel, 1973) and that research shows conformity, obedience to authority, and group influences among Americans (Kelman & Hamilton, 1989; Milgram, 1974; Ross & Nisbett, 1991), the import of these findings has not often been carried over to characterizations of culture. It seems that those who characterize Western cultures as individualistic attend mainly to one side of the picture.

It is informative that in the fairly recent history of social scientific thought, the opposite side of the picture, reflecting the idea that the individual is submerged into the group, has been portrayed as the dominant cultural orientation in the United States. For example, Fromm (1941) maintained that modern capitalistic societies, including the United States, foster conformity and a loss of personal identity. In Fromm's view, the self is subordinated to others in personal relationships and to the social and economic system. He lamented that the individual is but a "cog in the vast economic machine."

Others writing in the 1950s were popularly received for similar characterizations of the culture (Mills, 1956; Reisman, Glazer, & Denney, 1950; Whyte, 1956) as oriented to conformity and to group dependence, with individual initiative being overwhelmed by economic forces. They proclaimed that bureaucratic and hierarchical social institutions stifle freedoms, personal control, and individual creativity.

Therefore, the culture of the United States (and other Western societies) has been characterized in nearly opposite ways by different social scientists. In a sense, these characterizations capture the opposing attitudes and behaviors evident in research on concepts of freedoms and in the social psychological experiments. However, each of these characterizations provides a one-sided typing (stereotyping?) that fails to account for the heterogeneity of social judgments and behaviors. In line with Asch's analyses, the process of making social judgments, psychological attributions, and construal about social events implies that neither individuals nor cultures are appropriately characterized by a category reflecting consistent, integrated patterns. From this broader conception of individuals in Western culture, it is not plausible to portray their morality as framed only through the ideas of individuals with rights and the freedom to voluntarily enter into contracts.

### **Tradition, Social Hierarchy, Heterogeneity, and Social Opposition**

Many of the findings considered thus far that document heterogeneous moral and social judgments come from research in the United States, but findings were reviewed from non-Western cultures showing that concepts of freedom and rights vary by context. Anthropological research yields direct evidence of contextual variations in the judgments of people in non-Western cultures, including variations in concepts of persons. Spiro's (1993) extensive review of anthropological research shows that concepts of self, as well as other social concepts, vary across individuals in the same society and across societies: "There is much more differentiation, individuation, and autonomy in the putative non-Western self, and much more dependence and interdependence in the putative Western self, than these binary opposite types allow" (p. 117).

Spiro maintained that cultural ideologies and public symbols do not necessarily translate into individuals' conceptions or experiences of self and others. One ex-

ample comes from his research of Buddhism in Burma. A central doctrine of Theravada Buddhism is that there is no soul, ego, or transcendental self, but Spiro found that the Burmese he studied do not maintain these ideas. Instead, "They strongly believe in the very ego or soul that this doctrine denies . . . because they themselves experience a subjective sense of self, the culturally normative concept does not correspond to their personal experience" (Spiro, 1993, p. 119). Ethnographic evidence also shows that self-interested goals and concerns with personal entitlements are part of the thinking of the Balinese, Indians, Pakistanis, Nepalese, and Japanese. In their work, northern Japanese villagers are motivated not so much by group goals as by individual goals of power, self-esteem, and pride (see Spiro, 1993, pp. 134–136). Moreover, village women act in accord with the interests of others, their roles in the family, and "self-serving personal desires." Others have also documented that self-interest, personal goals, and autonomy are significant in the lives of Indians from various backgrounds (Mines, 1988; Misra & Giri, 1995; Neff, 2001), among the Toraja of Indonesia (Hollan, 1992), in China (Helwig et al., 2003a, 2003b; Lau, 1992; Li & Yue, 2004), Bangladesh (Chen, 1995), and Japan (Crystal, 2000; Crystal, Watanabe, & Chen, 2000; Crystal, Watanabe, Weinfurt, & Wu, 1998).

In accord with these findings, several anthropologists (e.g., Abu-Lughod, 1991, 1993; Appadurai, 1988; Clifford, 1988; Strauss, 1992; Wikan, 1991, 1996, 2002) have criticized conceptions of cultures as either homogeneous, coherent, and timeless or as embodying integrated, stable sets of meanings and practices readily reproduced in individuals through socialization. Abu-Lughod (1991) argued for the need to include, in analyses of culture, conflicts, disputes, arguments, contradictions, ambiguity, and changes in cultural understandings:

By focusing on particular individuals and their changing relationships, one would necessarily subvert the most problematic connotations of culture: homogeneity, coherence, and timelessness. Individuals are confronted with choices, struggle with others, make conflicting statements, argue about points of view on the same events, undergo ups and downs in various relationships and changes in their circumstances, and fail to predict what will happen to them or those around them. (p. 154)

Several anthropologists and philosophers (Nussbaum, 1999, 2000; Okin, 1989; Strauss, 1992; Wikan, 1991, 1996) have stressed the need to explore the varying

meanings individuals give to the dominant values and practices of the society, so as to ascertain if the actor's point of view looks different from the perspective of dominant institutions and ideologies.

Exploring the individual's understandings of dominant cultural values and practices was one of the aims of another study conducted with the Druze (Wainryb & Turiel, 1994). A second aim was to explore the hypothesis that there is more than one side to cultural practices. The varying perspectives individuals may take render cultural practices more nebulous and multifaceted; thus, a particular type of cultural practice is likely to contain differing messages. Cultural practices around social hierarchies are a case in point. One side of social hierarchy, which has been the focus of cultural analyses, is specified duties and roles, and the submergence of self into a network of interdependence. The other side, however, is that there is a strong sense of independence and personal entitlements embedded in hierarchical arrangements. Examples of where such entitlements hold are for those in higher castes and social classes relative to those in lower castes and classes (Turiel, 1994, 2002, 2003b; Turiel & Wainryb, 2000), and in relationships between males and females. Whereas practices revolving around social hierarchical arrangements convey duties and role prescriptions, they also convey that those in dominant positions have personal autonomy and entitlements—especially due to them by those in subordinate positions.

The research with the Druze examined personal, social, and moral judgments, focusing on decision making in the family regarding various activities of relevance in the community (e.g., choices of occupational and educational activities, household tasks, friendships, or leisure activities). Family decisions were examined because the society is hierarchically organized, with a strong patriarchal tradition. Many restrictions are placed on the activities of females, including their education, work, dress, social affiliations, and leisure time. Men are in control of finances and can easily divorce their wives, while wives cannot easily divorce their husbands. Individuals were presented with conflicts between persons in dominant (i.e., husbands and fathers) and subordinate (i.e., wives, daughters, and sons) positions in the family structure. In one set of situations, a person in a dominant position objects to the choices of a person in a subordinate position (e.g., a husband objects to his wife's decision to take a job); in another set, the person in the subordinate position objects to the choices of the person

who is in a dominant position (e.g., a wife objects to her husband's decision to change jobs).

The results showed that Druze males and females think men should have decision-making power and discretion. While most participants judged that wives or daughters should not engage in activities to which a father or husband objects, this was not reciprocal. Most judged that a man is free to choose his activities even if his wife, daughter, or son objects. It was also thought that sons should be able to make their own decisions over objections from their fathers. The inequality in decision making is based on different reasons for the decisions and on different ways of conceptualizing the relationships. Again, there is an interweaving of people's judgments in situations that constitute, for them, different contexts associated with the direction of the dialogue and negotiation. In the context of objections from a man to the activities of his wife or daughter, relationships were viewed in interdependent and hierarchical terms. In the context of objections from a wife or daughter to the activities of her husband or father (as well as a father who objects to a son's activities), the relationships were conceptualized as ones of independence for a person choosing the activities (i.e., men). Males and females attributed interdependence to females and to males in some contexts and both attributed independence to males. However, Druze females were aware of the pragmatics of social relationships in the family and sometimes attributed decision-making authority to males because males have the power to inflict serious negative consequences to those in subordinate positions (e.g., abandonment and divorce). Moreover, females evaluated many of these practices giving men power over the activities of females as unfair.

Analogous findings were obtained in research conducted in India (Neff, 2001) and Colombia (Mensing, 2002). As with the Druze, Indian males were more likely than females to be accorded freedom of choice and independence. In Colombia, too, there is a mixture of judgments about interpersonal obligations and interdependence, on the one hand, and the autonomy of persons, on the other.

The findings of these studies demonstrate the multiple aspects of social hierarchy; in traditional cultures there is a complex picture of judgments about role obligations, prescribed activities, personal independence and entitlements, pragmatic concerns, and fairness. For the activities used in these studies, the Druze judged it more acceptable to impose restrictions on a wife or

daughter than was the case when judging the legitimacy of restricting freedoms of speech, religion, or reproduction (as in the Turiel & Wainryb, 1998, study discussed earlier). The multiplicity of individuals' perspectives brings with it both acceptance and opposition to cultural practices. Whereas persons in dominant and subordinate positions share orientations to duties, status, prescribed roles, and personal autonomy, those in subordinate positions are aware of the pragmatics of power relationships and view themselves as having legitimate claims to independence and unmet rights. There is a tendency to restrict analyses of cultures to the public and institutionalized features of cultural practices and to the perspectives of those in a dominant position (i.e., caste, class, and gender). However, the perspectives of those in subordinate positions are significant reflections of culture and provide windows into conflicts, struggles, below-the-surface activities, and the interplay of opposing orientations such as independence and interdependence, or conflict and harmony. Along with participation in cultural practices, there can be distancing from them. Along with acceptance of one's role in the culture, there can be opposition to cultural practices (Turiel, 1998, 2002, 2003b; Turiel & Wainryb, 2000; Wainryb, 1995, 2006; Wainryb & Turiel, 1995).

Conflicts, struggles, and below-the-surface activities have been documented when social practices are examined from the perspective of those in subordinate positions. One example is Abu-Lughod's (1993) studies of Bedouin women in Egypt. Abu-Lughod reported that there are differences and disagreements among group members, conflicts between people, efforts to alter existing practices, and struggles between wives and husbands, and parents and children. Women develop strategies, often hidden from men, to assert their interests. These strategies, which include deception, allow women to avoid unwanted arranged marriages, assert their will against restrictions imposed by men, attain some education, and engage in prohibited leisure activities. A woman who finds some of her husband's demands unacceptable typically attempts to control and even dominate him through connections to her parents and, at a later age, to her grown sons (see also Mernissi's, 1994, reflections on her upbringing in Morocco of the 1940s).

Wikan's (1996) studies in poor neighborhoods of Cairo, Egypt, also revealed conflicts, struggles, and efforts at subverting cultural practices. In the poor areas

of Cairo, women come into conflict with men who try to control their activities. Women attempt to circumvent the effects of inequalities in their relationships with men and express unhappiness with practices like polygamy. Wikan's (1996) general conclusion is that "these lives I depict can be read as exercises in resistance against the state, against the family, against one's marriage, against the forces of tradition or change, against neighborhoods and society—even against oneself. But it is resistance that seems to follow a hidden agenda and to manage and endure in ways that respect the humanity of others" (pp. 6–7; for additional examples of studies in India and Bangladesh, see Chen, 1995; Chowdry, 1994; Menchen, 1989).

Examining the perspective of people in subordinate positions, as well as the way people in dominant positions construe their relationships with persons in subordinate positions, yields an alternative view of social hierarchies from those who have emphasized community as a moral good. Social hierarchy does not solely entail an asymmetrical reciprocity whereby those in dominant positions oversee the welfare of those in subordinate positions. Hierarchy often involves oppression and exploitation (Baumrind, 1997) and the use of status differences to further the self-interest, entitlements, and autonomy of those in positions of power and dominance (Wainryb & Turiel, 1994). When we look beyond public characterizations of social practices and when our analyses are not restricted to the perspectives of those in dominant positions, there is evidence for a conception of cultures as embodying variations in behaviors, diversity in orientations, and conflicting points of view resulting in disagreements, disputes, struggles among people, and acts of social opposition and resistance (Abu-Lughod, 1991; Turiel, 2002; Wikan, 1996, 2002).

Conflicts over inequalities among persons of differing status are not restricted to traditional, hierarchically organized cultures. Gender relationships in Western cultures usually are not strictly hierarchical nor are the activities of females restricted in the same ways as in some traditional cultures. Despite the emphasis on equality in the culture, there is considerable evidence documenting inequalities and struggles between men and women in several spheres of life (see especially Hochschild, 1989; Okin, 1989, 1996; Turiel, 1996). Unequal treatment of women is reflected in their under-representation in the political system, in positions of power and influence in business and the professions, and in fewer opportunities

for paid work. In addition, in many fields, women are paid substantially less than men for similar work, even when their qualifications are the same (Okin, 1989). Inequalities are also part of gender relationships in the family, with the interests of men given priority over those of women (Blood & Wolfe, 1960; Blumstein & Schwartz, 1983). Studies of dual-career families document a pervasive pattern in which women are expected to do more of the undesired household tasks, and men have entitlements such as greater time for leisure activities (see Hochschild, 1989, for a review). These conditions provide another example of the interweaving of duties, roles, and assertion of rights and personal entitlements. Often conflicts occur over men's orientation to maintaining role distinctions and role responsibilities in the family and women's concerns that there be greater equality and fairness (Hochschild, 1989; Okin, 1989).

The existence of conflicts, opposition and below-the-surface activities in cultures that include the vantage points of those in subordinate positions as different from those in dominant positions casts a different light on the intersection of gender and cultures. Although there are commonalities and shared experiences between men and women in a culture, the issues are more complicated because women from different cultures also share certain perspectives based on their roles in a hierarchy, the status held, their burdens, and the unfairness experienced. Similarly, men from different cultures share perspectives based on their roles in the hierarchy, their privileges and burdens, and a sense of personal entitlements based on the extent to which they are in dominant positions relative to women.

However, aspects other than gender further complicate perspectives based on social hierarchy. Males and females share dominant or subordinate positions with regard to their status as members of social classes in the hierarchy. It is likely that the perspectives of men or women of lower classes in non-Western and Western cultures have some similarities (as would the perspectives of those of higher classes). Correspondingly, differences exist between people of different social classes in a culture (an interesting comparison, again, is between an upper-middle-class woman and a working-class man with regard to roles in the hierarchy). These considerations have received very little attention in research on social and moral development (for an exception, see the analyses of Nucci et al., 1996, of people from different social classes in Brazil). It would be of

particular interest to consider how in some non-Western societies the economic dependence of women on men, and differential economic status in the caste hierarchy, bear on concepts of interpersonal obligations.

One example of research documenting conflict in a Western society pertaining to social class comes from Willis's (1977) ethnographic analyses of British working-class youth in school settings. Willis documented the conflicts of working-class youth with dominant cultural values and ideology to the extent they are represented by teachers, administrators, and even middle-class students. The working-class adolescents opposed and defied authority, criticized teachers, rejected many of their values, and often failed to adhere to their rules. Moreover, working-class adolescents were critical of other students perceived to be part of mainstream culture. Here, too, there is a mixture of individuation and connection. The working-class youth continually displayed behaviors that were independent and rebellious relative to school authorities, other students, and cultural symbols. Their independence, however, was linked to cohesiveness among working-class adolescents or what Willis referred to as the counterculture group. A corresponding example of tensions between social class groups comes from Wikan's (1996) findings that in Cairo, Egypt, people of poverty engage in resistance against society.

All these examples demonstrate that along with the cohesiveness usually ascribed to cultures, it is necessary to account for conflicts, struggles, ambiguities, and multiple perspectives. Multiple perspectives stem from both the varieties of social experiences and the differentiated domains of social thinking developed by individuals. Distinctions need to be made between culture as publicly conveyed ideologies or as social practices and the ways individuals interpret and make judgments about social experiences. Social and cultural practices can be nebulous, with many sides and connotations. They embody multiple messages and are carried out in multiple ways. It has been documented that experiences influencing social development go well beyond any one type (family, peers, culture) and must be viewed from the perspective of reciprocal interactions. The idea of development stemming from reciprocal interactions suggests that there are discrepancies between cultural ideologies, public documents, official pronouncements, or other manifestations of cultural orientations. More generally, the multiplicity of orientations in cultures, including

conflicts and ambiguities, means that morality cannot be simply characterized through particular ideologies like that of individuals with rights and freedom to enter into contracts or that of persons as interconnected in a social order of involuntary duties and roles.

## CONCLUSIONS

Heterogeneity and variability in social judgments and actions do not stem solely from the presence of different groups or cultures in a society. The types of variations documented pertain to given cultures and individual members of those cultures. However, those variations are not haphazard, nor do the features of situations simply determine how people will act. Rather, heterogeneity and variation suggest that the thinking of individuals is flexible and takes into account different and varied aspects of the social world. The variety of social experiences is relevant to an understanding of moral development because children attend to much more than one type or context of social experience. Moreover, these and other aspects of a vast social world affect development through reciprocal interactions that include a coordination of emotions, thoughts, and actions.

Very important social and psychological questions are embedded in the existence of social hierarchies within cultures. Do people accept their designated roles in a society even when they are in subordinate positions? Do people embrace cultural practices that grant greater power, control, and privileges to one group over another (such as males over females)? Do people in subordinate positions evaluate social hierarchies positively because of a respect for society or culture even though they hold an unequal status and are in subservient positions? Or do people in such positions perceive the inequalities as wrong and unjust and do they, in one way or another, critique societal arrangements and cultural practices through opposition, resistance, and subversion?

These questions go to the core of how cultures are to be characterized and to how individuals develop morally and socially. Research showing that people oppose cultural practices and act to resist and change societal arrangements and cultural practices they judge unfair leads to the view that morality does not involve compliance, and that its development is neither an accommodation to societal values or norms nor their internalization (Turiel, *in press-b*).

There is evidence that the origins of opposition and resistance are in childhood (Turiel, 2003b, 2006). Children's social development involves a combination of what can be referred to as cooperative and oppositional orientations. Evidence of the origins of opposition and resistance in early childhood comes from studies showing that young children do not accept rules or authority dictates that are in contradiction with their judgments of what is morally right or wrong (Laupa, 1991; Laupa & Turiel, 1986; Weston & Turiel, 1980). Moreover, there is a coexistence of positive, prosocial actions toward and conflicts with parents, siblings, and peers (Dunn, 1987, 1988; Dunn & Munn, 1985, 1987; Dunn, Brown, & Maguire, 1995; Dunn & Slomkowski, 1992). This combination reflects the multiple judgments that children develop. Children's moral judgments also produce acts of defiance or opposition when they perceive unfairness and harm. The research on deception discussed earlier and the research on family conflicts (Smetana, 1997, 2002) demonstrates that opposition and resistance are part of the lives of adolescents, as well.

As children interact with a varied social world, their development entails the formation of different but systematic types or domains of social reasoning. Whereas morality is an important domain, it needs to be understood alongside and in intersection with other aspects of understandings of the social world. Because the social world is varied, and because there are different domains of social judgment, moral prescriptions are not always applied in the same way. Social situations often require a balancing and coordination of different social and personal considerations related to features of the context. Consequently, although moral prescriptions dictate obligations based on right or wrong and how a person ought to act, they do not dictate rigid rules or maxims. There is more than one way to reach a particular set of goals. Habermas (1993) articulated this feature of morality, particularly in his analyses of how a traditional Kantian view failed to account for context. He argued that rational principles can take different forms in their application in contexts and are subject to change and elaboration through social discourse. However, those who critique abstract moral principles all too often postulate analogously abstract, decontextualized, and general cultural orientations. A critique of moral rationality like that of MacIntyre (1981) originally included the concern that rational principles do not address local and contextual circumstances but resulted

(see MacIntyre, 1988) in the propositions that morality best rests on religious tradition and authority and that agreements regarding moral principles should be inculcated through education designed by religious authorities. By relying on a system of religious tradition and authority for moral prescriptions, there is little room for contextual variations.

Especially in the United States, the current political and intellectual climate seems to be one that de-emphasizes thought, reasoning, rationality, and reflective analyses and not infrequently places them under attack. Emotions, with assumptions about their underlying evolutionary biological bases, are frequently regarded as the central determinants of morality along with the authority of the group, religion, or culture. As important as emotions—especially sympathy, empathy, and respect—are for moral functioning, emotions occur in and among persons who can think about them with regard to other people and in relation to complicated social agendas, goals, and arrangements. The relationships among emotions, moral judgments, reflections, and deliberations require a great deal of attention in research and theoretical formulations. Investigators are less likely to address these relationships if reflective analyses are attacked as, at best, irrelevant to the layperson and, at worst, corrupting of individuals and society (Wilson, 1993). Still, scholars critiquing the proposition of rational, deliberative, and reflective moral functioning, themselves engage in those very activities, attempting to persuade others through rational discourse. These human activities are not solely the province of scholars, however. Laypersons (children included), too, deliberate and reason systematically about emotions and morality and engage in discussion and argumentation.

## CHAPTER 14

# Gender Development

DIANE N. RUBLE, CAROL LYNN MARTIN, and SHERI A. BERENBAUM

### THE DEVELOPMENT OF GENDER-RELATED CONSTRUCTS AND CONTENT 859

Biological/Categorical Sex (1) 860

Activities and Interests (2) 864

Personal-Social Attributes (3) 870

Social Relationships (4) 876

Styles and Symbols (5) 880

Values Regarding Gender (6) 883

Summary of Developmental Trends 886

Being born a girl or a boy has implications that carry considerably beyond chromosomal, hormonal, and genital differences. Virtually all of human functioning has a gendered cast—appearance, mannerisms, communication, temperament, activities at home and outside, aspirations, and values. In this chapter, we consider the developmental processes involved in sustaining this gender system. How does a girl come to think of herself as a girl? When and why do children prefer same-sex playmates and activities? Do the sexes really differ cognitively? Do children's beliefs about the sexes influence their own behavior?

The issues surrounding gender span many controversial and intriguing topics. Given the broad scope of topics, the many studies that have been conducted, and space restrictions, however, we limit our coverage to updating the last *Handbook* chapters on gender development (Huston, 1983; Ruble & Martin, 1998). To maintain continuity, we build on the framework that Huston (1983) carefully developed, and that we (Ruble

### THEORETICAL ANALYSIS OF GENDER DEVELOPMENT 888

Biological Approaches 888

Socialization Approaches 897

Cognitive Approaches 906

An Integration of Perspectives 914

CONCLUSIONS AND FUTURE DIRECTIONS 915

REFERENCES 916

& Martin, 1998) modified and expanded. The multidimensional framework provides a good way to organize the area, and it helps to direct new research efforts.

In our 1998 chapter, we began by presenting general issues and trends in research on gender development. We refer interested readers to the previous chapter for: (a) a brief historical review of the broad perspectives (developmental and social psychological, evolutionary and, anthropological and sociological) that have shaped current theorizing about gender development; and (b) a brief description of central conceptual and methodological issues in the areas of sex differences, gender stereotyping, masculinity/femininity, gender schemas, and gender categories.

Our current review is organized in three major sections. First, we present a detailed *description* of what aspects of gender are changing across age, including sex differences, using a modified version of the matrix of gender-related constructs and content presented in previous editions (Huston, 1983; Ruble & Martin, 1998).

---

This chapter is dedicated to our mothers, Edith Berenbaum, and, in loving memory, to Marjorie W. Nelesen and Carolyn I. Martin. We are grateful to Faith Greulich and Matt DiDonato for assistance in gathering materials and organizing references. We are also grateful to Meredith Bachman, David Perry, and Martin Trautner for a number of very helpful suggestions, and to Elaine Blakemore for sharing her reviews of

---

the literature on sex differences in physical skills, cognitive abilities, personality, and social behavior. Preparation of this chapter was facilitated by a Research Award (MH37215) from the National Institute of Mental Health to D. Ruble, and by Research Awards from National Institute of Child Health and Human Development to Carol Martin (HD45816) and to Sheri Berenbaum (HD19644).

Second, we consider the *causes* of developmental and sex difference trends from three major theoretical orientations—biological, socialization, and cognitive—emphasizing aspects that have generated the most controversy. Finally, we suggest conclusions and future research directions. A source of continuing debate concerns terminology, especially sex versus gender. For many scholars, the debate involves assumptions of causality, with “gender” used for socially based characteristics and “sex” used for biologically based characteristics. Because causality is more complex than such a system implies, we instead adopt Deaux’s (1993) terminology: *sex* refers to the demographic categories of female and male, and *gender* refers to judgments or inferences about the sexes, such as stereotypes, roles, and masculinity and femininity.

Even this system is difficult to apply unequivocally, so we are not rigid about its application. In general, we use the term *gender* except when comparisons explicitly involve girls and boys or men and women as a category—for example, *sex differences* and *sex segregation*.

## THE DEVELOPMENT OF GENDER-RELATED CONSTRUCTS AND CONTENT

In this section, we update earlier reviews of the developmental course of the components of gender, using our modification (Ruble & Martin, 1998) of Huston’s (1983) multidimensional matrix (see Table 14.1).

**TABLE 14.1 A Matrix of Gender-Typing: Constructs by Content (All Entries Are Examples)**

Content Area	A. Concepts or Beliefs	B. Identity or Self-Perception	C. Preferences	D. Behavioral Enactment
1. <i>Biological/categorical sex.</i>	1A. Gender awareness, labeling, and constancy.	1B. Personal sense of self as male or female.	1C. Wish to be male or female.	1D. Displaying bodily attributes of one’s gender (e.g., clothing, body type, or hair); transvestism, transsexualism.
2. <i>Activities and interests:</i> Toys, play activities, occupations, household roles, or tasks.	2A. Knowledge of gender stereotypes or beliefs about toys, activities, and so on.	2B. Self-perception of interests and activities as related to gender.	2C. Preference for toys, games, or activities.	2D. Engaging in gender-typed play, activities, occupations, or achievement tasks.
3. <i>Personal-social attributes:</i> Personality traits, social behaviors, and abilities.	3A. Knowledge of gender stereotypes or beliefs about personality or role-appropriate social behavior.	3B. Perception of own traits and abilities (e.g., on self-rating questionnaires).	3C. Preference or wish to have gender-linked attributes.	3D. Displaying gender-typed traits (e.g., aggression, dependence) and abilities (e.g., math).
4. <i>Social relationships:</i> Sex of peers, friends, lovers; or play qualities.	4A. Concepts about norms for gender-based relationships.	4B. Self-perception of own patterns of friendships, relationships, or sexual orientation.	4C. Preference for social interactions or judgments about social relationships based on sex or gender.	4D. Engaging in social activity with others on the basis of sex or gender (e.g., same-sex peer play).
5. <i>Styles and symbols:</i> Gestures, speech patterns (e.g., tempo), appearance, or body image.	5A. Awareness of gender-related symbols or styles.	5B. Self-perception of non-verbal stylistic characteristics or body image.	5C. Preference for gender-typed stylistic or symbolic objects or personal characteristics.	5D. Manifesting gender-typed verbal and nonverbal behavior.
6. <i>Values regarding gender.</i>	6A. Knowledge of greater value attached to one sex or gender role than the other.	6B. Self-perceptions associated with group identification.	6C. In-group/out-group biases, prejudice, or attitudes toward egalitarian roles.	6D. In-group/out-group discrimination.

The four Constructs (columns) are: Concepts or Beliefs, Identity or Self-Perception, Preferences, and Behavioral Enactment. The six Contents (rows) are: Biological/Categorical Sex, Activities and Interests, Personal-Social Attributes, Social Relationships, Styles and Symbols, and Values. Definitions and examples are provided in the cells of the table. Our review is divided by matrix cells (ordered by row headings), beginning with a review of the literature on biological/categorical sex. The sections are designated with the numbers and letters corresponding to the cells in the matrix.

The matrix is organized around the content areas to allow for consistencies and variations in each content domain to be recognized. The matrix remains useful, especially in pinpointing areas needing additional research, and in providing clear distinctions among aspects of gender-typing. The multidimensional nature of gender-typing is evident in examining patterns across cells. The drawback of using the matrix is that it presents a rather piecemeal and atheoretical picture of gender development. Furthermore, there are some difficulties in distinguishing some of the constructs and content domains (e.g., preferences and behavior) and in ensuring that common developmental trends across cells are identified. The major theories of gender development that help to integrate the material will be presented and evaluated following the matrix review. These theories posit consistencies across certain cells of the matrix. For instance, several theories hold that concepts or beliefs about a content area, such as stereotypes about activities and interests, influence preferences and adoption of these attributes. Some theories suggest that gender identity influences preferences and adoption of attributes more broadly. This revision also reflects areas that have received recent attention: early gender labeling and identity, children with “disorders of sex development” (previously termed “intersex conditions”), and body image. Because this is a revision of our prior chapter and because of major space limitations, we have deleted most references from the prior edition, and instead cite Ruble and Martin (1998), suggesting that the reader look there for original citations.

### **Biological/Categorical Sex (1)**

The literature on biological/categorical sex spans a wide array of well-researched topics, including gender identity, gender constancy, and intersex conditions. Many of

these issues are controversial and the topics have wide-ranging theoretical importance. A key issue concerns how and when do children learn about their placement in a gender group. This issue has been theoretically important, especially in untangling biological and environmental contributors to gender identity.

### ***Concepts or Beliefs (1A)***

**Making Gender Distinctions.** How early can children discriminate the sexes? Recent research using habituation and preferential looking paradigms suggests that infants as young as 3 to 4 months of age are capable of distinguishing between males and females in a categorical manner (e.g., Quinn, Yahr, Kuhn, Slater, & Pascalis, 2002). Subsequently, as described in a recent review (Martin, Ruble, & Szkrybalo, 2002), 9- to 11-month-olds can discriminate faces by sex, habituate to faces of both sexes, and make intermodal associations (e.g., among female faces and voices). It has not always been clear whether infants have established gender categories prior to testing or whether ad hoc categories are formed during the testing. Recent research suggests that infant performance is influenced by experiences prior to the experiment; for instance, the sex of the primary caretaker influences infants' preferences for male or female faces (Quinn et al., 2002). Thus, these studies suggest that before children can walk or talk, they have in place perceptual categories that distinguish “male” from “female.”

When can children label the sexes? Early research suggested that most children cannot reliably sort pictures of males and females until after 30 months of age (S. K. Thompson, 1975). With other measures, however, many children appear to understand and use gender labels much earlier (e.g., Fagot & Leinbach, 1989; Weinraub et al., 1984). For example, in two recent studies, most 24- and 28-month-old children chose the correct picture in response to experimenter-provided gender labels (A. Campbell, Shirley, & Caygill, 2002; G. D. Levy, 1999).

These findings imply that many children understand gender labels by their second birthday. Research with other methods suggests that gender labeling may occur even earlier. For example, in a preferential looking paradigm, 50% of 18-month-old girls showed knowledge of gender labels (“lady” or “man”) but boys did not, and 50% of 18- and 24-month-old boys and girls showed above chance understanding of the label boy (Poulin-Dubois, Serbin, & Derbyshire, 1998). Other evidence

suggests that gender words occur early in vocabulary development (Stennes, Burch, Sen, & Bauer, 2005); parents report that the words “boy,” “girl,” and “man” are understood by many toddlers by 22 months (Fenson et al., 1994). In a longitudinal study (Zosuls, Greulich, Haddad, Ruble, & Tamis-LeMonda, 2006), parent diaries indicated that, by 22 months of age, 56% of boys and 86% of girls had at least one gender label in their productive vocabulary (e.g., boy/girl; man/lady). Taken together, these findings suggest a need to revise prior conclusions that children do not understand gender labels until 2½ years.

What cues are used to discriminate or label the sexes? Perceptual discriminations made before 6 months of age may be based on facial features alone, without hair styles/length or clothing cues (Quinn et al., 2002). In verbal labeling, young children rely heavily on hair cues, believing that figures with blonde, curly, long hair are females (Intons-Peterson, 1988a), but some preschoolers can recognize genital differences when realistic pictures are used (S. L. Bem, 1989). Recent data suggest that 3-year-olds can identify a neutral figure as a man or a woman using clothes and voice, with hair a better cue for identifying the figure as a woman than a man and face and body type better for identifying the figure as a man (Zucker, Yoannidis, & Abramovitch, 2001). In a developmental study that eliminated hairstyle and clothing cues so that facial structure was the only relevant cue children as young as 7 years could accurately identify the sex of adult faces; but accurate identification of child faces was not found until 9 years (Wild et al., 2000). Other research also suggests that children are able to distinguish gender in adults before they do so in children (e.g., Poulin-Dubois et al., 1998; Weinraub et al., 1984). In short, perceptually discriminating males from females (in habituation and visual preference studies) is based on minimal cues and occurs in infancy, but verbal identification of male or female shows a more complex developmental course.

**Gender Constancy.** One of the most controversial and compelling ideas in the literature is “gender constancy.” As proposed by Kohlberg (1966), children’s developing sense of the permanence of categorical sex (“I am a girl and will always be a girl”) is a critical organizer and motivator for learning gender concepts and behaviors. Slaby and Frey (1975) demonstrated that children move through a series of stages: first learning to identify their own and others’ sex (basic gender iden-

tity or labeling), next learning that gender remains stable over time (gender stability), and finally learning that gender is a fixed and immutable characteristic that is not altered by superficial transformations in appearance or activities (gender consistency). These stages were confirmed in other research, including cross-cultural studies (e.g., De Lisi & Gallagher, 1991). The first stage is acquired by age 3, and typically much younger, as discussed earlier. The second stage (stability) is acquired between 3 and 5 years in the United States (L. Taylor, Ruble, Cyphers, Greulich, & Shrout, 2006), but may be later in other countries (Ruble, Trautner, Shrout, & Cyphers, 2006). There is considerable controversy, however, about when children acquire consistency understanding, and thus full constancy. In this section, we focus on this age issue. In later sections, we review the evidence concerning the consequences of acquiring gender constancy.

From a cognitive developmental perspective, children would not be expected to show a complete understanding of constancy until they mastered conservation, usually during the concrete operational period (5 to 7 years of age; Maccoby, 1990). Moreover, recent research suggests that constancy is closely associated with probably the most relevant element of operational thinking: understanding the distinction between appearance and reality (Trautner, Gervai, & Nemeth, 2003). Studies designed to pinpoint the development of constancy show a wide age range with some finding complete understanding in children as young as 3 to 4 years (e.g., S. L. Bem, 1989), but others failing to find it in most 7-year-olds (e.g., De Lisi & Gallagher, 1991).

A number of methodological and theoretical issues may underlie the discrepancies, including sample variations, the use of verbal questions about hypothetical transformations versus actual transformations, whether children’s justifications are included in the criteria for understanding constancy, and the degree of realism of the measure and context (Ruble & Martin, 1998). Much of the discrepancy appears to be due to the consistency questions. Many children who first gave nonconstant responses to a consistency question (e.g., responding that Jack would be a girl if he wore lipstick) later gave the correct answer when asked if the child was *really* a girl or a boy, suggesting that they were originally responding to what sex they thought the child was *pretending* to be (Martin & Halverson, 1983). Thus, in many studies, constancy may be *underestimated*. However, several studies show a dip in scores on consistency questions

appearing sometime after age 3 to 4 years followed by a recovery between 5 to 9 years (e.g., De Lisi & Gallagher, 1991; Yee & Brown, 1994), suggesting perhaps that high levels of constancy in very young children may be *overestimates* of their understanding.

These problems with consistency items raise important questions about interpreting scores on constancy measures. Are high constancy scores in 3-year-olds pseudo-constancy (Emmerich, Goldman, Kirsh, & Sharabany, 1977), or are 3- and 4-year-olds capable of true constancy (e.g., S. L. Bem, 1989)? Recent research examining consistency scores with and without justifications suggests that high constancy scores by 3- to 5-year-olds are eliminated when justifications are included (L. Taylor et al., 2006). This is because young children generally do not provide a constancy-relevant justification for their responses (e.g., "It doesn't matter if he's wearing a dress, he'll always be a boy"), but rather focus on irrelevant details (e.g., "He still has a boy's face"). Thus, young children may focus more on gender categories than on role conflicts, and thus their response is simple: "Jack is a boy; of course he would still be a boy." As children grow older, conflicting gender role information may become more salient and may interfere with the application of the categorical distinction, contributing to errors on consistency questions. In support, some studies indicate that the dip in consistency scores occurs at approximately the same time that there is an increase in children's use of social norms to explain their answers (e.g., "If Jack wore lipstick, Jack would be a girl; boys can't wear lipstick"; Szkrybalo & Ruble, 1999). Finally, the recovery of constancy after age 5 years may represent an integration of understanding categorical distinctions with understanding gender role norms.

In summary, the age at which children attain complete constancy understanding has yet to be completely resolved. This issue remains important because of its implications for predicted associations between constancy and outcomes such as learning gender stereotypes or developing gender-typed preferences (see Cognitive Developmental Theory section). Care must be taken because the "errors" of older children may not reflect a lack of understanding and because high level responding among 3- to 4-year-olds may not reflect a true understanding of constancy.

**Beliefs about the Origins of Gender Group Differences.** Do children believe that the sexes differ be-

cause of biological factors, or do they believe differences are more likely due to societal factors, such as how children are raised? This issue is important, in part, because it may provide insight about when and why children show changes in flexibility in their gender-related perceptions and behaviors at different ages.

Several studies indicate that adults believe sex differences are based more on socialization than biological factors (e.g., Martin & Parker, 1995; Neff & Terry-Schmitt, 2002). In children and adolescents, attributions of differences to biological factors seem to decrease with age (J. Smith & Russell, 1984). When preschoolers were asked about the outcome of a child being raised by members of only one sex, they attributed characteristics to the target children based on their sex rather than on the basis of the rearing environment (M. G. Taylor, 1996).

### ***Identity or Self-Perception (1B)***

Gender identity is a person's sense of self as a male or female (Zucker & Bradley, 1995). At its most basic, this understanding is anatomical, but also includes feelings about a person's biological sex and behavioral self-presentation as male or female. Research on gender identity has generally followed two separate paths: (1) the typical development of *self-awareness* as male or female or (2) variations in gender identity. These two paths have also differed in their emphases, with the former focusing on cognitive aspects of gender identity and the latter on affective aspects.

**Typical Developmental Course.** Normative developmental research has focused on the age at which children attain basic gender identity because a child's awareness of being a boy or a girl is considered by cognitive theorists to motivate gender-typed behavior (Constantinople, 1979; Martin et al., 2002). Most children can accurately label their sex and place a picture of themselves with other same-sex children by 27 to 30 months, but recent research suggests that attaining basic gender identity occurs earlier for many children (e.g., A. Campbell et al., 2002; Zosuls et al., 2006).

**Variations in Core Gender Identity.** Recent work in typical children shows variability in several affective aspects of gender identity that relate to sex, age, and subsequent adjustment; this is discussed elsewhere (e.g., 1C, 2B) because it is not concerned with core identity as male or female. We focus here on research concerned

with the etiology of core gender identity and its disorders, which has been studied in two clinical populations. The first is children born with ambiguous genitalia because of disorders of sex development (intersex conditions) or boys who lack a penis due to a surgical accident or congenital defect. It was long believed that children adopt an identity consistent with their rearing, regardless of biological sex, as long as gender assignment is done early in life (before 18 to 30 months), is unambiguous, and genital appearance is made concordant with rearing sex (e.g., Money & Ehrhardt, 1972). This resulted in female rearing for such children because it is easier to construct female genitalia than male genitalia. Questions about this position (e.g., Imperato-McGinley, Peterson, Gautier, & Sturla, 1979) became prominent in the past decade (Colapinto, 2000; M. Diamond & Sigmondson, 1997; Reiner & Gearhart, 2004). Systematic evidence shows that gender identity is not determined simply by either biology or rearing, and that gender identity may change even in adulthood (see Biological Approaches).

The second population involves individuals with gender identity problems whose biological sex is not in doubt (for details, see Zucker & Bradley, 1995). Since 1980, the *Diagnostic and Statistical Manual (DSM)* of the American Psychiatric Association has included Gender Identity Disorder of Childhood (GIDC) for children who show both identity problems (e.g., wishing to be the other sex) and cross-gender behavior (e.g., wearing clothes and playing with toys typical of the other sex; Zucker, 2004). Children with GIDC show extreme sex-atypical behavior and are not androgynous. The revised *DSM* includes separate criteria for children versus adolescents and adults reflecting developmental differences in clinical presentation.

There are no epidemiological data on the prevalence of GIDC. Estimates suggest 2% to 5% of the population have GIDC or subclinical variants (Zucker & Bradley, 1995). Boys are referred for treatment more than girls, 3 to 6 times more in childhood, but only 1.2 to 1.3 times more in adolescence (Zucker, 2004). This may reflect referral bias due to cultural factors; for example, beliefs that girls may outgrow cross-gender behavior, and less tolerance of cross-gender behavior in boys than in girls. Girls display more extreme cross-gender behavior than boys before a clinical assessment is obtained (Zucker & Bradley, 1995).

Gender-atypical behavior in GIDC children usually begins during the preschool years but may begin earlier

(Zucker & Bradley, 1995). Early signs include wearing other-sex clothing, preoccupation with other-sex toys, and gender confusion or mislabeling. Children with GIDC develop gender concepts later than do typical children (Zucker et al., 1999). Extreme gender-atypicality may lead to peer ostracism in childhood and adolescence (Zucker & Bradley, 1995). Long-term outcome of children with extreme cross-gender identity is better studied in boys than in girls, with most showing bisexual and homosexual orientation without gender dysphoria, but a minority remaining identified with the other sex (Zucker, 2004). Individuals diagnosed with GID in adolescence are more likely than those diagnosed in childhood to persist with GID into adulthood (Zucker, 2004), suggesting reduced plasticity of gender identity with age, and perhaps some misdiagnoses.

Several broad factors have been hypothesized to cause GIDC, including hormones, temperament, family dysfunction, and encouragement of cross-sex behaviors (Zucker & Bradley, 1995). Research on gender identity raises questions about assumptions of the last 30 years. If stereotypes are less prevalent, why are children referred to clinics if they behave in a way considered normal for the other sex? If goals for boys and girls are the same, why is it considered a problem for boys to play with dolls? Perhaps it is because children with GIDC are rigid in their sex-atypicality, and likely to be teased and victimized by peers (Zucker & Bradley, 1995), to have behavioral and emotional problems (Egan & Perry, 2001; Zucker & Bradley, 1995), and to become homosexual adults (a problem for some parents).

Is GIDC truly a psychiatric disorder? It is unclear if emotional distress in GIDC is intrinsic or a consequence of social responses (Bartlett, Vasey, & Bukowski, 2000). A distinction has been made between discomfort with one's biological sex and discomfort with the gender role prescribed for one's sex, with GIDC to be reserved only for the former (Bartlett et al., 2000), but there is disagreement about whether most children with GIDC truly wish to be the other sex (Bartlett et al., 2000; Bartlett, Vasey, & Bukowski, 2003; Zucker, 2002).

### **Preferences (1C)**

How satisfied are children with their sex? Very few children in Western cultures say they want to be the other sex, although more girls wish to be boys than vice versa (Antill, Cotton, Russell, & Goodnow, 1996; Goldman & Goldman, 1982), with this difference increasing into adolescence but decreasing from the 1950s to the

1980s (Ruble & Martin, 1998). Parents of 4- to 11-year-old clinic-referred children report 1% to 16% of boys and 4% to 8% of girls wish to be the other sex, compared to 0% to 2% of boys and 2% to 5% of girls from a nonclinic sample (Zucker & Bradley, 1995). Among typical fourth to eighth graders, gender-contentedness was higher in boys than in girls and negatively correlated with age (Egan & Perry, 2001).

### ***Behavioral Enactment (1D)***

Despite wide varieties of socialization pressures, cultural differences, and even biological influences, most children develop a clear sense of self as male or female and master the roles generally associated with their assigned sex. There are separate criteria in the *DSM* for GID of childhood and of adolescence/adulthood, but both sets of criteria require for diagnosis a specific *pattern* of feelings and behavior. Some adults with GID have sex-reassignment surgery. Among adult males with GID, there is heterogeneity in other aspects of gender-related behavior; for example, there is an equal distribution of those sexually attracted to biological males or females (Blanchard, 1989).

### **Activities and Interests (2)**

Are there parallels in the development of children's concepts and beliefs about gender-related activities and interests and their self-perceptions, preferences, and behaviors? This question is important for understanding the mechanisms driving children's behavior. Do self-reported preferences and behavioral measures of children's activities and interests yield similar trends? Processes governing conscious choices may be quite different from those governing behavior. For instance, self-reports may involve demand characteristics more than behavioral measures.

### ***Concepts or Beliefs (2A)***

Earlier *Handbook* reviews have concluded that stereotypes about clothing, activities, toys, and games are known as early as age 2½ (Huston, 1983; Ruble & Martin, 1998). Recent work suggests that children are aware of some stereotypes even before 2½ years (Martin et al., 2002; C. F. Miller, Trautner, & Ruble, 2006; Powlisha et al., 2001). On nonverbal looking-time tasks, infants have some knowledge of activities and objects associated with each gender. For example, one study using a preferential looking-time paradigm showed that 18- and

24-month-old girls (but not boys) were able to match gender-typed toys (e.g., doll/car) with the face of a boy or a girl (Serbin, Poulin-Dubois, Colburne, Sen, & Eichstedt, 2001). Other studies have examined infants' responses to mismatches, which purportedly lead to longer looking times because they involve surprise or novelty. For example, 24-month-old boys and girls paid significantly more attention to gender-inconsistent pictures than consistent pictures, but only when they involved female-typical behavior (e.g., man putting on make-up; Serbin, Poulin-Dubois, & Eichstedt, 2002).

Looking-time studies are promising for understanding children's earliest understanding of gender, suggesting that children as young as 18 months begin to link activities to gender, but further research is needed before clear conclusions can be drawn. Nevertheless, studies using other paradigms provide some converging evidence for early developing stereotypes (A. Campbell et al., 2002; Poulin-Dubois, Serbin, Eichstedt, Sen, & Beissel, 2002). Taken together, these recent studies suggest that some children understand concrete gender stereotypes by 2 years of age, but that the level of such understanding found depends on the measure, the stereotype, and the child's sex.

Stereotype knowledge of child and adult activities and occupations increases rapidly between ages 3 and 5 (reaching a ceiling by kindergarten or first grade) depending on the particular item (e.g., Blakemore, 2003). A meta-analysis of developmental studies of stereotype knowledge (Signorella, Bigler, & Liben, 1993) suggested that gender stereotypes are well developed at the end of preschool, showing further change only when a broad range of topics is examined.

Most stereotype measures assess knowledge at a relatively simple level, identifying which gender category is associated with particular objects, so it is not surprising to find high levels of stereotyping in very young children. Studies assessing stereotype knowledge in different ways, however, suggest continued development throughout childhood. For example, free descriptions of what boys, girls, grown-up women, and grown-up men are like show increasing use of stereotypes with age from preschool through fifth grade (C. F. Miller, Lurye, Zosuls, & Ruble, 2006). Further, horizontal stereotypic associations (attribute to attribute) develop later than vertical associations (male/female label to attribute; Ruble & Martin, 1998). For example, children 8 years or older can use attribute information about a target to make horizontal associations about other stereotypic attributes (e.g., judge that a girl who likes a male-typical

game will also choose a male-typical after-school activity; Lobel, Gewirtz, Pras, Shoeshine-Rokach, & Ginton, 1999), but 6-year-olds are limited in these horizontal associations (Martin, Wood, & Little, 1990).

What kinds of stereotypes do children learn first? Although this question has not been systematically addressed, there are some interesting clues. Very young children (around 26 months) appear to be most aware of gender differences associated with adult possessions (e.g., shirt and tie), roles, physical appearance, and abstract characteristics associated with gender (e.g., softness), and 5 to 6 months later show evidence of awareness of stereotypes about children's toys (Ruble & Martin, 1998). In free descriptions, preschool children are most likely to refer to dolls and appearance (e.g., dresses or jewelry) for girls and toys and behaviors (e.g., hits or action heroes) for boys (C. F. Miller, Lurye, et al., 2006). During the elementary school years, the range of and extent to which occupations, sports, and school tasks or subjects are differentially associated with males and females continues to increase (Ruble & Martin, 1998; C. F. Miller, Lurye, et al., 2006).

Do stereotypes become more flexible with age? Clear developmental trends are difficult to describe because *flexibility* means many things: for instance, the willingness to apply an attribute to both sexes rather than just to one or the other, or the recognition of the relativity of stereotypes (e.g., that norms could be different in another culture). The term has been applied either to changes in knowledge (e.g., about variability or relativity) or to personal acceptance of stereotypes, with the latter being closer in meaning to attitudes or values that the sexes "should" be different. Ideally, these latter trends would be reviewed in the Values section below. However, it is difficult to distinguish between knowledge and attitudes on the basis of currently available measures; thus, all are reviewed here. And because it is difficult to define flexibility precisely, we use the term "flexible" to apply to any nonrigid application of stereotypic items, whether because of knowledge or because of personal attitudes.

Based largely on a comparison of studies that allow children to classify items as equally appropriate for both sexes (i.e., "both" responding), prior *Handbook* chapters concluded that after about 7 years of age, children's knowledge of stereotypes continues to increase but that their acceptance of stereotypes as inflexible or being morally right begins to decline (Huston, 1983; Ruble & Martin, 1998). For example, interview studies suggest that with age, children increasingly recognize the cultural

relativity of gender norms, though this understanding appears to reach a ceiling at some point during middle elementary school (e.g., Blakemore, 2003; L. Taylor et al., 2006). In addition, a meta-analysis of stereotype attitudes and knowledge studies showed that "both" responding for questions worded "who can" or "who should" engage in an activity increase with age among elementary school children (Signorella et al., 1993). Studies using conceptually similar measures that do not rely on "both" responses show similar trends (C. F. Miller, Trautner, et al., 2006). Interestingly, the meta-analysis revealed curvilinear age trends, with flexibility of association or attitudes lowest when children begin school.

Recent longitudinal studies support these conclusions. For example, flexibility of occupational stereotyping increased between second and sixth grades (Helwig, 1998). Also, children given a measure of stereotyping annually from ages 5 to 10 showed a peak in rigidity at either 5 or 6 years of age and then a dramatic increase in flexibility 2 years later (Trautner et al., 2005). Notably, analyses of individual differences in stereotyping showed that neither the level nor timing of peak rigidity affected this developmental trajectory, suggesting that all children follow the same basic developmental path of stereotype rigidity and flexibility across development, despite variations in when it begins and what level it reaches.

Taken together, these data suggest that children entering elementary school have extensive knowledge about which activities are linked to being male or female. Until approximately 7 to 8 years of age, when horizontal associations emerge, stereotypes are held quite rigidly, perhaps because younger children do not seem to recognize that there can be individual variation in masculinity and femininity within the male and female categories.

Beyond flexibility and rigidity, certain developmental trends often vary for girls and boys. As revealed in meta-analysis (Signorella et al., 1993), preschool girls scored higher than boys on stereotype knowledge (see also O'Brien et al., 2000), but no clear sex differences were found in flexibility. Similarly, in free descriptions of males and females, preschool to fifth grade girls used more stereotypic terms than did boys (C. F. Miller, Lurye, et al., 2006). But, by middle childhood, girls have more flexible stereotypes (e.g., L. Miller & Budd, 1999; Whitley, 1997), including cultures outside the United States (Zammuner, 1987). Finally, children view the male role as more rigidly proscribed than the female role (e.g., Henshaw, Kelly,

& Gratton, 1992). In short, some, but not all, studies suggest that girls are both more knowledgeable and, after the preschool years, more flexible in their personal acceptance of gender stereotypes, whereas boys hold stereotypic views more rigidly and are held to them more by others.

Stereotyped knowledge, rigidity/flexibility, and inferences have also been found to vary across ethnicity/cultures by some researchers. Given the relatively limited number of studies, it is premature to draw definitive conclusions. When differences are found, however, relative to children of European origin, Hispanic/Latino children (e.g., B. A. Bailey & Nihlen, 1990) and Asian children (Lobel, Gruber, Govrin, & Mashraki-Pedhazur, 2001) have shown greater stereotyping, whereas African American children have shown less (e.g., Albert & Porter, 1988; but see Liben & Bigler, 2002, for an exception). Even countries that share a European background vary with respect to degree of stereotyping. For example, Italian children were more likely to stereotype toys and activities than were Dutch children (Zamuner, 1987). It would be interesting to examine the extent to which developmental trends and types of earliest stereotypes (e.g., appearance) generalize beyond Western cultures.

Predictions and evidence concerning changes in flexibility during adolescence have been mixed. Gender-related beliefs and behaviors may become intensified (e.g., J. P. Hill & Lynch, 1983), as an adolescent's newly emerging identity as a sexual being may lead to heightened concerns about gender role expectations and increased polarization of attitudes. In contrast, continuing cognitive maturation should facilitate a more flexible and relativistic view of gender norms (Eccles, 1987). Most indexes of stereotype flexibility show an increase through early adolescence (Liben & Bigler, 2002). Studies of changes between early and later adolescence show mixed results depending on the nature of the stereotype, the measure, and the sex of the participants (Ruble & Martin, 1998; Whitley, 1997).

### *Identity or Self-Perception (2B)*

To what extent is there a connection between children's activities and interests and their self-perceptions and identities? For example, do children perceive their interests and activities as related to their gender (e.g., they like trucks because they are boys)? Examining developmental changes in such connections is important for theories of gender development, discussed later, which suggest that developmental changes in gender identity

influence gender differentiation. As Liben and Bigler (2002) suggest, it is important to examine the direction of effects: Does identity influence activities and interests or do activities and interests influence identity? Unfortunately, research has not focused on such questions, but rather on what kinds of activities children prefer (see 2C) or how children perceive themselves in term of traits (see 3B).

Some recent research is indirectly relevant to such issues. Perry and colleagues' research on gender identity in children (e.g., Egan & Perry, 2001) addresses two components closely connected to activities and interests. *Gender typicality* is thought to reflect children's idiosyncratic weighting and integration of diverse information about their gender-related interests and activities (Perry, 2004), so that different children feel gender typical for different reasons (e.g., athletic prowess versus competence in math and science). *Felt pressure* refers to pressure felt from parents, peers, and the self to conform to gender stereotypes. In terms of developmental trends, Perry (2004) suggested that felt pressure may develop in preschool but that perceived typicality may not emerge until later when children engage in social comparison. Such hypotheses remain to be tested. Available data suggest few age effects among elementary school children over age 7 (e.g., Egan & Perry, 2001). Further research into the developmental course of these identity-related beliefs is important, in part because children who feel gender typical and who experience little pressure for gender conformity are less distressed than other children (Carver, Yunger, & Perry, 2003).

Other relevant research involves the relation between self-concept and academic interests and abilities (e.g., Byrne & Gavin, 1996; Marsh, Byrne, & Yeung, 1999). Stereotypic patterns are found: Boys' academic self-concept is correlated more strongly with math than with verbal self-perceptions, and the reverse is true for girls (Skaalvik & Rankin, 1990). Even first grade children show some effects of gendered self-beliefs: math is relevant for boys' self-concepts but not for girls' (Entwisle, Alexander, Pallas, & Cadigan, 1987). Such relations are important because children may avoid courses or future occupations that are believed to be unimportant or irrelevant for their academic self-concept. For example, over time, girls gave lower ratings to liking of math and the importance of math competence for self-concept, and such values were related to enrollment in advanced math and physics in high school (Eccles, 1989). Students' views of future selves also appear to involve

stereotypic activities and interests, with boys more likely to see their futures emphasizing science, numbers, reasoning, and girls more likely to see futures emphasizing people, culture, and self-expression; this future divide was more extensive for college than high school students (Lips, 2004).

### **Preferences (2C)**

Unfortunately, it is difficult to discern clear developmental trends for activity and interest preferences because conclusions depend on variables used. For example, some studies focus on sex differences in interest in female- or male-typical activities (e.g., does the gender gap in interest in math increase at adolescence) and infer greater flexibility of preferences during developmental periods when those differences are smaller. Such an approach cannot inform us, however, about changes in relative interests (e.g., in math versus language arts) for males versus females. For example, in some cases, small sex differences may be driven by girls' relatively greater or lesser interests in male-typical versus female-typical activities. In such cases, the girls may have become more flexible but not the boys. Other studies examine developmental trends within sex for different types of activities (e.g., female typical, male typical, and neutral). Increasing flexibility would be shown for girls, for example, by decreasing interest in female-typical activities and increasing interest in male-typical and neutral activities. Relative interest in activities may be determined by a number of factors other than gender typicality. For example, girls' liking of tea sets and household chores may decline with age but imply nothing about developmental trends in interest in other female-typical activities. They may have switched to jump ropes or pajama parties. Such interpretational difficulties also apply to behavioral engagement in gender-typical activities (see 2D). Thus, for both preferences and behaviors, the conclusions drawn about developmental changes depend on which comparison is made, even in the same study (e.g., see McHale, Shananhan, Updegraff, Crouter, & Booth, 2004). Space limitations preclude detailed review of studies examining age and sex differences in gender-typed preferences to resolve conflicting conclusions across studies, but we call attention to some of these difficulties when discrepant developmental patterns are found.

**Infancy.** Recent research has examined gender-typed preferences in infancy, using nonverbal methods.

In a longitudinal study of children tested at 3, 9, and 18 months, A. Campbell, Shirley, Heywood, and Crook (2000) examined whether children would look longer at gender-typical than atypical activities and toys. There was some evidence that boys but not girls showed gender-typed preferences at 9 and 18 months. One problem interpreting the data is that both boys and girls showed a strong preference for male-typical activities, which involved much more gross motor activity (e.g., wrestling versus whispering). A cross-sectional study using a similar paradigm (Serbin et al., 2001) showed that 12-month-old boys and girls preferred looking at dolls over trucks, with no sex difference. At 18 and 23 months, however, clear preferences were observed, with boys looking more at trucks and girls looking more at dolls. Despite the small number of studies and inconsistent results, the preferential-looking paradigm appears promising, and the data provide preliminary evidence that gender-typed preferences may begin before 2 years of age.

**Preschool.** Recent research (e.g., Servin, Bohlin, & Berlin, 1999) supports earlier conclusions that trends for toy and activity preferences are similar to those for stereotypes: an increase in gender-typed preferences during the preschool years, with well-established preferences by 5 years, and more gender-typed preferences for boys than for girls (Huston, 1983; Ruble & Martin, 1998). There are qualifications to these conclusions. First, preferences vary tremendously by activity. Because some measures ask about chores (e.g., Sex Role Learning Inventory [SERLI]; Edelbrock, & Sugawara, 1978), children's preferences are not strongly gender-typed, even though their stereotype knowledge is (Serbin, Powlishta, & Gulko, 1993; Turner, Gervai, & Hinde, 1993). For other play activities (e.g., trucks, dolls), gender-consistent preferences are very strong, over 80% at age 4 and reaching 100% by age 7 (Emmerich & Shepard, 1982). Second, the size of the sex difference varies by activity. Because SERLI items for boys are mostly play things, whereas for girls they are household chores, it is not surprising that girls consistently show less clear same-gender preferences (Serbin et al., 1993; Welch-Ross & Schmidt, 1996). When other items are used, boys do not always show greater gender-typing (e.g., Serbin et al., 1993). Nevertheless, even using other measures, many studies still suggest that girls are less likely to prefer same-gender activities than are boys (e.g., Perry, White, & Perry, 1984; Turner et al., 1993).

**Middle Childhood.** Because some aspects of stereotyping become less rigid but also more elaborated as children move into middle school, activity/interest preferences might also be expected to change at this time. Early studies showed that boys' and girls' preferences follow different developmental paths after age 5, with boys showing increasingly stereotyped preferences and girls remaining stable or declining (Huston, 1983). More recent research has shown mixed support for this conclusion. In some cases, a sex by age interaction was found (e.g., Helwig, 1998); but other studies showed that gender-typed preference scores for both sexes were stable between kindergarten/first grade and fifth/sixth grade (e.g., Egan & Perry, 2001; Serbin et al., 1993) or declined (Welch-Ross & Schmidt, 1996).

The mixed results may be due to variations across studies in the kind of preferences assessed (Ruble & Martin, 1998). Also, patterns may vary depending on whether assessment involves children's preferences for same-gender activities or rejection of other-gender activities. For example, in a longitudinal study, Aubry, Ruble, and Silverman (1999) found that preferences for gender-atypical items declined steeply between preschool and third grade, whereas preferences for gender-typical items were relatively stable across age. In addition, Bussey and Perry (1982) found that third and fourth grade boys rejected gender-atypical behavior more than girls, but there was no sex difference in preferences regarding gender-typical behavior. In short, it appears that when gender-typed preferences increase with age, it is likely to reflect avoidance of other-sex activities and interests; and when a sex difference is observed, it is likely to show that boys are more rigidly gender-typed during the middle grades.

**Adolescence.** As for stereotypes (see 2A), researchers have asked whether children's gender-related preferences become intensified or more egalitarian as children enter adolescence. Preferences generally become more flexible between middle childhood and early adolescence (e.g., Katz & Ksansnak, 1994), but flexibility regarding certain kinds of interests, may decline during this period. For example, in a meta-analysis of computer-related attitudes and self-efficacy beliefs, Whitley (1997) found a small but significant overall sex difference ( $d = .23$ ) showing that males were more positive than girls about computers at all ages, but this difference peaked at high school. Recent longitudinal research from 1st to 12th grades showed that sex differ-

ences in subjective task values (e.g., interest, importance, or usefulness) for gender-typed school activities (e.g., math, language arts, sports) did not all increase at adolescence, thus failing to support theories of gender intensification (Fredricks & Eccles, 2002). Other research has found clear sex differences in adolescents' interests in academic subjects. In a study of high school students in the United States, Taiwan, and Japan, boys in all cultures were more likely to report preferences for mathematics, science, and physical education, and girls were more likely to report preferences for language arts, music, and art (E. M. Evans, Schweingruber, & Stevenson, 2002).

Some studies suggest that an increase in flexibility during adolescence occurs only or primarily for girls (e.g., Ruble & Martin, 1998). One recent longitudinal study, however, showed this increasing flexibility from sixth to seventh grade only for girls' endorsement of feminine occupations; otherwise, preferences for activities and occupations were reasonably stable across this 2-year period (Liben & Bigler, 2002). A similar pattern of results was reported in a longitudinal study among middle school-age Australian children (Antill et al., 1996). As Liben and Bigler (2002) speculate, the reduction in some gender-typed preferences by adolescent girls may indicate both increasing tolerance for females to engage in male-typical roles and recognition that male-typical activities and roles have higher status.

In short, the dominant finding is that girls are less rigid in their stereotypic toy and activity preferences than are boys. With few exceptions, this difference appears at all ages. Although some evidence suggests an increase in flexibility in middle childhood and adolescence, particularly for girls, findings are mixed. Gender differences in growth trajectories appear to be domain specific, and are likely to be influenced by changing stereotypes (e.g., math) and opportunities (e.g., sports; Fredricks & Eccles, 2002).

### ***Behavioral Enactment (2D)***

Children's engagement in gender-stereotypical activities has been examined in a wide range of settings, including free-play in home, school, and laboratory observations, as well as household chores, television preferences, and school courses selected. Some studies suggest that boys and girls show at least some differential play by as early as 2 years of age (e.g., A. Campbell et al., 2002). Whether gender-typed toy play emerges prior to 2 years of age is less clear. In one study, the toy

play of infants aged 10, 14, and 18 months was observed during structured free play with parents (Roopnarine, 1986). Girls played more with dolls and offered toys to parents more than did boys. The results of this study have been interpreted to show gender-typed play by 10 months, but the samples for each age group were too small to detect interactions and tests within age were not conducted. Moreover, it was not clear if play was child or parent initiated. Other studies of unconstrained free play by children younger than 2 years have reported mixed results (Ruble & Martin, 1998). For example, in a longitudinal study, girls played more with female-typical toys (e.g., kitchen set, princess outfit) than with male-typical toys (e.g., tool set, baseball outfit) or neutral toys at 18 months and at 30 months, but boys did not show sex-differentiated play until 36 months (Katz & Kofkin, 1997). In another study, 12- to 14-month-old boys played longer than girls with male-typical toys, but the sexes did not differ significantly in play with female-typical toys (though the means were in the expected direction; Servin et al., 1999). By 36 months, both boys and girls played longer with gender-typical than atypical toys. Thus, the former study suggests that gender-typing may emerge at a younger age in girls, and the latter study suggests that gender-typing may emerge earlier in boys. This apparent discrepancy in showing earlier gender-typed play in girls versus boys may reflect a difference in the operationalization of gender-typed behavior: that is, showing more play with same-sex compared to other-sex play versus showing sex differences in play with specific toys. Indeed, a recent study using both operationalizations supports this conclusion. Zosuls et al. (2006) found that, at 17 and 21 months, girls engaged in more gender-typed play (doll versus truck) than boys did. Nevertheless, boys played more with the truck than girls did. Thus, although some gender-differentiated play may be found among infants and toddlers, this trend increases dramatically with age such that clear and strong findings that both boys and girls play more with gender-typical toys are seen at 36 months.

During preschool, the two sexes engage in such different activities, they are almost like two separate cultures: girls play more frequently with dolls, tea and kitchen sets, dress-up, and engage in fantasy play involving household roles, glamour, and romance, whereas boys play with transportation and construction toys, and engage in fantasy play involving action heroes, aggression, and themes of danger (Dunn & Hughes, 2001; Maccoby, 1998). For example, an analysis of the stories

told by preschool children revealed that boys and girls became increasingly polarized across a school year (Nicolopoulou, 1997): Most girls' stories involved themes of family relationships with virtually no aggression or violence; the reverse was true for boys. The research also suggests that gender-typical activity involvement increases dramatically during the preschool years. For example, in one large study, parents from the United Kingdom, the United States, and the Netherlands reported on their preschool children's activities and interests (Golombok & Rust, 1993). There was a steady increase in sex-differential involvement between 18 and 60 months, with parents reporting much less overlap in the interests of boys and girls at 5 than at 2 years. In another large study of parent reports' of children's use of time among a diverse sample, sex differences in some activities such as video games increased dramatically between 2 to 7 years of age, and at 3 to 4 years of age, girls spent more time than boys on personal care, social interaction, and chores (Huston, Wright, Marquis, & Green, 1999).

Do boys show stronger evidence of gender-typed toy play, as some researchers have suggested (e.g., A. Campbell et al., 2000)? The studies described earlier suggest that, if anything, infant girls are more likely to play with gender-typical versus atypical toys than are boys. By preschool age, this pattern changes. Studies of young children show mixed results (Ruble & Martin, 1998). The evidence is clearest for children's willingness to play with other-gender toys. Young boys appear to avoid highly stereotyped other-gender behavior more than do girls (e.g., Bussey & Bandura, 1992).

Sex differences in interests and activities persist into middle childhood and adolescence. Several studies reveal clear gender-typing across a variety of domains: sports, household jobs, toys owned, and interests/hobbies (Antill, Russell, Goodnow, & Cotton, 1993; McHale, Kim, Whiteman, & Crouter, 2004; McHale, Shanahan, et al., 2004). Boys and girls differ in the themes that draw their interest: girls like to read adventures, ghost/horror, animal, school-related, relationship/romance stories, and poetry more than boys do. Boys like to read science fiction/fantasy, sports, and war/spy stories, comic books, and joke books more than girls do (Coles & Hall, 2002; C. Hall & Coles, 1999). Girls tend to develop stories with affectionate themes; boys use aggressive themes. Boys and girls also differ in the themes in drawings, with boys depicting mechanical and moving objects and girls depicting human figures,

flowers, and butterflies (Iijima, Arisaka, Minamoto, & Arai, 2001).

A few studies have found changes in gender-typed behavior in adolescence that support the gender intensification hypothesis, especially for girls. With age, girls spend more time in interpersonal activities, personal care, and household chores and less time in sports; for boys, participation in sports either remains stable or increases (Ruble & Martin, 1998). Of particular current interest is how such interests may be affected by increased opportunities for girls' sports participation afforded by Title IX, the Educational Amendments Act (e.g., McHale, Kim, et al., 2004), especially given links between athletic activity and adjustment (Pedersen & Seidman, 2004). A recent longitudinal diary study examining middle elementary and adolescent girls' relative involvement in female- versus male-typical activities (most of the latter involving sports) found that behaviors were least stereotypical at age 13 but that involvement in male-typical activities declined in middle adolescence (8th to 10th grades; McHale, Shanahan, et al., 2004).

Finally, a few studies have looked specifically at gender-atypical behavior early in development, in part because such behaviors are related to later homosexuality (J. M. Bailey & Zucker, 1995; D. J. Bem, 1996; Green, 1987) and are associated with difficulties in psychological adjustment (Egan & Perry, 2001; Yunger, Carver, & Perry, 2004). Some aspects of gender-atypical behavior are uncommon in early and middle childhood, such as playing more with other-sex children than same-sex children (e.g., Maccoby, 1998; Martin & Fabes, 2001). But, other forms of gender-atypical behavior are not uncommon, particularly among girls: for example, studies of toy play typically find that girls will play with both boy-typical and girl-typical toys, with both boys and girls becoming more interested in boy-typical activities (especially sports) and less interested in girl-typical activities across middle childhood (Sandberg & Meyer-Bahlburg, 1994).

### **Personal-Social Attributes (3)**

Section 3 addresses questions similar to Section 2, but with respect to personal-social attributes (e.g., traits, abilities, and behaviors) rather than activities and interests. For instance, do the traits that children ascribe to themselves show parallel trends to gender-typed beliefs

about the traits that girls and boys should have or do they occur independently of belief systems? The main behaviors being examined are those typically considered in the very large literature on sex differences (e.g., aggression, nurturance, ability at math or English), except that we focus on developmental changes in such differences.

### ***Concepts or Beliefs (3A)***

Many studies of the development of stereotypes about personal-social attributes have used a measure based on the Sex Stereotype Questionnaire, in which children are told stories about masculine and feminine traits and are asked to select whether the stories fit better with a male or female figure (Best et al., 1977). The original studies of U.S. participants showed that the knowledge of kindergartners was little better than chance, with a large increase in knowledge between kindergarten and third grade, and continuing steady increase in knowledge throughout elementary school, such that the knowledge level of high school students approached that of college students on whom the measure was standardized (J. E. Williams & Best, 1990). Recent research confirms that gender stereotype knowledge of personal-social attributes emerges at approximately 5 years of age and increases steadily throughout childhood (e.g., Powlishta, Sen, Serbin, Poulin-Dubois, & Eichstedt, 2001; Serbin et al., 1993; Signorella et al., 1993). This pattern occurs across cultures even if the level and actual content of the stereotypes differ (Gibbons, 2000; J. E. Williams & Best, 1990; Zammuner, 1987). Interestingly, both adults and children apply trait stereotypes more strongly to child than to adult targets (Powlishta, 2000). In addition, the extent of trait stereotyping and the nature of developmental trends vary across methods. For example, children made stronger distinctions between boys and girls on social (aggression and prosocial behavior) and academic (math and spelling competence) stereotypes when direct comparisons between males and females were made than when they were not (Heyman & Legare, 2004). Children younger than 5 years of age often show little evidence of trait stereotyping. Instead, preschool children tend to attribute positive characteristics to their own sex and negative characteristics to the other (Ruble & Martin, 1998). This bias may peak at age 5 (Urberg, 1982), though it continues at least into middle elementary school (Heyman & Legare, 2004).

Are any particular trait stereotypes learned earlier than 5 years of age? Such data may provide clues about

how young children structure their initial learning about gender categories. Multiple studies have reported that 2- to 4-year-old children distinguish between boys and girls on particular traits (e.g., cruel), emotions (e.g., fearful), or trait-related behaviors (e.g., hits; can't fix things; Ruble & Martin, 1998). Some recent evidence suggests that preschoolers may even have quite sophisticated knowledge about aggression, an attribute likely to be highly salient in preschool classrooms, with preschool children associating physical aggression with males and relational aggression with females (Giles & Heyman, 2005). Thus, preschoolers may be most aware of differentials along a power dimension, as they apply high power adjectives to boys (e.g., strong, fast, hit) and adjectives related to fear and helplessness to girls (e.g., can't fix bike, need help, cry a lot, fearful). Children also use a general evaluative dimension in which males are labeled negatively (e.g., aggressive, cruel) and females are labeled positively (e.g., affectionate, nice). Even in free descriptions, when they are not explicitly cued with particular choices, preschool and kindergarten girls (but not boys) frequently use negative, power-linked terms to describe boys (e.g., plays rough; mean); whereas kindergarten (but not preschool) boys and girls frequently use positive evaluative terms (e.g., nice/sweet/kind) to describe girls (C. F. Miller, Lurye, et al., 2006). As Serbin et al. (1993) suggested, young children may apply a general stereotype that girls are sugar and spice . . . and boys are snakes and snails. Interestingly, early stereotypes appear to highlight distinctions identified as two of the three most important dimensions of meaning (i.e., power and valence; Osgood, Suci, & Tannenbaum, 1957).

As with concrete activities and objects, flexibility in beliefs about gender-typed traits increases following a period of rigidity after they are learned (Trautner et al., 2005). Developmental trends for traits appear similar to those for activities and interests with a peak in rigidity as children enter school and a subsequent increase with age in flexibility (Signorella et al., 1993). Relatively few studies have extended beyond elementary school, but, for the most part, the pattern seems similar to that described earlier for activities: Flexibility increases through early adolescence (Ruble & Martin, 1998) and is often higher for girls (Antill et al., 1996). Research directly comparing younger and older adolescents suggests that trait flexibility may stabilize or decline during high school (e.g., Neff & Terry-Schmitt, 2002).

Moreover, one study showed this curvilinear pattern using a combination of cross-sectional and longitudinal analyses (Alfieri, Ruble, & Higgins, 1996), with flexibility increasing through the 1st year of junior high school and then declining.

Thus, consistent with the earlier conclusions concerning concrete stereotypes, stereotypes about traits show fluctuating flexibility throughout the adolescent years in response to two opposing influences—increasing cognitive flexibility and increasing pressures to conform to gender stereotypes in preparation for sexual roles and adult status (Eccles, 1987; Katz & Ksiansnak, 1994). In addition, variations across studies in the assessment of flexibility affect conclusions about these developmental changes.

### *Identity or Self-Perception (3B)*

In the 1970s and 1980s, researchers explored sex differences in gender role orientation using “masculine” and “feminine” characteristics, but later research showed these characteristics to be better conceptualized as instrumental and expressive traits. How early do children view themselves in terms of these personality traits and do these patterns change over time? Only tentative conclusions can be drawn because of methodological differences across studies. In studies with 3- to 4-year-olds, both sexes endorse socially desirable characteristics, and their perceptions of themselves are beginning to differentiate along gender-typed lines but not yet enough to show a significant difference. For 5-year-olds, the findings are mixed. By age 8 to 9 years, however, most but not all studies show that boys and girls rate themselves in terms of gender-typed patterns of traits (Ruble & Martin, 1998) and this continues into adolescence (Klingenspor, 2002; Washburn-Ormachea, Hillman, & Sawilowsky, 2004). Cross-sectional studies suggest that self-perceptions of instrumental and expressive traits become more sex-differentiated with age up through early adolescence, even though considerable overlap remains between the sexes (Ruble & Martin, 1998).

The stability of children's endorsements of gender-typed personality traits is of interest because some theorists expect that certain life events will influence their adoption. Testing the gender intensification hypothesis (J. P. Hill & Lynch, 1983), many longitudinal studies have focused on the preadolescent to adolescent time span. Only limited support for gender intensification has been found, mainly for increased sex differences in

masculinity/instrumentality. Other studies show a general pattern of stability over time, or that both masculinity/instrumentality and femininity/expressiveness increase with age (Ruble & Martin, 1998). In a recent longitudinal study designed to examine how instrumentality and expressivity in adolescence were influenced by children's earlier activities and experiences with same-sex and other-sex peers and family members, the findings showed support for gender socialization occurring through children's activities and social partners for instrumental traits but not for expressive traits (McHale, Kim, et al., 2004).

The study of gendered personality traits has changed direction in recent years. Rather than emphasizing sex differences per se, many of the recent studies examine a wide array of correlates of instrumental and expressive characteristics. For example, 6- to 11-year-old children with instrumental traits reported higher levels of motivation when competing with other children (Conti, Collins, & Picariello, 2001). In adolescents, there are positive associations between expressivity and positive outcomes such as perspective taking, sympathy, and having an ethic of caring (Carlo, Eisenberg, Koller, DaSilva, & Frohlich, 1996; Eisenberg, Zhou, & Koller, 2001; Karniol, Grosz, & Schorr, 2003). Others have examined links between instrumental and expressive characteristics and social judgments (Lobel, Bar-David, Gruber, Lau, & Bar-Tal, 2000; Lobel et al., 1999). Understanding the association between depression and other internalizing disorders and gender role orientation has become a dominant theme in the past 10 years with expressivity being positively linked (Broderick & Korteland, 2002) and instrumentality negatively linked (Marcotte, Alain, & Gosselin, 1999). Importantly, in adolescents, instrumentality partially mediated the relationship between sex and internalizing symptoms, and expressivity fully mediated the relation between sex and externalizing symptoms (M. L. Hoffman, Powlisha, & White, 2004). Thus, gendered personality characteristics appear to account for what are commonly thought to be differences between the sexes in adjustment outcomes.

Personality researchers have investigated how the sexes compare on the major dimensions of personality, specifically, the Big Five. Over the ages of 12 to 18, girls scored higher than boys on Neuroticism, Extraversion, Openness, and Agreeableness (McCrae et al., 2002) and did not differ in Conscientiousness. Girls increased in Neuroticism and both sexes increased in

Openness as they grew older. The increase in Neuroticism may reflect hormonal changes and/or transitions in schooling and is consistent with increases in depression for girls during adolescence (McCrae et al., 2002).

Finally, in terms of gender-linked dimensions of self-concept, when sex differences are found, they are small and follow gender-typed patterns (e.g., Eccles et al., 1989; Wilgenbusch & Merrell, 1999). Boys' self-concepts tend to be higher in math, sports, and physical appearance and girls' self-concepts tend to be higher in music, and verbal/reading ability, and sometimes social competence (Hay, Ashman, & Van Kraayenoord, 1998; Klomsten, Skaalvik, & Espnes, 2004; Marsh, Craven, & Debus, 1998; Watt, 2004). Sex differences develop early and remain relatively consistent over time with a few exceptions (Cole et al., 2001; Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002; Wigfield et al., 1997).

Do young girls and boys share the same perceptions of their beliefs about school performance? In a cross-cultural study of over 3,000 children in second to sixth grade, children's achievement in specific domains closely matched their competence-related beliefs, suggesting that they have realistic self-assessments. However, in contexts where girls achieved better than boys, their self-assessments were equal to boys, not higher. Girls did not credit themselves with being talented even when they performed better than boys (Stetsenko, Little, Gordeeva, Grasshof, & Oettingen, 2000).

### *Preferences (3C)*

Do children prefer certain kinds of gender-linked personality traits for themselves? In our consideration of the findings in the previous section (B3), we discussed a closely related issue: how children perceive their current or actual selves in terms of such traits—that is, their identity. Few researchers have examined trait preferences, even though preferred characteristics may influence children's future behavior. In one relevant study, Swedish children aged 11 to 18 years rated characteristics of their ideal self (Intons-Peterson, 1988b). Both sexes endorsed several instrumental qualities (e.g., never gives up) and several expressive qualities (e.g., kind). Only 19 of 59 characteristics showed sex differences, but these were not the top-rated characteristics (except "gentle," which was rated more highly by females). With age, the importance of expressive characteristics increased and instrumental traits decreased. It

is curious that there has been so little research on this issue, given recent work on the dimensions of gender identity (Egan & Perry, 2001). Future research should examine the potential significance of variations in children's perceptions of what "kind" of boy or girl they would like to be.

### **Behavioral Enactment (3D)**

As in past *Handbooks* (Huston, 1983; Ruble & Martin, 1998), we do not review individual studies in the voluminous literature on sex differences in traits and abilities. Instead, we focus on meta-analyses, which provide quantitative summaries, including effect sizes (here  $d$ , the difference in means between the sexes expressed in standard deviation units), and analyses showing whether effects change across characteristics of the population (e.g., age) or study (e.g., subjectivity of measurement, year of publication). Guidelines for effect size (Cohen, 1988) suggest that  $d$  of .2 is small (85% overlap in distributions), .5 is moderate (67% overlap) and probably noticeable, and .8 is large (53% overlap) and very noticeable (by convention,  $d$  is calculated as the male mean minus the female mean, so positive values reflect males higher than females and negative values females higher than males). Much has been written about benefits and limitations of meta-analysis, but we note two points: First, small mean differences can be associated with large differences at the tails of the distributions; second, meta-analyses assume that the distribution of scores in the two sexes is the same, with one shifted away from the other. We focus on developmental trends in sex differences and whether differences are larger in some domains than others. Our review relies heavily on Blakemore's recent summary of sex differences in physical skills, cognition, personality, and social behavior, which includes empirical studies and meta-analyses, covering studies through 2004 (Blakemore, Berenbaum, & Liben, 2006).

**Physical and Motor Skills.** Meta-analyses of activity level (e.g., D. W. Campbell & Eaton, 1999) show an increasing sex difference with age: infants  $d = .20$ , preschool  $d = .44$ , elementary school  $d = .64$ , with the differences largest in familiar, nonthreatening settings and when peers are present. Sex differences in physical and motor skills generally relate to girls' earlier neurological development and better fine motor skills and boys' greater muscle strength. Boys are slightly stronger

than girls in early childhood, becoming more so through childhood and after puberty—for example, the sex difference in grip strength is .25 to .50 in early childhood, .50 to 1.0 in middle childhood, and 1.0 to 2.0 in adolescence (Sartorio, Lafrotuna, Pogliaghi, & Trecate, 2002; J. R. Thomas & French, 1985). There are few sex differences in milestones of reaching, sitting, crawling, and walking, but differences in motor skills begin to appear in the 2nd year. Abilities that depend on neurological development, such as eye-hand coordination and toilet training, develop earlier in girls than in boys (Blakemore et al., 2006). Data from a large sample of children aged 5 to 18 show that girls develop sooner than boys on fine motor skills and upper body tasks, whereas boys do better on tasks requiring rapid movement (Largo et al., 2001a, 2001b). Meta-analysis (J. R. Thomas & French, 1985) and recent studies (Blakemore et al., 2006) show males to be better than females on many motor tasks, with the largest differences in throwing velocity and distance, whereas females excel on fine eye-motor and flexibility tasks. Sex differences in many (but not all) physical and motor abilities increase with age, and much of boys' increasing superiority appears to reflect their greater practice of these skills, in part from involvement in sports (Blakemore et al., 2006), although biological factors likely also play a role (Kimura, 1999).

**Cognitive Skills.** There are no sex differences in overall intellectual ability, but the sexes differ in the *pattern* of cognitive abilities (for reviews see Halpern, 2000; Kimura, 1999). The biggest cognitive sex difference is in spatial ability. There are several ways to parse the domain (Halpern, 2000; Linn & Petersen, 1985), but males outperform females in most aspects of spatial ability, with the size of the difference varying across abilities. More is known about differences in adults than in children because many tests are too difficult for children and tests that are used with children measure multiple abilities. The largest sex difference is in mental rotation, especially rotation of objects in three dimensions:  $d = .56$  to 1.0 in adolescents and adults, and about .40 in children (Blakemore et al., 2006; Halpern, 2000). There are also differences in spatial perception, which requires recognition of the vertical or horizontal ( $d = .4$ ), targeting (i.e., hitting a target with a ball;  $d = 1.0$ ; Kimura, 1999), and abilities related to navigating in the real world (Blakemore et al., 2006; Halpern, 2000). There is a huge sex disparity in National Geography Bee

winners (despite equal participation from boys and girls); the sex ratio increases at each level of competition, so that in most years, all 10 finalists are boys (Liben, 1995). There do not appear to be sex differences in visualization (e.g., hidden figures), but this may be due to visualization tests measuring multiple abilities. There is one spatial domain in which females outperform males: memory for spatial location ( $d = -1.0$ ; Blakemore et al., 2006; Kimura, 1999).

The sexes differ in mathematic abilities, with the differences again varying by type of ability and age. Meta-analyses show a greater male advantage in selected samples (Hyde, Fennema, & Lamon, 1990) and on certain standardized tests (e.g., SAT,  $d = .4$ ; Hyde & Frost, 1993). There is no sex difference in mathematical concepts; females outperform males in computation, especially before puberty ( $d = -.14$ ); and males outperform females on problem-solving tasks, especially at older ages ( $d = .29$  by high school; Hyde et al., 1990). Girls receive higher grades in mathematics than boys, as they do in all classes. Girls now take almost the same number of math classes as boys do, but boys still perform better on standardized tests after course-taking has been considered. There are a variety of factors that may contribute to the sex difference in math, including biological factors, spatial ability, strategies used to solve math problems, attitudes toward math, and stereotype threat (Blakemore et al., 2006).

Females outperform males on verbal tasks, again with the difference varying across ability and age. Girls have a small advantage in language learning in early childhood, but boys catch up by age 6 (e.g., Bornstein, Hahn, & Haynes, 2004; Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991). Boys are more likely than girls to have disorders of spoken and written language (Halpern, 2000; Hyde & McKinley, 1997). Meta-analyses (Hyde & Linn, 1988) show that males are better than females in analogies ( $d = .22$ ), but females have a small advantage over males in other verbal skills:  $d = -.11$  for overall verbal skills,  $d = -.20$  for general verbal ability tests,  $d = -.02$  for vocabulary,  $d = -.03$  for reading comprehension,  $d = -.09$  for essay writing, and  $d = -.33$  for speech production. A summary of several large studies of adolescents showed larger sex differences than reported in meta-analyses in reading comprehension (0 to  $-.3$ ) and writing ( $-.5$  to  $-.6$ ; Hedges & Nowell, 1995); the latter is consistent with national data on writing proficiency (Halpern, 2000). Females also do better than males on verbal

abilities not included in meta-analyses, such as phonological processing,  $d = -.5$  to  $-1.0$  (Majeres, 1997, 1999), verbal fluency,  $d = -.5$  to  $-1.0$  (Halpern, 2000), and verbal learning and memory,  $d = -.5$  (Halpern, 2000; Hedges & Nowell, 1995; Kimura, 1999; Kramer, Delis, & Daniel, 1988). Females' superior learning and recall of lists of common objects is largely due to their use of efficient clustering strategies ( $d = -.5$ ). Females also outperform males on perceptual speed, with small to moderate differences ( $d = -.2$  to  $-.6$ ).

There are also sex differences in variability in cognitive abilities, particularly in spatial and mathematical abilities (Hedges & Nowell, 1995). For example, more than twice as many males as females have high spatial ability, and the same sex ratio is found on SAT Math scores above the 95th percentile.

Some have argued that cognitive sex differences have declined across time (e.g., Feingold, 1988; but compare to Hedges & Nowell, 1995), but methodological issues make it difficult to know if these changes are real. Such trends might reflect factors correlated with publication year, such as sampling (e.g., college enrollment shifted from overwhelming male to predominant female, changing sex differences in selectivity), publishing trends (e.g., greater likelihood that nonsignificant findings are published now than previously), and use of tests that never showed large sex differences (Halpern, 2000).

**Subjective Well-Being and Self-Evaluation.** A variety of indicators show that females experience lower levels of well-being than males. Females are more likely than males to be clinically depressed and to exhibit more depressive symptoms, beginning in adolescence, with likely contributors being hormonal changes at puberty (e.g., Angold, Costello, & Worthman, 1998), and girls' greater risk factors before puberty combined with greater challenges in adolescence (Nolen-Hoeksema & Girgus, 1994). Meta-analyses of global self-esteem reveal small but consistent effects (.2 to .3) favoring males (Kling, Hyde, Showers, & Buswell, 1999; Major, Barr, Zubek, & Babey, 1999; Wilgenbusch & Merrell, 1999), with differences appearing around age 10 and perhaps increasing in late adolescence.

The prevalence of some mental disorders varies by sex. For example, in childhood and adolescence, there is male preponderance of speech and language disorders, Autism, Attention-Deficit/Hyperactivity Disorder (ADHD), Oppositional and Conduct Disorder, and female preponderance of Separation Anxiety Disorder; in adulthood, males

predominate in substance abuse, females in Dysthymic Disorder, Generalized Anxiety Disorder, and certain phobias (for specific data, see Hartung & Widiger, 1998). Reported sex ratios may be biased by sampling issues and problems with *DSM* criteria (Hartung & Widiger, 1998).

**Personality Traits and Social Behavior.** The question of whether males and females display the attributes that are stereotypically associated with them, such as aggression and dependency, has been the subject of meta-analyses. Studies of aggression have yielded some of the most consistent findings for any domain, at least for children. Boys engage in more aggressive behaviors than girls ( $d = .5$ ; Knight, Fabes, & Higgins, 1996; Maccoby & Jacklin, 1974). Differences emerge early in life and are found cross-culturally, suggesting that biological factors may be involved (Maccoby & Jacklin, 1974). There is controversy over whether the sex difference in aggression decreases or increases with age (Knight et al., 1996; Ruble & Martin, 1998). The discrepancy reflects a larger difference with observational measures, more often used with children than with adolescents and adults (Knight et al., 1996). Sex differences in aggression vary by context; for example, differences are larger when aggression is spontaneous rather than provoked or required in experimental situations (Bettencourt & Kernahan, 1997; Bettencourt & Miller, 1996). There are large sex differences in real-world aggression: Men commit more violent crimes than women, and the more serious the crime, the more the sex difference is apparent (Rutter, Giller, & Hagell, 1998). Males take more risks than females do throughout childhood and into early adulthood ( $d = .2$ ), contributing to their higher rates of injury (Byrnes, Miller, & Schafer, 1999). Girls engage in social or relational aggression (i.e., behaviors intended to damage another's friendships and social status) more than they engage in physical aggression, but it is not clear whether they engage in it more than boys do (e.g., Underwood, Scott, Galperin, Bjornstad, & Sexton, 2004).

Despite stereotypes that females are more helpful and oriented to the needs of others, there are not strong and consistent sex differences in children's prosocial behavior. Sex differences tend to be small, and the likelihood of finding them varies by study characteristics (Eisenberg & Fabes, 1998; Eisenberg, Martin, & Fabes, 1996). Meta-analysis of helping behavior shows girls to help others more than boys (Eisenberg & Fabes, 1998), but the reverse is true for adults, partly

because studies with adults often involve helping that is heroic and instrumental—more consistent with the male role. Girls interact more with babies than do boys, with the magnitude of the difference depending on the context (Blakemore et al., 2006). Much attention has focused on sex differences in level and orientation of moral reasoning (Gilligan, 1982). Meta-analyses suggest no sex differences in level of morality (Walker, 1984, 1986). In four data sets, males had a slightly higher stage of morality at some ages, and females did at other ages, but all effects were very small (Dawson, 2002). There are small differences in the type of moral arguments used: Females are more likely than males to use a morality of caring ( $d = -.28$ ) and less likely to use a morality of justice ( $d = .19$ ), with the largest effects seen during adolescence and young adulthood (Jaffee & Hyde, 2000).

Stereotypes suggest that females are more passive and dependent, and more easily influenced than males, but this is not empirically verified. Differences are particularly small for observational and experimental studies of children interacting with parents and peers, but girls are rated by others as dependent, possibly because of stereotypes (Maccoby & Jacklin, 1974). Meta-analyses show women to be more easily influenced than men ( $d > -.3$ ), with effects of context (Ruble & Martin, 1998). Females are more likely to be helped than males ( $d = -.5$ ), although this may reflect perceptions about females' dependence and not that they need help (Ruble & Martin, 1998). Nevertheless, females may be more likely to seek help of certain kinds and more willing to accept help (see Eisenberg et al., 1996, for review).

Are females more socially oriented and sensitive as stereotypes suggest? Meta-analyses in some areas suggest that they are. Girls and boys do not differ in ability to understand what others are thinking or feeling, but women appear to be better than men at decoding others' emotions and have a greater tendency to take the perspective of another (Eisenberg et al., 1996). In addition, females at all ages are more accurate at decoding emotions from visual and auditory stimuli,  $d = -.25$  (e.g., J. A. Hall, Carter, & Horgan, 2000). Girls are better than boys at decoding the facial emotions of others; effects are small ( $d = -.13$  to  $-.18$ ), except in infancy ( $d = -.70$  to  $-.92$ ; McClure, 2000). Females also appear to be more socially expressive and responsive, with moderate to large effects, for example, for social gazing, expression of emotion, and general facial expressiveness (Ruble & Martin, 1998).

**Emotionality.** Females are believed to be more emotional, which generally means more anxious, fearful, more easily upset, and more empathic and emotionally expressive, whereas males are believed to express more anger and to be more likely to hide or deny emotional reactions. As described earlier, there are sex differences in anxiety and depression.

Adult men and women differ in emotional expressiveness and in expression accuracy. Females show more expression than males in faces ( $d = -.45$ ) and gestures ( $d = -.27$ ; J. A. Hall et al., 2000). They are also more accurate in conveying emotions, spontaneously and posed ( $d = -.25$ ), in facial cues but not in voice (J. A. Hall et al., 2000). The sexes differ in patterns of emotional responding, with women generally reporting more sadness, fear, shame, and guilt, and men reporting more anger. Cross-cultural data suggest the universality of these differences (Fischer, Rodriguez Mosquera, van Vianen, & Manstead, 2004). With respect to the development of emotion, Eisenberg et al. (1996) provide the following account on the basis of their review. During infancy and toddler years, few consistent sex differences in the expression of emotion are found, although males may exhibit more irritability and anger, and girls more fearfulness. During the early elementary school years, boys start to hide negative emotions, such as sadness, and girls express less anger and emotions such as disappointment that might hurt others' feelings. By adolescence, girls report more sadness, shame, and guilt, and say they experience emotions more intensely, whereas boys are more likely to deny experiencing these emotions.

Empathy is slightly more likely to be displayed by females than males, with differences dependent on methodology and context (Eisenberg et al., 1996). For example, self-report measures show large differences favoring females, but physiological or unobtrusive observations do not (Eisenberg & Fabes, 1998). Meta-analysis supports the idea that individuals' self-perceptions are biased by their stereotypes (Ickes, Gesn, & Graham, 2000).

**Summary.** The sex differences reported by Macoby and Jacklin (1974) in their comprehensive review have been well documented, and work since has expanded the categorization of sex differences. Differences are found for aspects of spatial, mathematical, and verbal skills, with effects largest for spatial abilities and on standardized tests, but questions remain about the age at which these differences first appear. Males are more physically aggressive than females and

more likely to take risks. Females are better at expressing and decoding emotions than are males. There are also strong and consistent sex differences in activity level and physical and motor skills. Overall, sex-difference patterns vary considerably by content area, developmental level, and context. In general, personal-social behaviors show negligible to moderate differences but no large differences, whereas interests and abilities show differences across the full range of effect sizes (for details of effect sizes, see Blakemore et al., 2006; Halpern, 2000).

#### **Social Relationships (4)**

Children's gendered social relationships include peer relationships and friendships and sexual relationships. To what extent do children's concepts, self-perceptions, preferences, and enactment show parallels in this domain? When do children develop knowledge about the desirability of relationships with same-sex playmates, and what is the developmental course of children's preferences and behaviors regarding same- and other-sex relationships?

#### **Concepts or Beliefs (4A)**

Children have different conceptions of relationships with girls and boys and these views change developmentally. Young children understand that certain relationships are more acceptable than others (i.e., same-sex play and friendships are more acceptable than other-sex play and friendships). For instance, children showed strong stereotypes about others' relationships (i.e., they believe boys prefer to play with other boys more than with girls) that increased from 4 to 6 years, and these beliefs correlated with same-sex play partner preferences (Martin, Fabes, Evans, & Wyman, 1999).

Knowledge about sex differences in relationships increases with age. Young children show little evidence of knowing how boys' and girls' play differs (e.g., that girls play inside more than boys; Martin et al., 1999). Preschoolers recognized that boys prefer to play in groups but not that they have more shared friendships than girls. By grade 2, children believe that boys have more shared friendships, and by grade 6, they recognize that friends have access to more information about each other than nonfriends (Markovits, Benenson, & Dolenzky, 2001). Older children (9 to 11 years) believe that, for competitive but not for cooperative games (i.e., those games that boys may be more likely to play), playing in

larger groups is more enjoyable than playing in dyads (Benenson, Gordon, & Roy, 2000).

Children's conceptions of friendship differ by sex (Ladd, 2005). By middle to late childhood, girls regard friendships as higher in positive qualities (i.e., intimacy and closeness) than do boys, but the sexes have similar levels of conflict in these relationships. In conflict situations, girls place greater priority on relationship goals (such as wanting to maintain a friendship) and boys are more likely to try to seek control over friends (Rose & Asher, 1999). In early and middle adolescence, girls' friendships focus on issues of intimacy, love, and communion, whereas boys' friendships tend to focus on agency, power, and excitement (Rose, 2002). Because of the greater intimacy of girls' relationships, they are more fragile and prone to disruption through divulging of confidential information during conflict (Benenson & Christakos, 2003).

Insights about gendered relationships can be gleaned from research on how children evaluate exclusion. About 30% to 50% of preschool children used gender stereotypes to condone exclusion during play, especially in situations involving activities rather than roles. Although children have stereotypes about play with peers that are used in certain situations, principles of equity and fairness may override their use (Theimer, Killen, & Stangor, 2001).

#### ***Identity or Self-Perception (4B)***

Although many scholars argue that it is best to study gender as it is constructed within a social context, little attention has been paid to how children perceive themselves in terms of their social relationships. To what degree do children incorporate stereotypic beliefs into their self-concepts about their relationships, and how do their gender identities relate to relationship choices? There is little developmental research on such questions. Some evidence has been obtained from gender-atypical children. For instance, tomboys report liking boys as playmates more than other girls do (J. M. Bailey, Bechtold, & Berenbaum, 2002), and children with GIDC report preferences for other-sex playmates (Zucker & Bradley, 1995). However, identity is not consistently linked to relationship preferences: Girls with early androgen exposure but with female gender identity show some tendency to prefer boys as playmates (Berenbaum & Snyder, 1995).

The association between identity and relationships has also been studied in the context of sexuality. Sexual identity is often but not always related to sexual behav-

ior. Sexual identity is a person's identity in relation to preferred sexual partners and it may not correspond with sexual behavior. For instance, a person may engage in sex with same-sex others without identifying as gay or lesbian. Sexual identity is presumed to be later developing and more dependent on social, historical, and cultural factors than is sexual orientation (Savin-Williams & Diamond, 2000). Women are less likely to report congruence between sexual behavior and identities (Dempsey, Hillier, & Harrison, 2001; L. M. Diamond, 2000) and are more likely to change their sexual identity (L. M. Diamond, 1998; Savin-Williams & Diamond, 2001), suggesting that sexual identity is more fluid for women than men (Baumeister, 2000; L. M. Diamond, 2003b).

#### ***Preferences (4C)***

Children's self-reported preferences for same-sex peers have been widely documented (behavioral choices are described in 4D). Preschool, kindergarten, and middle school children consistently like same-sex (known or unknown) peers and prefer them as friends more than other-sex peers, and this tendency increases with age until adolescence when other-sex interests become apparent and strong same-sex preferences decreases (Lobel et al., 2000; Powlishta, Serbin, Doyle, & White, 1994; Serbin et al., 1993; Sippola, Bukowski, & Noll, 1997). Young children maintain same-sex preferences even when unknown children have nontraditional interests (see Ruble & Martin, 1998, for review), although the extent of gender-nonnormative behavior may moderate these preferences, especially for boys (Zucker, Wilson-Smith, Kurita, & Stern, 1995; also see Bussey & Bandura, 1992). In adolescence, boys with cross-sex interests are not liked but girls' interests do not appear to matter as much to ratings of liking (Lobel et al., 1999).

#### ***Behavioral Enactment (4D)***

Young girls and boys differ in how they act in their social relationships but both sexes show strong same-sex preferences in the types of relationships they choose. As children grow older, the sex-differentiated nature of their relationships changes to reflect interest in sexual relationships.

**Play Qualities of Girls and Boys.** Boys and girls differ in their play qualities. Interactions among boys are marked by rough-and-tumble play, attempts to attain dominance, and constrictive interaction styles, whereas interactions among girls are more often cooperative and

enabling of others (Ruble & Martin, 1998). Even by preschool, a number of differences can be identified in the play styles of boys and girls. Boys often play further away from adults than do girls (Benenson, Morash, & Petrakos, 1998; A. Campbell, Shirley, & Candy, 2004), so their play is less supervised and may be more peer-than adult-oriented (Fabes, Martin, Hanish, 2003; Martin & Fabes, 2001). The differences between girls' and boys' play tends to be exaggerated in groups versus dyads (Fabes et al., 2003). Boys show higher activity level, more exercise play, and more rough-and-tumble play (Di Pietro, 1981; Eaton & Enns, 1986; Fabes et al., 2003; Martin & Fabes, 2001; Pellegrini, 1987; Pellegrini & Smith, 1998). Rough-and-tumble play may exacerbate sex segregation because boys initiate this type of play and girls withdraw from it (Pellegrini & Smith, 1998).

Play qualities and games continue to show sex differences as children age. In middle childhood, boys are more likely than girls to be involved in ball games and fantasy play and are more physically aggressive. Girls are more likely to be involved in conversations, sedentary play, skipping, verbal games, and positive affect during play (Blatchford, Baines, & Pellegrini, 2003). Girls tend to self-disclose and provide greater emotional support, spend more time talking to, and report feeling more intimate with their friends than do boys (Buhrmester, 1996; Lansford & Parker, 1999). Girls engage in co-rumination, extensively discussing problems, and focusing on negative feelings (Rose, 2002).

Both sexes tend to interact in small groups of two or three members, but from about the age of 5, boys are more likely than girls to associate in larger groups (Fabes, Martin, & Hanish, 2003; Maccoby, 2002). Boys are involved in larger organized group games and occupy more space on playgrounds than do girls. This difference appears even in young children who are not yet playing team sports. It appears that dyadic play is not a function of the kinds of activities or materials involved in play. For example, in one study boys and girls showed different patterns of interaction when given the same materials to use however they wanted: Boys organized themselves into larger groups and engaged in coordinated activities, whereas girls formed dyads with more prolonged interactions. These patterns were more pronounced at age 6 than at age 4 (Benenson, Apostoleris, & Parnass, 1997). Group size influences how children play: Larger groups promote competition and conflict, especially in boys, whereas dyadic interaction promotes consideration of others' interests, less competition, and more emotional support (Benenson et al., 2002; Benen-

son, Nicholson, Waite, Roy, & Simpson, 2001; Roy & Benenson, 2002). Boylike behavior may result not from the direct influence of individual boys' personalities or temperaments but from boys' tendencies to respond in particular ways in boy groups (Maccoby, 2002). In contrast, girls' behavior appears to be more similar across different play contexts (Benenson et al., 2002; Trautner, 1995). How children play in groups also depends on the play partner. Boys engage in more active play with other boys than with girls. The reverse pattern is found for girls: They are more active with boys. Both sexes adjust their behavior somewhat to fit their play partners' styles, but other-sex group encounters are relatively rare, so likely have little overall impact on children (Fabes, Martin, & Hanish, 2003).

**Development of Sex Segregation.** One of the most pervasive sex differences involves whom children choose as play partners (Maccoby, 1998). Children and adolescents consistently report spending more time with same-sex peers and siblings (McHale, Kim, et al., 2004). Whereas many sex differences are quite small, sex accounts for a very large proportion of the variance (70% to 85%) in children's play partners (Maccoby, 1998; Martin & Fabes, 2001). Sex segregation appears to be universal, occurring in many higher species of nonhuman primates (Wallen, 1996) and in Western and non-Western societies, although the extent depends on the number of children available, their ages (e.g., Whiting & Edwards, 1988), and the setting (highest when children have more playmate choices and in less structured settings; Maccoby, 1998). Sex segregation is evident early in the school term (Martin, Fabes, Hanish, & Hollenstein, in press) and is influenced by activity involvement: Boys were more likely to segregate when involved in a competitive game than during a less competitive game (Boyatzis, Mallis, & Leon, 1999). Whether there are individual differences in the stability of sex segregation has received attention because of its importance in identifying causes of segregation. Although stability has been reported to be low or modest (e.g., M. L. Hoffman & Powlishta, 2001; Maccoby & Jacklin, 1987), it is high when larger samples and extensive observations are used (Martin & Fabes, 2001).

Sex segregation emerges at an early age: for girls, by 27 months; for boys, by 36 months (La Freniere, Strayer, & Gauthier, 1984). Other studies confirm this pattern of emergence (Ruble & Martin, 1998). Sex segregation is evident in social networks and in friendship choices. By preschool, children spend little time with other-sex peers:

Only about 10% of children's interactions occur solely with a child of the other sex and about 25% involve mixed-sex groups (Fabes, Martin, & Hanish, 2003). In very young children, other-sex friends are common, but other-sex friendships decline from 1 to 6 years of age (Howes, 1988). In middle childhood, sex segregation becomes even more pronounced (Maccoby, 1998). By middle childhood, only about 15% of children have other-sex friends (Kovacs, Parker, & Hoffman, 1996). Throughout childhood, boys and girls prefer same-sex friends and have more positive interactions with them as compared to other-sex friends (Vaughn, 2001). Nonetheless, some young children develop friendships with other-sex children and these often go underground during school hours. Prior to adolescence, both girls and boys expect greater enjoyment in interaction with same-sex peers, but these expectations vary depending on setting (Strough & Covatto, 2002).

During adolescence, peer networks change. In early adolescence, children congregate in small cliques of same-sex peers and have same-sex friends (Bukowski, Sippola, & Hoza, 1999) but, by middle adolescence, although same-sex preferences are still obvious, heterosexual dating couples also become apparent and various types of other-sex relationships emerge (Sippola, 1999). In middle adolescence, about 40% to 50% of young people have romantic relationships; by later adolescence, most have experienced a romantic relationship (e.g., Connolly, Craig, Goldberg, & Pepler, 1999). Even with the increase in other-sex relationships, girls (but not boys) report feeling more comfortable with same-sex peers (Lundy, Field, & McBride, 1998). Longitudinal data across grades 9 to 11 show that children's same-sex networks remained about the same while their other-sex networks increased in size (Richards, Crowe, Larson, & Swarr, 1998) and other-sex networks facilitated romantic relationships by helping adolescents to meet potential partners (Connolly, Furman, & Konarski, 2000).

Sibling interactions influence adolescent friendships, especially for girls. For example, girls who had a brother were more likely to report using control strategies with friends than girls who had a sister (Updegraff, McHale, & Crouter, 2000). Sibling interactions appear to provide children with opportunities seldom available in school for learning about other-sex interactions (McHale, Crouter, & Tucker, 1999).

Few children report preferences for other-sex relationships. Girls with early androgen exposure, tomboys, and children with GIDC are somewhat more likely than typical girls to prefer other-sex playmates (J. M. Bailey

et al., 2002; Berenbaum & Snyder, 1995; Zucker & Bradley, 1995). Sexual minority youth (e.g., homosexual) report predominantly same-sex peer networks, but friendships differ by sex, with males reporting more other-sex friends than same-sex friends and females reporting more same-sex friends than other-sex friends (L. M. Diamond & Dube, 2002).

**Causes of Sex Segregation.** Why do children show sex-segregated interactions? Many potential explanations have been proposed to account for sex segregation, involving both distal and proximal mechanisms. For instance, evolutionary theorists propose that selection factors increase the likelihood that the sexes will be drawn together in same-sex dyads or groups, which are hypothesized to prepare children for adult roles (Geary, 1999; Geary & Bjorklund, 2000).

A proximal explanation involves behavioral similarity, i.e., individuals are drawn to others who behave similarly to themselves. Many dimensions of behavioral similarity have been proposed including physiological and temperament differences between the sexes (e.g., Fabes, 1994; Serbin, Moller, Gulko, Powlishta, & Colburne, 1994). For example, children who are active and like rough-and-tumble play may be more inclined to play with boys than with girls (Fabes, Shepard, Guthrie, & Martin, 1997; M. L. Hoffman & Powlishta, 2001; Martin, Fabes, et al., 2006; Pellegrini & Smith, 1998). Computer simulations of preschool children's play show that real play patterns can be mimicked by using simple rules based on compatibility along a few behavioral and affective dimensions (Griffin, Hanish, Martin, & Fabes, 2003; Schmidt, Griffin, Hanish, Martin, & Fabes, 2004).

Children may also sex segregate because of their gender theories or cognitions (i.e., they believe they will be similar to same-sex others; Martin, 1994; Martin & Dinella, 2002; Martin et al., 2002). Evidence supports this idea: children's beliefs that they are similar to their own sex and different from the other sex have been found to predict children's observed sex segregation (Martin et al., 2006). Behavioral similarity and gender-based theories are not mutually exclusive and may both act to influence sex segregation (Barbu, Le-Maner-Idrissi, & Jouanjean, 2000; Martin et al., 2006). A recent proposal about sex segregation based on dynamic systems theory integrates these earlier explanations (Martin et al., in press): Children's interactions are considered to be a dynamic system in which children's partner choices are influenced by many small and large forces working in concert—including behavioral,

cognitive, and social forces—and each of these contribute to the formation and maintenance of peer relationships and groups.

A number of fascinating questions remain about sex segregation. What characterizes children who consistently play with other-sex peers and what enables them to cross boundaries (Sroufe, Bennett, Englund, Urban, & Shulman, 1993; Thorne, 1993)? What are the circumstances that promote and inhibit socialization by same- and other-sex peers? By what processes do peers influence one another, and which children are most vulnerable to peer influence (see Socialization Approaches section)?

### **Development of Sexual Behavior and Orientation.**

In 4B, we discussed how sexual identity can be discrepant from sexual behavior. In this section, we focus on sexual attraction and behavior, and briefly on theories that consider how all domains of sexuality develop. Interestingly, with few exceptions (e.g., Hyde & Jaffee, 2000), most of the research and theorizing on the development of sexual orientation concerns the development of orientation in sexual minorities, even though a complete picture of sexual development requires understanding the experience, meaning, and development of same-sex and other-sex sexuality in all individuals (L. M. Diamond, 2003a).

On average, sexual attraction begins at age 10, but varies by sex, culture, and sexual orientation (Herdt & McClintock, 2000). Much recent research has focused on same-sex sexual orientation and posits stages marked by awareness of same-sex attractions in late childhood/early adolescence, and then a period of testing and exploration, and finally the adoption of a sexual minority label, disclosing sexual identity to others, and involvement in same-sex romantic relationships. This developmental course is more typical for males than for females. Sexual minority men experience earlier same-sex sexual attractions and behavior than do sexual minority women (L. M. Diamond, 1998; Savin-Williams & Diamond, 2001). For males, there is more congruence between the sex of the person of sexual and romantic attractions (i.e., they are attracted to and fall in love with people of the same sex); for females, the link between desire and love may be looser (L. M. Diamond, 2000, 2004). Thus, different models are needed to describe the development of sexual orientation in men versus women (Savin-Williams & Diamond, 2000).

Interesting precursors to sexual orientation have been identified. Some evidence of early gender atypicality is

apparent in individuals who grow up to identify themselves as homosexual or bisexual. Boys (more so than girls) with gender identity issues are more likely to have homosexual or bisexual orientations than are other children (Zucker & Bradley, 1995). A meta-analytic review suggests that homosexual individuals are more likely than heterosexual individuals to report retrospectively cross-gender interests in childhood (effect size for men = 1.3; women = 1.0; J. M. Bailey & Zucker, 1995).

The origins of sexual orientation have been hotly debated. The core of the debate concerns whether sexual orientation is innate. Although some authors have suggested that social factors relate to homosexuality or bisexuality, many others have examined genetic, hormonal, and brain structural evidence to suggest a biological component (e.g., LeVay, 1993). Biological contributors to sexual orientation also may work indirectly through an influence on temperament, which in turn may influence feelings of gender atypicality. Feeling gender atypical may lead to viewing the self as more similar to the other sex and may promote feelings of eroticism toward the relatively unfamiliar same-sex others (D. J. Bem, 1996, 2000). Alternatively, identity may drive behavioral changes. Children questioning their heterosexuality may begin to engage in gender-atypical behavior and develop self-perceptions in line with their newly developing identity as a sexual minority (Carver, Egan, & Perry, 2004).

### **Styles and Symbols (5)**

Gendered styles and symbols range from body image and hairstyles to speech patterns and communication. Do children know the gendered meanings of voices, interaction and communication styles, gestures, hairstyles, and clothing? To what extent are their self-perceptions, preferences, and behavioral patterns in these domains gender-typed? Most research in styles and symbols concerns communication patterns and, more recently, body image. Although communication involves both substantive and stylistic variations, to be consistent with the last *Handbook* chapter, we continue to cover this material in the styles and symbols section.

#### **Concepts or Beliefs (5A)**

Young children know gender-related symbolic associations. For example, preschoolers have clear stereotypes about colors and associate physical cues such as colors and clothing with gender-typed interests in others (e.g., Picariello, Greenberg, & Pillemer, 1990). As discussed

in the last *Handbook* chapter, in studies of metaphorical associations, children attribute to boys things that are angular, rough, and dangerous (e.g., a bear), and to girls things that are soft, light, and graceful (e.g., a butterfly). Children select toys using metaphorical cues rather than known stereotypes when these are in conflict (e.g., a pink truck may be appealing to girls).

Hairstyles and clothing (and adornment in general) are important external stylistic markers strongly associated with gender and are learned at a very young age. In a study of stereotypic norms and their violations (see 6C; Blakemore, 2003), 100% of first grade children knew the norms for girls' and boys' clothing and hairstyles, and by third grade for play styles. Appearance cues appear to be more important for girls than boys. When asked to tell what they know about the sexes (a measure of the accessibility of stereotypes), girls provided more appearance stereotypes than boys, and both sexes provided more appearance stereotypes when describing girls than when describing boys (C. F. Miller, Lurye, et al., 2006).

Children demonstrate stereotypic knowledge about speech patterns and roles associated with the sexes. When children ages 4 to 7 were asked to enact their father's speech, they used a deeper-pitched voice and loud voice; when enacting their mother's speech, they tended to use higher-pitched voice, exaggerated intonation, and female-stereotyped vocabulary (Andersen, 1996). Young children also illustrate stereotypic knowledge of gendered language, recognizing the links between sex and gendered linguistic markers, such as "adorable" as a female-type word, and intensifiers (e.g., so, very) as markers of female speech (Gleason & Ely, 2002).

Children begin to develop body image stereotypes about others concerning weight around age 5 (Hendy, Gustitus, & Leitzel-Schwalm, 2001). It appears that children also develop a preference for muscular male bodies at a young age (Spitzer, Henderson, & Zivian, 1999). These stereotypes relate to children's own body perceptions as they grow older (see 5B).

### ***Identity or Self-Perception (5B)***

To understand how children view themselves as gendered in their style, we review evidence concerning clothing preferences, types of mannerisms, and body image. Although the evidence on these topics has been sparse, recent interest in body image has provided a clearer picture of the extent to which identity and self-perception are evidenced through stylistic and symbolic markers.

**Clothing Styles and Mannerisms.** Dress and mannerism provide ways to actively construct gender yet have not been well studied. Many interesting questions need to be addressed (see Ruble & Martin, 1998). Are children who select their own clothing aware of the effects of their choices? What are the links between gender identity and adoption of gender-typical styles and mannerisms?

**Body Image.** Extensive research has demonstrated that images of one's body play a significant role in predicting depression, eating disorders, and low self-esteem, especially in adolescent girls (e.g., J. K. Thompson, Heinberg, Altabe, & Tantleff-Dunn, 1999). At age 5, both sexes are similar in body image (i.e., girls do not yet show more body dissatisfaction; Hendy et al., 2001). Between 6 and 8 years of age, sex differences appear, with girls showing more body dissatisfaction than boys, and more desire to be thin (e.g., A. J. Hill & Pallin, 1998; Ricciardelli & McCabe, 2001; Schur, Sanders, & Steiner, 2000; Tiggemann & Wilson-Barrett, 1998), which are consistent over time and related to disordered eating behavior and eating attitudes (Davison, Markey, & Birch, 2002; Ricciardelli & McCabe, 2001). Preadolescents show similar patterns of sex differences in body image and dissatisfaction (K. Thomas, Ricciardelli, & Williams, 2000). Body image concerns for boys center on being more muscular (McCabe & Ricciardelli, 2003; Smolak, Levine, & Thompson, 2001) and for girls on weight.

The sex difference in body image continues in adolescence (Byely, Archibald, Graber, & Brooks-Gunn, 2000). A large percentage of adolescent girls report significant body dissatisfaction (J. K. Thompson et al., 1999), which is linked with emotional distress, appearance rumination, and unnecessary cosmetic surgery (Ohring, Graber, & Brooks-Gunn, 2002; J. K. Thompson et al., 1999), as well as depression and disordered eating (e.g., Grant et al., 1999; Stice & Bearman, 2001; Stice & Whitenton, 2002). A number of studies link body image to media and societal pressures for attractiveness and thinness for females (Smolak et al., 2001; Stice & Whitenton, 2002; J. K. Thompson & Stice, 2001; Werthein, Koerner, & Paxton, 2001). Peer pressure affects body dissatisfaction (Carlson Jones, 2001; Vincent & McCabe, 2000). A recent study demonstrated that changes in boys' body dissatisfaction over adolescence related to internalization of the male muscular ideal; girls' body dissatisfaction related to their body mass, social comparisons, and appearance conversations with

friends (Carlson Jones, 2004). Body dissatisfaction is associated in girls with earlier pubertal maturation (Ohring et al., 2002) and, in both sexes, with maternal pressure to lose weight (Ricciardelli & McCabe, 2001).

### **Preferences (5C)**

Anecdotal data suggest that young children express strong preferences to dress in a way that indicates their sex, regardless of parents' preferences, with girls preferring frilly dresses and bows and boys, baseball caps and sneakers. But, few studies have addressed verbal preferences (see 4D for research on adoption of styles of dress).

In one study of 5- to 10-year-olds, children preferred same-sex peers dressed in stereotypic or neutral clothing over children dressed in counter-stereotypic clothing (Albers, 1998). They also associated play activities with clothing styles, indicating that they may form broader stereotypes about the characteristics of gender normative versus nonnormative children.

Color preferences have been examined in a number of studies mostly in adults. Although the pattern is not replicated in every study, it appears that young adults often show stereotypic color preferences: Females prefer pinks but not darker reds, and males prefer shades of blues (Ellis & Ficek, 2001). Some people, especially females, have genes that provide additional color discrimination, and this may contribute to sex differences in color preferences (Jameson, Highnote, & Wasserman, 2001). There is speculation that color preferences are linked to sex differences in the visual centers of brain and that these differences contribute to children's sex-typed toy choices (Alexander, 2003).

Although very little work has been done to assess whether girls and boys show different artistic preferences or produce different images, one study found that by the age of 4, children preferred gender-stereotypic art and both sexes showed equally extreme patterns of gender-typed preferences. Furthermore, both girls and boys produced gender-stereotypic art (as rated by judges; also see Boyatzis & Albertini, 2000). It is particularly interesting to find these preferences at such a young age. Also, the degree to which the art was gender-typed is surprising: even when it was non-representational, judges determined that it was "masculine" or "feminine" based on color use and shapes that were drawn (Boyatzis & Eades, 1999).

### **Behavioral Enactment (5D)**

Both verbal and non-verbal forms of expression may communicate information about gender, either intention-

ally or unintentionally. The extent to which males and females differ in their use of language and non-verbal communication styles has been of interest to researchers because these differences may reflect differences in power and status; however, a number of studies suggest that they may also vary depending on context.

**Communication Styles.** Research on adults has demonstrated that women and men differ in styles of speaking and nonverbal communication, and has examined how these differences reflect roles and context (Ruble & Martin, 1998). The same issues are apparent in the developmental literature. Although it is difficult to disentangle stylistic from context effects, some evidence suggests that both of these views may hold merit, and that they should be viewed as complementary (Leaper & Smith, 2004). And it is important to keep in mind that although sex differences are found, the similarities in girls' and boys' styles are more apparent.

Consistent stylistic effects have been identified in recent studies. Although researchers often find more similarities than differences, girls use strategies to demonstrate their attentiveness, responsiveness, and support, whereas boys use strategies to demand attention and establish dominance. Girls tend to use affiliative and help-seeking speech acts; boys tend to use controlling and domineering exchanges (Leaper, Tenenbaum, & Shaffer, 1999; Leman, Ahmed, & Ozarow, 2005; B. R. Thompson, 1999). Meta-analysis shows sex differences in children's language use (Leaper & Smith, 2004). Girls differed from boys by being more talkative ( $d = -.11$ ), using more affiliative speech (language used to establish or maintain contacts with others;  $d = -.26$ ) and less self-assertive speech (language used to influence others;  $d = .11$ ). For many of these sex differences, there is an increase between preschool and elementary school. However, girls were more talkative only in early childhood (1 to 2½ years,  $d = -.32$ ).

Evidence also has accumulated concerning situational differences in children's communicative behavior. In meta-analyses (Leaper & Smith, 2004), sex of partner influenced the magnitude of sex differences in language use. For instance, sex differences in assertive speech were evident in same-sex interactions ( $d = .18$ ) but not in mixed-sex interactions ( $d = .04$ ). Sex differences in affiliative speech were larger in unstructured situations ( $d = -.65$ ) than in structured situations ( $d = -.20$ ). A number of other studies also have demonstrated context effects (e.g., Holmes-Lonergan, 2003; Leaper et al., 1999; Leman et al., 2005). Culture also influences com-

municative styles. For example, African-American adolescent girls were less likely to show gender-typed forms of communication than were White girls (Leaper et al., 1999).

**Nonverbal Communication.** Early studies reveal girls and boys to use different mannerisms and gestures, with girls more likely to use limp wrists, arm flutters, and flexed elbows when walking, boys to put hands-on-hips more than girls, and gender nonnormative boys to exhibit feminine mannerisms (Ruble & Martin, 1998). In college students, observed gender-related physical characteristics and mannerisms (e.g., deep voice and broad shoulders) have been found to relate to personality traits, interests, roles, and gender identity in men but not women, suggesting some coherence in the various domains of gender for men (Aube, Norcliffe, & Koestner, 1995).

Children use gestures to communicate even before they use language, and boys and girls do so differently. Parents' ratings of their children's gestures and symbolic play actions (e.g., feeding a doll with a spoon) revealed sex differences from 9½ to 36 months of age (but not before; Fenson et al., 1994; Stennes et al., 2005).

**Clothing and Appearance.** Clothing, jewelry, cosmetics, and hairstyles provide a wealth of information about a person's sex, socioeconomic background, status, lifestyle, nationality, and age. Parents use clothing to mark the sex of their children for strangers, and these cues are accurately interpreted much of the time (Ruble & Martin, 1998). In adults, much has been written about how women actively construct their identity through the "gendering" of their clothing. Little interest has been shown in children's construction of gender or the extent to which they are aware of using clothing as markers of gender, possibly because there is an assumption that parents choose children's clothing.

In the few studies that have examined this issue, the findings are clear: Children prefer to dress in sex-appropriate clothing, and girls particularly prefer feminine clothing. Ruble and her colleagues (Greulich, Ruble, Khuri, & Cyphers, 2001; Ruble, 2004) describe how girls between the ages of 3 to 6 years often become quite insistent on wearing clothes that are highly female stereotypic, such as pink frilly dresses, a phenomenon she has labeled PFD. This may be one of the strongest gender effects found in childhood. Further research is needed to assess whether these gendered enactments in the early years relate to other forms of gendered behavior

and whether they are indicative of stable individual differences in gender roles.

As children make their own clothing choices, they may signal their gender-related interests or roles by selecting particular styles and rejecting others. For instance, a girl with interest in "masculine" activities and sports may wear boyish pants, T-shirts, and athletic shoes rather than dresses and pink clothing. Clothing choices of tomboys are more masculine than those of nontomboys (Dinella & Martin, 2003). Wearing clothing typically associated with the other sex—"cross-dressing"—is common in children identified as having GIDC and this may partly signal their atypical preferences.

It is unclear whether clothing choices are practical or serve as signals for others. Interesting questions about whether children's clothing choices (e.g., dresses) preclude certain activity choices (e.g., rough-and-tumble play) remain. Girls who dress in feminine styles may be reluctant to engage in active or dirty activities because of their clothing, and/or they may rigidly adhere to gender norms (Ruble & Martin, 1998). Moreover, a cycle may develop in which girls' clothing choices modify their behavior, decreasing their competence for certain activities over time, leading to even less interest in those activities. Any factor that modifies children's interests may have a large impact on later abilities and behavior.

## Values Regarding Gender (6)

What are children and adolescents' evaluative beliefs and preferences about gender? At what age do they become aware that males and females may be differentially valued, and how does that affect their self-perceptions, personal preferences, and behaviors such as discrimination? This section examines these questions using a range of different types of evaluations.

### *Concepts or Beliefs (6A)*

In many cultures, more positive evaluations are applied to men and masculine activities than to women and feminine activities (e.g., Berscheid, 1993). When do children become aware of the cultural values placed on the sexes? The social psychological literature has distinguished between personal evaluations (i.e., private regard) about a social group (in this case, male versus female) and perceptions of others' evaluations (i.e., public regard; Sellers, Smith, Shelton, Rowley, & Chavous, 1998). Almost no research has directly examined children's public regard for gender (e.g., beliefs that men are highly regarded by others; see Ruble et al.,

2004, for a review). Kohlberg (1966) hypothesized that at a very young age, children are attentive to sex differences in power, and research on stereotype knowledge described earlier is consistent with this hypothesis. One study examining the development of knowledge about cultural values suggests that children older than 10 years perceive that females are devalued. For example, when asked to describe what would happen if they woke up one day to find they had changed sex, 11-, 14-, and 18-year-olds in Sweden and the United States offered different evaluations of the male and female role, acknowledging gender-based discrimination, greater restrictions for females, and the lower value of the female role (Intons-Peterson, 1988a). A recent study found that children may be aware of gender discrimination as young as 5 to 7 years, but more so at 8 to 10 years (Brown & Bigler, in press). Discrimination was perceived, however, only when children were explicitly told that it was a possible reason why a teacher might respond more favorably to a boy than to a girl (or vice-versa). Girls but not boys were more likely to perceive such discrimination against girls than against boys.

#### ***Identity or Self-Perception (6B)***

As children begin to recognize that males and females are differentially valued, their own self-perceptions may be affected when their identity as a group member is salient. According to social identity theory (Tajfel, 1978), the social categories into which individuals are divided have evaluative implications and thus consequences for self-esteem. For example, girls who attribute their failure on a computer project to the idea that girls are incompetent in this domain may experience sadness and shame (Lutz & Ruble, 1995). These ideas have received little direct empirical attention with children. Although considerable evidence suggests that girls evaluate themselves more negatively than boys in many situations (Ruble, Greulich, Pomerantz, & Gochberg, 1993), the specific link to gender values is not clear. The results of one study suggest that as 5- to 8-year-old children learn about positive and negative traits associated with the sexes, they gradually begin to view themselves in terms of such traits (Aubry et al., 1999). Presumably, the level of private or public regard for their own sex may show associations with self-esteem. One program of research has reported results consistent with this hypothesis. For one aspect of private regard (i.e., feeling content with one's gender, such as liking to be a girl), Perry and his colleagues have shown a positive relation

with self-esteem and other indices of adjustment among third to eighth grade children (Carver et al., 2003; Egan & Perry, 2001). Another kind of private regard (i.e., believing that one's sex is superior, such as believing that girls are friendlier than boys) was not associated with self-esteem in these studies. This hypothesis has not been tested for public regard, however, and represents an important direction for future research. Future research should also examine self-perceptions in situations in which categorical group identification is more or less salient. Finally, as Eckes and Trautner (2000) suggest, future research needs to examine the influence on gender-related self-evaluations of cultural forces, such as variations in cultural views of femininity and masculinity or the importance of adhering to gender norms. For example, the relations reported earlier between private regard and adjustment may differ by race and ethnicity (Corby, Hodges, & Perry, in press).

#### ***Preferences (6C)***

How do children personally evaluate gender categories and related activities and interests? Do they view males and masculine activities as somehow better or more valued? Do they view cross-gender behavior or traits as wrong? One problem with examining personal values about gender (i.e., private regard) is that they are rarely measured directly by, for example, asking children whether they think it is better to be a man or woman or to do masculine or feminine jobs. Instead, such values must be inferred from related measures. In this section, evidence regarding three types of gender-related values is examined: (1) in-group biases, (2) prejudice against females, and (3) attitudes about egalitarian gender roles.

**In-Group/Out-Group Biases.** According to cognitive theories, children's growing awareness of their membership in one sex category is likely to create a number of identity validation processes, one of which is to view one's own sex, the "in-group," more favorably than the other (Kohlberg, 1966; Martin & Halverson, 1981; Tajfel, 1978). In a direct examination of this prediction, 3- to 11-year-olds in South Wales were asked how they "feel" about girls and boys (Yee & Brown, 1994). By age 5, both girls and boys were markedly more positive about their own sex than about the other sex, and even 3-year-old girls (but not boys) showed significant in-group favoritism. Children also tend to show in-group evaluative biases in assigning more positive than negative traits to their own sex in the early and

middle school years (Ruble & Martin, 1998), particularly when asked to make a direct comparison between males and females (Heyman & Legare, 2004). This positivity bias declines with age, at least after age 4 to 5 years (e.g., Heyman & Legare, 2004; Powlishta et al., 1994) and the decline is often stronger for girls (Egan & Perry, 2001; Yee & Brown, 1994). Finally, in-group biases may be inferred from findings that children show greater liking for peers of their own sex (e.g., Heyman, 2001), and typically play with same-sex others after the age of 3 (Maccoby, 1998; see Section 4C). Overall, there is considerable evidence of in-group evaluative biases, especially among preschool children.

**Prejudice against Women.** One reason for the high level of interest in gender development is a search for the origins of women's disadvantaged status in most cultures. Is there any evidence that, aside from in-group biases, children value males more than females, and if so, how early does this begin? Interestingly, despite general cultural biases attributing greater prestige and power to males (and some evidence that children are aware of such status differences by middle childhood—see 6A), most of the available evidence suggests that children are more likely to derogate males than females. For example, Yee and Brown (1994) found that although both boys and girls felt more positively about their own sex, boys were described in more negative terms overall. Similarly, Heyman (2001) found that children's interpretations of ambiguous behavior were more negative for male than female targets. It would be interesting in future research to examine judgments about adult males and females.

Why do children not show this expected devaluation of females relative to males? Young children may be particularly attentive to attributes implying moral goodness, such as helpfulness and conformity with adult norms (Paley, 1988; Ruble & Dweck, 1995). As children begin to stereotypically associate such attributes more with females than with males (see 3A; “girls are sugar and spice and everything nice”), they may initially value females more. Indeed, this positive evaluation of females continues to some extent into adulthood (Eagly, Mladinic, & Otto, 1991). However, for adults, cultural standards emphasize masculine attributes of prestige, power, and competence (Powlishta, 2000). As Glick and Fiske (1996) argue, prejudice toward women may be characterized as ambivalent: Women are often portrayed as nice but incompetent. As these adult standards

are acquired, evaluations of females would be expected to decline relative to evaluations of males and to be characterized as ambivalent in this way. Indeed, a recent developmental analysis suggests that gender prejudice moves from a simple form of childhood hostility toward the other sex to a complex and ambivalent set of adult attitudes that combine, particularly for men, both hostile and benevolent forms of prejudice (Glick & Hilt, 2000).

Some evidence reviewed in our prior *Handbook* chapter indirectly supports this account (Ruble & Martin, 1998). A recent study of perceived competencies of men and women in gender-typed occupations found that children as young as 5- to 7-years-old view males as more competent overall (G. D. Levy, Sadovsky, & Troseth, 2000). In an interesting experimental study, 11- to 12-year-olds but not 6- to 8-year-olds evaluated novel occupations portrayed with male workers as higher in prestige than identical jobs portrayed with female workers (Liben, Bigler, & Krogh, 2001). Both studies found that even younger children evaluated existing occupations traditionally performed by males as higher in status.

**Egalitarian Attitudes.** Do children think it is desirable for individuals to be free to engage in whatever behaviors they prefer, or do they feel it is wrong to engage in activities not stereotypically associated with one's gender? There are several types of relevant data. Especially close to the notion of values are studies that ask what males, females, or both “should” be like or do. As described in Section 2A, meta-analysis suggests a curvilinear developmental trend, such that values about gender may increase in rigidity until 5 to 7 years of age but subsequently become more flexible, at least through early adolescence (Signorella et al., 1993).

Another approach is to examine developmental trends in children's personal evaluations (good or bad) of individuals who engage in cross-gender behavior. It seems reasonable to expect that such evaluations would show curvilinear developmental trends similar to those just described for stereotypic attitudes. Some research is consistent with this prediction. For example, negative reactions to atypical behavior (e.g., desire not to be friends with a boy who wears nail polish) increased between 3 to 5 years of age but decreased between 5 to 7 years (L. Taylor et al., 2006), and gender-atypical behavior was evaluated more negatively by kindergartners and eighth graders than by children in middle elementary school (Stoddart & Turiel, 1985). Other studies

have found very different developmental patterns, however, suggesting that some negative reactions may be relatively stable (G. D. Levy, Taylor, & Gelman, 1995) or increase between preschool and middle elementary school (Carter & McCloskey, 1984). In a promising attempt to explore possible reasons for these discrepancies across studies, Blakemore (2003) examined developmental changes in 3- to 11-year-old's reactions to several different types of gender norm violations. Unfortunately, no clear pattern emerged. Negative evaluations of norm violations increased with age for many items but were unrelated or curvilinearly related to age for other items, with no clear linkages between age trends and characteristics of the items. One clear finding was that when an age difference was found, older children evaluated norm violations by boys more negatively than did younger children.

Thus, the exact nature of developmental trends in children's reactions to atypical behavior varies with the sex of target, the type of target behavior, and the type of reaction assessed. Unfortunately, it remains unclear exactly what processes underlie such differences. Further, although sex of target differences are not always found, when they are, boys are judged more negatively for violating norms than are girls (Antill et al., 1996; Zucker et al., 1995), especially when they involve appearance (Blakemore, 2003). Finally, past research has suggested sex differences in egalitarian attitudes among children. Boys are often more negative about gender norm violations than are girls (e.g., Blakemore, 2003), and girls are more likely to consider it wrong to exclude another child from an activity simply because it violates gender norms (e.g., allowing a boy to participate in a ballet class; Killen & Stangor, 2001).

Another approach addresses attitudes about role equality, with such research suggesting that attitudes become more flexible or egalitarian with age in contrast to developmental changes in reactions to gender norm violations, as described earlier (e.g., Huston & Alvarez, 1990; L. Taylor et al., 2006). Sex differences in such trends have been found, however. Studies examining attitudes toward equal roles, using, for example, the Attitudes toward Women Scale (e.g., "Girls should have the same freedoms as boys"; Galambos, Petersen, Richards, & Gitelson, 1985), suggest that boys value gender equality less than girls and become increasingly negative between sixth and eighth grades, whereas girls become increasingly positive (e.g., Galambos, Almeida, & Petersen, 1990). More recent research has shown a similar sex difference in valuing equality regarding involve-

ment in careers and shared household demands, with older adolescent boys (relative to girls and younger adolescent boys) having more traditional role-differentiated attitudes, such as believing that working is detrimental to the family for women but not for men (Jackson & Tein, 1998).

### ***Behavioral Enactment, Adoption (6D)***

Values are expressed in behavior through overt indices of preferential or discriminatory treatment. A common paradigm for examining discriminatory behavior is a reward allocation task in which individuals are asked to distribute resources to different groups or individuals based on performance and personal attributes. Although some research has shown in-group favoritism based on ethnicity, only one study to our knowledge has examined such behaviors as a function of sex (Yee & Brown, 1994). In this study, girls tended to give rewards on the basis of in-group favoritism, whereas boys tended to reward on the basis of equity. Although these trends did not vary significantly across age (3 to 11 years), it is noteworthy that at age 3, both boys and girls gave nicer prizes to girls regardless of actual performance, and the clearest indication of in-group favoritism for both sexes occurred at age 5. Values are also expressed in the way children respond to cross-gender behavior. Children, especially boys, who deviate from gender norms suffer more from peer ridicule (Zucker, 1990) and peer rejection (Cohen-Kettenis, Owen, Kaijser, Bradley, & Zucker, 2003). Thorne (1993) found that boys who violated norms for masculinity were teased, shunned, or referred to as "girls."

### **Summary of Developmental Trends**

The extensive data base on gender development produces the following portrait. By 1 year of age, many infants respond to gender cues. Most children learn to label themselves and others as male and female by 2½ years of age (and many before age 2), show some limited understanding of gender stereotypes, play more often with same- rather than other-gender toys (especially dolls and cars), and show the first signs of more positive contacts toward same- rather than other-sex peers. In addition, early indication of GIDC may be seen at this age. Three-year-old children master gender stability, show better than chance responding to measures of gender stereotyping of children's toys and activities, colors, and certain traitlike characteristics, and state gender-typed play preferences.

During the remaining preschool years (age 4 to 5), most indices of gender knowledge and behavior increase dramatically. Many children show complete gender constancy understanding, are able to link traits to gender (especially power-related and evaluative traits), show in-group positivity biases, and expect same-sex peers to play together. In addition, sex differences in a few personal-social characteristics, such as aggression and decoding facial expressions, are seen at this time. This also appears to be an age of heightened gender rigidity.

A number of important changes in gender development occur during the elementary school years. Children develop more complex stereotypic associations and add more information to their stereotypes. During middle elementary school, children become aware of male-favored status differences and, at the same age, girls are more likely than boys to prefer to be the other sex. Elementary school children also show increasingly flexible stereotypic beliefs through, at least, early adolescence, and girls often become more flexible in their activity preferences and behaviors. A few indices do not show increasing flexibility, however, such as children's segregation into same-sex groupings, which remains high during elementary school, and negative evaluations of peers who engage in cross-gender behavior. Sex differences in certain spatial skills and emotional perception and expression are seen in middle childhood and increase with age.

Finally, further changes are found during adolescence. Some evidence supports the existence of gender intensification after early adolescence. A few studies suggest that stereotyping becomes somewhat less flexible. Trends for preferences are less clear and appear to diverge for males and females, with boys less likely to become flexible. However, in middle adolescence, both sexes show gender-typed activities and interests in many contexts (i.e., at home or school) and sexual identity may emerge. In addition, sex differences in mathematical problem solving, physical skills, and depression emerge or increase during adolescence. Taken together, the various trends show a number of parallel developments among cognitions, preferences, and behavior.

The development of the multidimensional matrix by Huston (1983) marked an important turning point in the study of gender. By disentangling the various content domains, she gave researchers a clearer picture of the many aspects of gender that exist. Furthermore, developmental researchers were sensitized to the implicit assumption underlying much of the thinking in the area—that gender-typing in one domain will predict

gender-typing in another. Rather than assuming unity in measures, developmentalists have been faced with the issue of how to assess each aspect of gender and have begun using multimethod assessments to discover whether relations exist among the various aspects. In future research, it will be interesting to incorporate a recently proposed third dimension of the matrix: levels of analysis (Eckes & Trautner, 2000).

What is the state of the field regarding the unity of gender-typing constructs? The multidimensionality of gender-typing (e.g., Antill et al., 1993; Hort, Leinbach, & Fagot, 1991; Serbin et al., 1993) has been inferred from failures to find relations among gender-related variables, but is most often used to refer to failures to find connections between gender-typed preferences or behavior and emerging cognitions about gender. Nevertheless, it appears that basic knowledge about one's own sex and the sex of others does develop at about the same time as gender-typed behavior and may influence that behavior (see Cognitive Approaches section).

It may be informative to examine issues of unity among subsets of variables. For instance, much of gender differentiation may be thought of as a set of *self* variables, and it may be productive to examine to what extent coherence appears among such variables as categorical gender, the development of gender identity, preferences for same-sex playmates, interests in gender-typed activities, and later preferences for other-sex sexual partners. Many of these components in the matrix did show parallel developmental trends, but it is unclear whether they cohere within individuals, so associations and causal relations need to be assessed in longitudinal or, in some cases, experimental studies (e.g., varying the salience of gender labels). It would also be productive to examine whether individual differences show stability over time. Are 3-year-old girls who dress in pink frilly dresses, play primarily with girls, and play with dolls likely to become 9-year-olds who avoid sports, show feminine interpersonal characteristics, and select female-typical occupations? To date, there has been relatively little research about such issues (Maccoby, 2002; McHale, Crouter, & White-man, 2003), though retrospective studies suggest that some early gender-typed interests may continue into middle childhood and adolescence (e.g., Giuliano, Popp, & Knight, 2000).

One interesting benefit of the matrix framework (Table 14.1) is that gaps in the literature can easily be identified. Although relatively clear conclusions can now be drawn about the development of gender-related

stereotypes, verbal preferences, and behaviors (especially regarding concrete activities and interests and relationships), much less is known about corresponding trends in children's gender-related self-perceptions and identity (Column B) or about the development of children's gender-related values and attitudes (Row 6).

In summary, the matrix has been particularly useful in studying questions about the relations among the various constructs and content domains. We agree with Huston (1983) that gender researchers should take the multidimensionality of gender-typing seriously, but we also recommend avoiding the assumption that no unity exists at all. The likelihood of finding expected correlations may be influenced by a number of factors (Aubry et al., 1999; C. F. Miller, Trautner, et al., 2006). Thus, researchers should base examinations of cross-construct associations on careful theoretical and methodological analyses of which, and under what conditions, relations are expected.

## THEORETICAL ANALYSIS OF GENDER DEVELOPMENT

In this section, we analyze possible processes underlying the developmental and sex differences trends we have just described, focusing on three broad approaches: (1) biological, (2) socialization, and (3) cognitive. These three perspectives have historically represented the dominant theories applied to gender development, but it has become increasingly difficult to make clear distinctions among them, because intersections across perspectives drive much of current theorizing and research. Particularly problematic is the distinction between socialization and cognitive perspectives because current theories incorporate elements of both. To facilitate comparisons with prior reviews, we have maintained these labels, but call attention to their limits at various places. In each section, we use mechanisms derived from each of the theoretical perspectives to describe gender development and consider the evidence relevant to the most pressing issues in each theoretical orientation.

### Biological Approaches

Biological perspectives have gained in visibility and acceptability. Converging data from multiple methods (facilitated by methodological advances) provide compelling support for biological contributors to gender de-

velopment. The nature-nurture debate has given way to questions about the mechanisms by which biology and the social environment work together to produce behavior. Political and social implications of sex differences are not dependent on their causes. Biological factors do not imply determinism, because behaviors with a strong biological influence may be relatively easy to modify, as exemplified by the diet used to prevent retardation in children with phenylketonuria. Environmental factors do not imply free will and easy malleability, because social forces may be difficult to counteract, as exemplified by racism.

Biological approaches to gender development emphasize the parallels between physical and psychological sexual differentiation. The brain is part of the body and the brain underlies behavior, so it should not be surprising that the same factors that govern sexual differentiation of the body—genes and hormones—also govern sexual differentiation of the brain and thus behavior. Further, it is logical for there to be a biological basis for the sex differences in reproductive and related behaviors essential for the survival of our species. Thus, biological approaches generally focus on *distal* evolutionary explanations of gender development and *proximal* mechanisms mediated by genes and hormones.

### Evolutionary Psychology

Evolutionary psychologists view behavior as the result of adaptive pressures, so that our brains—and, therefore, our behaviors—developed to solve problems faced by our ancestors, and good solutions enabled them to survive and reproduce. The sexes have faced different adaptive pressures related to differences in reproduction: Women have a greater physical investment than men in childbearing (gestation and postnatal support), leading them to be careful in choosing a mate, and leading men to compete for mates; men cannot be certain of the paternity of offspring that they rear. These pressures are hypothesized to result in behavioral sex differences seen in contemporary society, including females' greater interest in babies and males' greater aggression and preferences for multiple sex partners (Buss, 2000; Geary, 1998).

There are many appeals to an evolutionary approach: It places behavior on an equal footing with physical characteristics, correctly conceptualizes behavior (as other characteristics) as adaptation to problems faced by our ancestors, and provides a single explanation for a range of sex differences. Nevertheless, evolutionary the-

ories are currently incomplete because they do not make unique predictions (results often can be explained by other theories, such as social learning), are difficult to falsify (there are no methods available to decide whether a behavior “evolved” because it was adaptive or a by-product of another trait), and concern factors that make all boys and men similar to each other and different from all girls and women (but not all men and women behave in ways predicted by evolutionary theory).

### ***Comparative Approaches***

Another perspective on evolution relies on cross-species comparisons to understand the origins of behavior in developmental and cultural context. Its value for understanding sex-related behavior can be seen in two recent papers. The first described a sex difference in wild chimpanzees in learning to use tools to fish for termites. Compared to males, female chimps learned at a younger age and were more likely to use techniques resembling those of their mothers (Lonsdorf, Eberly, & Pusey, 2004). The second paper described a study of toy preferences in vervet monkeys, showing sex differences paralleling those seen in children (Alexander & Hines, 2002).

A comparative approach seems promising for examining the development of sex-related behavior, given evidence that primates, and perhaps other animals, learn from others in their social groups and that they form and use cognitive categories and concepts that can be generalized and adapted to new circumstances (E. K. Miller, Nieder, Freedman, & Wallis, 2003). It is important to know, for example, whether juvenile monkeys sex segregate (Maccoby, 1998), what gender concepts they have, and how they use knowledge of sex membership (their own and other’s) in their behavior. Comparative studies can also provide information about proximal mechanisms that can be studied in human beings, such as characteristics underlying toy preferences.

### ***Parallels between Physical and Psychological Sexual Differentiation***

Evolutionary and comparative approaches put human gender development into context. Proximal explanations focus on biological mechanisms accounting for differences between males and females, specifically processes of physical sexual differentiation.

Genetic sex is determined at conception. The difference between the sexes is determined by a gene on one of 23 pairs of chromosomes. Females have two X chromosomes, males one X and one Y, with the latter con-

taining *SRY* (the sex-determining region). The two sexes start out with the same sets of structures that differentiate into male or female gonads, internal reproductive organs, and genitals (Grumbach, Hughes, & Conte, 2002). The path to male development is initiated by *SRY*, which causes the indifferent gonad to develop into testes at about weeks 6 to 7 of gestation. After this, sexual differentiation largely depends on hormones secreted by the gonads, particularly androgens; estrogens have little role during prenatal development. Although both sexes produce and respond to androgens and estrogens, there are large sex differences in the concentrations of these hormones. The external genitalia start out the same in the two sexes; high levels of androgen beginning at prenatal weeks 7 to 8 cause male external genitalia to develop. Although this normally occurs only in males, females can develop masculinized genitalia if they are exposed to high levels of androgen early in development. Female-typical development is largely a default process, occurring when *SRY* is absent and androgen is low, but completely normal female development requires other genes. Hormones exert effects through cell receptors, so complete masculinization requires both high levels of androgen and functioning androgen receptors.

### ***Hormonal Influences on Behavior and Brain in Nonhuman Animals***

Hormones are also responsible for sexual differentiation of the brain and behavior. In nonhuman species, exposure to androgens early in development because of experimental manipulations or natural variations (e.g., females who gestate in the uterus between two males) causes masculinization of sex-typed sexual, social, and cognitive behaviors. Similarly, experimental manipulations and natural variations in levels of androgens and estrogens later in life (e.g., estrus cycle variations, menopause) alter behavior.

Several principles from animal studies have implications for human behavioral development (for reviews, see Becker, Breedlove, Crews, & McCarthy, 2002; Ryan & Vandenbergh, 2002; Wallen, 2005). First, hormones affect behavior in two ways: (1) by producing permanent changes to brain structures and the behaviors they subserve, usually early in life (“organizational” effects) and (2) by producing temporary alterations to the brain and behavior (through ongoing changes to neural circuitry) as the hormones circulate in the body, primarily throughout adolescence and adulthood (“activational” effects; although the distinction between organizational

and activational hormone effects is not absolute). Second, there are multiple sensitive periods for permanent effects of hormones, and these periods may differ for the brain and the genitals. The human sex difference in testosterone is largest during prenatal weeks 8 to 24, postnatal months 1 to 5, and puberty through adulthood (Smail, Reyes, Winter, & Faiman, 1981). The key sensitive period for human brain and behavioral sexual differentiation has been considered to occur right after the genitals differentiate, but other times may be important. For example, some behaviors in monkeys are masculinized by androgen exposure early (but not late) in gestation, whereas other behaviors are masculinized by exposure late (but not early) in gestation (Goy, Bercovitch, & McBair, 1988). Third, the specific form of the hormone affecting behavior differs across species and across behavior within species. For example, androgen masculinizes behavior through conversion (aromatization) to estradiol in rodents but appears to affect behavior directly in primates (Wallen & Baum, 2002). Fourth, effects of hormones may be quite specific so that different behaviors are affected by different hormones acting at different times in development. For example, in rodents, androgen given early in development produces permanent changes in spatial learning, whereas ovarian estrogen given at puberty and beyond affects memory.

### *Human Behavioral Effects of Prenatal Hormones*

It is not possible to investigate the effects of hormones in people by manipulating their levels, but much has been learned from children and adults whose hormone levels were atypical for their sex during early development as a result of genetic disease or maternal ingestion of drugs during pregnancy to prevent miscarriage. Evidence from these natural experiments has been supplemented by data from normal individuals with typical variations in hormones.

**Congenital Adrenal Hyperplasia.** The most extensively studied natural experiment, congenital adrenal hyperplasia (CAH) is a genetic disease in which the fetus is exposed to high levels of androgens beginning early in gestation because of an enzyme defect affecting cortisol production. Females with CAH have external genitalia masculinized to varying degrees, but they have ovaries and a uterus and are fertile. Most girls are diagnosed at birth and treated with cortisol to reduce androgen excess (or they will experience rapid growth and

early puberty) and surgically to feminize their genitalia. If sexual differentiation of human behavior is affected by androgens present during critical periods of development, females with CAH should be behaviorally more masculine and less feminine than a comparison group of females without CAH. And they are in many, but not all, ways, as described below. Males with CAH have few prenatal effects and are treated postnatally with cortisol to maintain growth and prevent early puberty and other consequences of the disease. They are reared as boys, develop male gender identity, and generally display male-typical behavior (for reviews, see Berenbaum, 2001, 2004; Meyer-Bahlburg, 2001).

In early studies, girls with CAH were reported to be tomboys, and this was interpreted to reflect behavioral effects of androgen (Money & Ehrhardt, 1972). Interpretation was complicated by methodology (e.g., nonblind interviews, small samples, inadequate comparisons), factors associated with the disease and treatment (e.g., other hormones), and the possibility that behavior resulted from parent treatment in response to the appearance of the girls' genitals (Quadagno, Briscoe, & Quadagno, 1977).

Subsequent studies addressing these problems found girls with CAH to be masculinized and defeminized in aspects of their feelings, preferences, and behavior. In childhood and adolescence, girls with CAH reported being more interested in male-typical occupations than in female-typical occupations (Berenbaum, 1999; Servin, Nordenström, Larsson, & Bohlin, 2003), and they reported liking and engaging more with boys' toys and activities and less with girls' toys and activities than did typical girls (e.g., Berenbaum, 1999; Berenbaum & Snyder, 1995; Servin et al., 2003). Girls with CAH were more likely than control girls to report preferences for boy playmates (Berenbaum & Snyder, 1995; Hines & Kaufman, 1994; Servin et al., 2003).

Differences have also been observed in behavior. Girls with CAH aged 3 to 12 played with boys' toys more than comparison girls (Berenbaum & Snyder, 1995; Nordenström, Servin, Bohlin, Larsson, & Wedell, 2002; Servin et al., 2003). When choosing a toy to keep, about 50% of girls with CAH chose a transportation toy, whereas no control girl did (Berenbaum & Snyder, 1995; Servin et al., 2003). They drew pictures with masculine characteristics (e.g., moving objects, dark colors, a bird's-eye perspective), as opposed to those with feminine characteristics (e.g., human figures, flowers, light

colors; Iijima et al., 2001). There have been no studies directly observing peer choices in girls with CAH.

Evidence is accruing that masculinized preferences and play in girls with CAH result directly from prenatal androgen. Play with boys' toys has been related to the degree of prenatal androgen excess inferred from genetic defect and other indicators of disease severity (Berenbaum, Duck, & Bryk, 2000; Nordenström et al., 2002). Effects of parent socialization have not been demonstrated. For example, the amount of time that girls with CAH played with boys' toys was not increased when parents were present (Nordenström et al., 2002); parents wished that their daughters with CAH were *less* masculine than they were (and wished that their daughters without CAH were more masculine than they were; Servin et al., 2003); and parents of girls with CAH were observed to encourage them to play with *girls'* toys (Pasterski et al., 2005). The lack of evidence for parent effects on masculinized behavior in girls with CAH is consistent with data from androgenized female monkeys showing mothers' behaviors to be unrelated to offsprings' masculine behavior (Goy et al., 1988). Although these results strongly suggest that the boy-typical activities and interests of girls with CAH are due to prenatal androgen excess, it is possible that differential parent treatment is subtle and best detected in within-family designs (McHale et al., 1999).

Females with CAH appear to be masculinized and defeminized in other domains. Compared to typical females, adolescent and adult females with CAH reported that they would be more likely to use aggression in a conflict situation (Berenbaum & Resnick, 1997) and that they were less maternal and nurturant (Helleday, Edman, Ritzen, & Siwers, 1993). Parents reported that girls with CAH were less interested in babies than were their unaffected sisters (Leveroni & Berenbaum, 1998). These findings are less firmly established than those on activities and interests, and no studies have examined behavioral enactment of these characteristics or studied their associations with degree of prenatal androgen or parental treatment.

Beginning in childhood and continuing into adulthood, females with CAH have been found to score higher on spatial tasks (Berenbaum, 2001; Hines, Fane, et al., 2003). This difference has not been observed in all studies, perhaps due to low statistical power associated with relatively small samples and a moderate-size effect. Similar considerations apply in interpreting lack

of differences between CAH and typical females on measures of other abilities, such as perceptual speed and verbal fluency (Berenbaum, 2001).

Gender identity is typical in the majority of girls and women with CAH, although degree of identification may be reduced compared to typical females (Berenbaum & Bailey, 2003; Hines, Brook, & Conway, 2004). Gender change in females with CAH is uncommon but still more common than in the general population (Meyer-Bahlburg et al., 1996; Zucker et al., 1996). Degree of prenatal androgen excess and genital appearance do not appear to contribute to variations in gender identity. Finally, women with CAH are more likely than typical women to have bisexual or homosexual orientation, although most are exclusively heterosexual (Hines et al., 2004; Zucker et al., 1996).

**Complete Androgen Insensitivity Syndrome.** In this rare condition, XY males produce male-typical levels of androgen, but lack cell receptors allowing them to respond to the hormones. Consequently, they have female-typical genitalia and are reared as girls. They provide an opportunity to study the behavioral effects of genes on the Y chromosome and the nature of the hormone responsible for human behavioral sexual differentiation. If androgen affects behavior through conversion to estrogen (as happens in rodents), individuals with complete androgen insensitivity syndrome (CAIS) should be masculinized as a result of normal male levels of androgen converted in the brain to normal male levels of estrogen (estrogen receptors are normal). But, if the important hormone is androgen itself (or its other forms), individuals with CAIS should have female-typical gender development because they cannot respond to the high levels present. Gender development might also be masculinized by effects of genes on the Y chromosome, as suggested by animal studies (de Vries et al., 2002).

There is little evidence about gender development in CAIS, especially in childhood because it is rare and generally not diagnosed until menarche fails to occur. Limited data show individuals with CAIS to be female-typical with respect to gender identity, sexual orientation, and masculinity and femininity of interests (e.g., Hines, Ahmed, & Hughes, 2003). Female-typical gender development in CAIS could result from low androgens or rearing as girls, and argue against a role for aromatized estrogen or specific genes on the Y chromosome, but definitive answers await additional study.

Other evidence against a role for aromatized estrogens comes from females whose mothers were treated with diethylstilbestrol (DES), which used to be prescribed for pregnancy complications and which masculinizes aspects of brain and behavior in female rodents. Studies have generally found DES-exposed women to be similar to their unexposed sisters on measures of gender role and cognition; differences in brain organization and sexual orientation are not consistently found (reviewed in Cohen-Bendahan, van de Beek, & Berenbaum, 2005).

**Boys without a Penis.** Much attention has been directed to rare clinical conditions in which boys are lacking a penis but all other aspects of sexual differentiation are male-typical. Until recently, these children were usually reared as females, because it was believed that gender identity is determined by rearing and that normal psychological development depends on having normal-looking genitalia (although some surgical correction is now possible, the penis will never look or function normally; Money & Ehrhardt, 1972). There are two primary situations in which a boy might lack a penis: (1) *ablatio penis*—the penis is lost through an accident, such as a mishandled circumcision, and (2) *cloacal exstrophy*—a rare congenital defect affecting the bladder and external genitalia, causing a malformed or absent penis but otherwise normal male-typical physical development.

Because these conditions are rare, psychological outcome data come from case reports and small studies. Much attention has been focused on an individual born a boy but reared as a girl after a mishandled circumcision. Although early reports suggested that this child adapted well to the female assignment (Money & Ehrhardt, 1972), later reports revealed considerable unhappiness with the assignment, resulting in self-reassignment to the male sex (Colapinto, 2000; M. Diamond & Sigmundson, 1997). This was interpreted to show the primacy of biology in determining gender identity, but close inspection of the evidence suggests a complex picture. The child was reared as a boy early in life (the accident happened at age 7 months, reassignment was made in the 2nd year, and the initial feminizing genital surgery was not completed until 21 months), so there was a long and perhaps sensitive period when he was reared as a boy. Further, another individual with a similar history but with earlier female reassignment had a female identity (Bradley, Oliver, Chernick, & Zucker, 1998). Although

differing in gender identity, both cases had similar masculinized interests (e.g., occupation) and sexual orientation (i.e., arousal to women).

Boys with *cloacal exstrophy* reared as girls are also heterogeneous with respect to gender identity, but it is unclear what accounts for the variability. In a recent study of 14 children, 6 or 8 (depending on the criteria) were stated to identify as male, which was taken as evidence for biological determination of gender identity (Reiner & Gearhart, 2004). But, interpretation is difficult because of unsystematic and subjective assessments, likely effects of interviewer expectations, and some conflating of gender identity with male-typical activity interests. Further, gender change may arise not just from biology, but in response to complex social conditions, for example, a mismatch between behavior and parent expectations or peer stigmatization for atypical interests. Although much attention has been directed to that study, it is probably not representative of gender identity outcome in boys with *cloacal exstrophy* reared as girls: A recent review shows that the majority identify as girls (Meyer-Bahlburg, 2005).

Evidence from males with *ablatio penis* and *cloacal exstrophy* shows the importance of biological influences on activities and interests, consistent with the importance of androgen seen in CAH and CAIS. Gender identity, however, is not simply related to prenatal androgen (or to the Y chromosome), given the variability in outcome both within and across studies of *ablatio penis*, *cloacal exstrophy*, and other disorders of sexual differentiation such as *micropenis* and *partial androgen insensitivity syndrome* (e.g., Meyer-Bahlburg, 2005; Wisniewski et al., 2001; Zucker, 1999).

**Normal Variations in Prenatal Hormones.** Considerable progress has been made in examining the generalizability of results obtained in clinical populations. This involves studies of childhood or adult gender-related behavior in relation to hormones obtained in early development from umbilical cord blood, amniotic fluid, or mother's blood during pregnancy (although none directly measure fetal hormone levels) or to markers of prenatal hormones (for review of methods and findings, see Cohen-Bendahan et al., 2005).

A project examining umbilical cord blood in relation to behavior in infancy and childhood generally found few associations that would have been predicted from studies in nonhuman animals and human clinical sam-

ples (e.g., Jacklin, Wilcox, & Maccoby, 1988). Two problems make it difficult to interpret findings: (1) timing of hormone sampling is not optimal (the likely sensitive time for hormonal influences on brain development is prenatal rather than neonatal), and (2) the umbilical cord contains blood from both mother and fetus.

Two projects studied hormones in amniotic fluid in relation to later behavior. Most analyses revealed non-significant associations (Finegan, Niccols, & Sitarenios, 1992; Grimshaw, Sitarenios, & Finegan, 1995; Knickmeyer, Baron-Cohen, Raggatt, & Taylor, 2004; Knickmeyer et al., 2005; Lutchmaya, Baron-Cohen, & Raggatt, 2002a, 2002b) although testosterone was associated with some traits that show sex differences: Testosterone in girls was positively correlated with speed of mental rotation at age 7 (Grimshaw et al., 1995), and testosterone in boys was negatively correlated with eye contact in infancy (Lutchmaya, Baron-Cohen, & Raggatt, 2002a) and positively correlated with restricted interests at age 4 (Knickmeyer et al., 2004). It is unclear whether negative findings indicate lack of association between behavior and testosterone within the normal range or study limitations (e.g., behavioral measures that do not show sex differences, small samples, single measure of testosterone, limited variability in testosterone).

Two studies examining hormones in mother's blood during pregnancy found markers of high testosterone to be associated with masculinized gender role behavior in daughters. A broad measure of gender role behavior in adult females was found to be associated with their own hormones in adulthood, hormones in mother's blood during pregnancy, and their interaction (e.g., Udry, 2000). High levels of masculinizing hormones were suggested to be associated with masculinized behavior, but detailed results were not reported and the specific hormone associated with behavior varied across reports. Consistent with suggestions that prenatal weeks 8 to 24 are the key sensitive period, behavior was related to hormones during the second trimester only. In children aged 3½ years, mother-reported involvement in boy-typical activities was highest in girls whose mothers had high levels of testosterone in blood samples collected between weeks 5 and 36 of gestation (Hines, Golombok, Rust, Johnston, & Golding, 2002). In boys, activities were not related to maternal testosterone.

Increasingly, studies in typical samples have examined associations between behavior and morphological

measures considered "markers" of prenatal hormone exposure. For example, fingerprint patterns, relative finger lengths, and otoacoustic emissions (sounds produced by the ear) have been related to a host of gender-related traits, most prominently sexual orientation, spatial ability, and activity interests. Potentially valuable as nonintrusive, easily collected, retrospective measures of prenatal hormone exposure that can be used at all ages, these markers are not yet suitable for widespread use given insufficient validation (Cohen-Bendahan et al., 2005).

### *Hormone Influences in Adolescence*

Do the changes in sex hormones and physical appearance at adolescence contribute to gender development? Research on pubertal change has focused on possible relations with two general categories of behavior. First, emotion-related characteristics (e.g., negative affect, anxiety, self-esteem, and aggression) are studied because some sex differences in distress and psychopathology emerge at puberty and because hormones are thought to account for adolescents' moodiness. Second, cognitive abilities are studied also because of an emergence or increase in sex differences at puberty (although some sex differences emerge earlier, see 3D) and because variations in abilities have been associated with variations in circulating hormones in adults.

#### **Emotion, Aggression, and Problem Behavior.**

Hormonal increases at pubertal onset generally do not appear to increase negative affect or moodiness in the normal range (Buchanan, Eccles, & Becker, 1992; Susman et al., 1998). But they appear to increase girls' risk for serious depression at puberty, especially in those with genetic vulnerability (Angold, Costello, Erkanli, & Worthman, 1999).

Related studies have examined associations between hormones and affect across the entire pubertal transition. Not surprisingly, such relations are neither simple nor large (and thus not always found; reviewed by Brooks-Gunn, Petersen, & Compas, 1995; Buchanan et al., 1992). For example, in one study of negative affect in girls aged 10 to 14, hormones accounted for 4% of the variance, social factors 8% to 18%, and the interaction of negative life events and pubertal factors 9% to 15% (Brooks-Gunn & Warren, 1989). Absolute hormone levels might be less important than the *changes* in levels (Buchanan et al., 1992).

Hormone effects are clearer in studies linking hormones to aggression and behavior problems, particularly in boys (Buchanan et al., 1992; Susman et al., 1987). In an experimental study of hormone treatment of children with delayed puberty, testosterone in boys and estrogen in girls increased self-reported aggression (Finkelstein et al., 1997). Circulating testosterone is weakly related to aggression,  $r = .14$  from a meta-analysis, similar in males and females, but with larger effects in adolescents than in adults (perhaps due to maximal variability in both measures at this age; Book, Starzyk, & Quinsey, 2001). Even when associations between hormones and behavior are observed, it is difficult to determine causality. For example, testosterone levels increase in adult sports players who win, and in their fans (e.g., Bernhardt, Dabbs, Fielden, & Lutter, 1998; Booth, Shelley, Mazur, Tharp, & Kittok, 1989), with mood a possible mediator of winning's effect on testosterone (e.g., McCaul, Gladue, & Joppa, 1992). Testosterone may not affect aggression per se but may affect social dominance (i.e., attempt to achieve social power such as leadership; e.g., Mazur & Booth, 1998; Rowe, Maughan, Worthman, Costello, & Angold, 2004). Behavioral effects of testosterone also depend on social context: In a longitudinal study of psychopathology, testosterone was related to nonaggressive symptoms of Conduct Disorder in boys with deviant peers and to leadership in boys with nondeviant peers (Rowe et al., 2004).

Other studies have examined affective changes in relation to hormonal changes across the life span beyond puberty; for example, those associated with the menstrual cycle or menopause. In general, these studies find little association between hormones and mood (see Klebanov & Ruble, 1994, for review of menstrual cycle effects), although hormones may trigger depression in vulnerable individuals (Steiner, Dunn, & Born, 2003).

Timing of pubertal onset has behavioral significance (Steinberg & Morris, 2001; Weichold, Silbereisen, & Schmitt-Rodermund, 2003). Early-maturing girls have more emotional distress and problem behavior (e.g., delinquency, substance use, early sexuality) than on-time peers (e.g., Ge, Conger, & Elder, 1996) and these problems persist into adulthood (Weichold et al., 2003). Among boys, late maturers have low self-esteem compared to on-time peers, whereas early maturers are more popular and have better self-image (Ruble & Martin, 1998) but are more likely to engage in delinquent, antisocial, and sexual behaviors and substance use (J. M. Williams & Dunlop, 1999). The relative contri-

butions to behavior of specific aspects of pubertal change, and of social and psychological factors initiated by those changes are being investigated. Social factors that mediate and moderate these effects, especially in girls, include association with older and other-sex peers, childhood problems, parenting practices, and neighborhoods (Caspi, Lynam, Moffitt, & Silva, 1993; Ge, Brody, Conger, Simons, & Murry, 2002; Weichold et al., 2003).

**Cognition.** Circulating hormones relate to patterns of cognitive abilities. Most evidence comes from observational studies in adults, although some confirmation comes from studies in which hormones are administered exogenously (Berenbaum, Moffat, Wisniewski, & Resnick, 2003; Hampson, 2002; Liben et al., 2002). Verbal fluency and memory are enhanced by circulating estrogens beginning at least in adolescence. Spatial ability is enhanced by moderate levels of androgen in adults, that is, levels that are high for normal females and low for normal males. Two recent studies of hormones at puberty produced conflicting results, with one finding effects of testosterone on spatial ability in boys and girls (Davison & Susman, 2001) and another finding no effects of testosterone in boys or of estrogen in girls (Liben et al., 2002).

**Interpretive Issues in Studying Hormone Effects in Adolescence.** Some of the inconsistencies and puzzles about effects of hormones in adolescence reflect the complexity of the effects and the challenges of assessing pubertal hormones. Self- and parent-reports of pubertal development are not good proxies for hormonal status (Dorn, Susman, Nottelmann, Inoff-Germain, & Chrousos, 1990). Even direct hormone assays are limited unless they are repeated to capture intraindividual variability and the pulsatile nature of hormone secretion and are sensitive enough to detect small variations across individuals, especially during early puberty when estrogen levels are below sensitivity limits of conventional assays (J. L. Cameron, 2004).

The multiple determinants of adolescent development have become increasingly obvious, and it is important to study how biological factors exert effects indirectly and interact with social factors to produce gender-related changes during adolescence (e.g., Ruble & Martin, 1998; Susman, 1997). School transitions, to junior high and then to high school, for example, affect children's self-perceptions and mood, especially for girls. Gender

identification or socialization processes prior to adolescence may differentially affect girls' and boys' reactions to adolescent transitions.

### ***Brain Structure and Function***

Ultimately, all aspects of gender development are mediated through the brain. The brain changes in response to environmental events, but there has been less study of the ways in which brain sex differences are shaped by behavioral differences than the reverse. Research concerning structural and functional similarities and differences in male and female brains has increased dramatically with the availability of imaging techniques, including structural magnetic resonance imaging (MRI) to observe fine-grained details of brain structure and functional magnetic resonance imaging (fMRI) to measure brain activation in response to specific tasks, such as looking at emotional pictures or solving a problem. A review of this literature is beyond the scope of this chapter, but we provide a sample of the work and sources for additional information.

**Overall Brain Structure.** Research comparing the brain sizes and structures of men and women has a checkered history. Overall, the brain size of men tends to be 10% to 15% larger than for women, with much of the difference due to differences in body size (Halpern, 2000). Contemporary research has focused less on overall brain size than on sex differences in specific parameters of brain structure and specific brain regions, and whether differences within sex relate to behavior or abilities. There may be sex differences in concentration of gray and white matter (containing cell bodies and fiber tracts, respectively). Some, but not all, studies suggest that females have more cortical gray matter (e.g., Good et al., 2001; Rabinowicz, Dean, Petetot, & de Courten-Myers, 1999; Witelson, Glezer, & Kigar, 1995), whereas males have more white matter (e.g., De Bellis et al., 2001; Giedd et al., 1999). This might have implications for processes involving coordination among multiple brain areas.

### **Organization of the Cerebral Hemispheres.**

Early research on sex differences focused on the two cerebral hemispheres. In most people, the left hemisphere is specialized for language tasks and the right for perceptual and spatial processing, with some variation among individuals in the extent to which the brain is lateralized. Meta-analysis shows that women are somewhat

less lateralized than men, but the difference is small (Voyer, 1996). These functional differences have parallels in structure: Men show more morphological asymmetry than women in parts of the brain, including cerebral hemispheric volume, patterning of gyri and sulci, language-related areas, and distribution of gray matter (Good et al., 2001; Kovalev, Kruggel, & von Cramon, 2003; Yücel et al., 2001). Sex differences in lateralization have been hypothesized to account for differences in cognition and behavior (L. J. Harris, 1978; J. Levy, 1974), but there is little direct evidence. Prenatal testosterone has been suggested to influence lateralization, but effects are likely to be small and difficult to observe, so it is not surprising that results are inconsistent (Bryden, McManus, & Bulman-Fleming, 1994; Mathews et al., 2004). There may also be sex differences in the organization of the brain within the hemispheres (Kimura, 1999).

**Regional Brain Structures.** Sex differences in the size of specific brain regions are suggested to underlie cognitive and behavioral sex differences, for example, differences in orbital frontal cortex or amygdala underlying differences in emotion and differences in temporal lobe relating to language (for summaries and illustrative results, see Goldstein et al., 2001; Nopoulos, Flaum, O'Leary, & Andreasen, 2000; Raz et al., 2004). Results are inconsistent across studies, in part because of methodological variability, sample heterogeneity, and high statistical errors due to small samples and many regions examined. Furthermore, large brain size does not always mean optimal function. Developmental changes in the brain, including sex differences, are only beginning to be understood (Giedd, 2004; Giedd et al., 1999; Gogtay et al., 2004).

The preoptic area of the anterior hypothalamus is of interest because it has a high density of hormone receptors and is sexually dimorphic in nonhuman animals (Wallen & Baum, 2002). One of four nuclei of the human anterior hypothalamus (INAH-3) has consistently been found to be smaller in women than in men and may also be smaller in homosexual than in heterosexual men (e.g., LeVay, 1993).

There is also much interest in the corpus callosum (CC), a bundle of fibers connecting the left and right cerebral hemispheres and allowing transfer of information between the hemispheres. A report on autopsied brains showed certain portions of the CC, especially the splenium, to be more bulbous and larger in women than

in men (de Lacoste-Utamsing & Holloway, 1982). Subsequent studies and meta-analyses, most using MRI in normal individuals, are inconsistent, with some suggesting that women do have a larger CC after adjustment for brain size (Driesen & Raz, 1995), and others concluding that they do not (Bishop & Wahlsten, 1997). Sex differences in CC are potentially important because women's reduced lateralization might be associated with more communication between the hemispheres.

There is need to study the behavioral significance of sex differences in brain size and to consider that correlates of size may differ by sex. In one study (Davatzikos & Resnick, 1998), CC (particularly splenium) size was positively correlated with cognitive performance in women but not in men.

**Regional Brain Function.** Paralleling MRI studies on sex differences in the *size* of specific brain regions are fMRI studies examining sex differences in the *activation* of specific regions in response to psychologically relevant stimuli or tasks. We illustrate work focusing on brain regions that might underlie sex differences in cognition or emotion. In a study of language processing (Shaywitz et al., 1995), women and men activated different brain regions as they decided if nonsense words rhymed, with women using both the left and right inferior frontal gyrus for the task and men using only the left. There was little overlap between the sexes in patterns of brain activation, but the activation difference did not translate into a performance difference, perhaps because the task was easy. In a study of navigation, men and women activated different regions as they went through a three-dimensional virtual-reality maze, which men performed more quickly than women. Men were more likely to use the left hippocampus and women the right parietal and prefrontal regions—a difference suggested to reflect processing differences—that is, men's use of geometric cues versus women's use of landmarks (Grön, Wunderlich, Spitzer, Tomczak, & Riepe, 2000).

The amygdala has been a focus because of its role in processing emotion (Hamann & Canli, 2004). Meta-analysis (Wager, Phan, Liberzon, & Taylor, 2003) revealed no sex difference in overall activation to emotional stimuli, but men show greater lateralized activation, consistent with their generally increased hemispheric asymmetry. Recent studies showed sex differences in specific aspects of emotional processing

(Hamann & Canli, 2004), including sexual arousal (Hamann, Herman, Nolan, & Wallen, 2004).

**Hormones and the Brain.** Empirical studies are beginning to test hypotheses about the role of hormones in brain sex differences and about the ways that the brain mediates behavioral effects of prenatal and circulating hormones. Initial imaging studies of brain structure in females with CAH have not shown them to differ from controls (Merke et al., 2003). Future work might focus on task-specific brain *activation* related to activity interests and spatial ability, examining brain regions likely to subserve those behaviors (e.g., parietal lobe and hippocampus for spatial ability). With respect to circulating hormones, there is some evidence that estrogen affects gender-related cognition through effects on brain activity (Maki & Resnick, 2001). Future work might focus on how pubertal hormones affect the brain differently in the sexes, resulting in the rise in depression in girls and aggression in boys.

### *Integration and Conclusions*

The biologically-oriented work of the past few years has enhanced knowledge about hormonal influences on gender development and potential neural mechanisms that mediate both hormone effects and environmental input. Just as sex hormones affect the body, they also influence behavior. Hormones present during early development (organizational effects) play a substantial role in aspects of gender development, particularly self-perception, preferences, and behavioral enactment (columns B, C, and D of the matrix) of some content areas. Prenatal androgens influence activities and interests (row 2 in the matrix), some personal-social attributes (row 3), such as interest in babies and spatial abilities, and aspects of gender-based social relationships, such as play and sexual partners (row 4), with smaller effect on psychological aspects of categorical sex (row 1). Most evidence comes from individuals with clinical conditions, primarily girls with CAH. The limitations of these natural experiments are being overcome, and there is increasing confirmation from typical samples for behavioral effects of hormones.

Many important questions remain unanswered about hormone effects on gender development. Do prenatal hormones affect gender-related styles and values (rows 5 and 6) or concepts and beliefs (column A) of any content area? How do prenatal and pubertal hormones affect

the *development* of gender-typing? Why do hormones have different effects on different characteristics, with prenatal androgen having a big effect on some (e.g., activities and interests), a modest effect on others (e.g., sexual orientation), and a small effect on still others (e.g., gender identity)? Biological and social moderators of hormone effects likely vary across aspects of gender-typing and account for variations within and between the sexes. What are the psychological mechanisms that mediate the effects? For example, what is it about boys' toys that makes them attractive to children who have been exposed to high levels of androgen during prenatal development? Infant males and females differ in some sensory and perceptual characteristics (McGuinness & Pribram, 1979) and perhaps androgen effects on these characteristics mediate effects on toy play (Alexander, 2003). Hormones also affect peripheral structures, such as muscles, and these might affect behavior.

Sex hormone increases during adolescence do not have many direct behavioral effects within the normal range, but they may increase girls' depression and boys' aggressiveness and behavior problems. The complexity of hormone-behavior links is highlighted by evidence showing that behavioral changes at puberty may be mediated by social and psychological changes, such as peer associations. Sex hormones circulating in the body throughout adolescence and adulthood influence gender-related behavior, but generally different aspects than are influenced by prenatal hormones, with particular effects of estrogen on memory, and androgen on social dominance.

Brain structure and function also differ in some ways between the sexes, including regions involved in gender-related behavior. But it is necessary to make the explicit link between the brain and behavior and to show how the links are forged—for example, how structural differences are produced by prenatal exposure to sex hormones, and how patterns of brain activation are affected by sex-differential experience and circulating sex hormones at puberty. An area that has been neglected concerns neural processing of gender concepts and beliefs. Is gender processed in the brain in the same way as other categories? What are the neural correlates of stereotyping? How does the brain change with interventions to reduce stereotyping, and what does that tell us about the formation and maintenance of stereotypes?

There is increasingly sophisticated understanding of biological effects and recognition that they are not im-

mutable. Genes are activated or suppressed by environmental factors. Hormones and brain functioning are almost certainly influenced by the different environments in which girls and boys are raised, by their different toy and activity choices, and by joint effects of genes and the social environment.

### Socialization Approaches

Gender permeates every aspect of a child's social environment. In Bronfenbrenner's (1977) terms, the meaning of gender is communicated through the cultural values and practices of the macrosystem (e.g., power and economic differentials between men and women), which in turn influence the microsystems a child experiences at home, school, and neighborhood (Leaper, 2002). But how do we conceptualize the direct and interactive effects of these various influences? Which features from the environment are noticed and incorporated into gender development, *and* by what processes? In this section, we tackle such questions as we summarize the past 10 to 15 years of socialization research.

### Socialization Processes

In the 1970 *Handbook*, Mischel presented the social learning perspective on the development of gender-typing. This perspective calls attention to direct reinforcement for conformity to gender norms, as when adults compliment a girl when she wears a dress but not when she wears pants. In addition, social learning theories (as well as other theories: e.g., S. L. Bem, 1981; Kohlberg, 1966; Martin & Halverson, 1981) emphasize the importance of observational learning. Children may engage in more same- rather than other-sex behavior because they are differentially exposed to same-sex models (Crouter, Manke, & McHale, 1995), and children's tendencies to segregate by sex means that they are exposed more often to same-sex peers than other-sex peers (Maccoby, 1998; Martin & Fabes, 2001).

In the past 30 years, social learning perspectives have undergone a number of modifications and elaborations (Bandura, 1986). Social cognitive theory was recently applied to gender development by Bussey and Bandura (1999), highlighting a central role for cognitive processes. For example, when children attend to same-sex models, they are assumed to focus on and extract information about how behaviors are enacted, the

sequencing of events, and the consequences associated with enacting behavior. We describe social cognitive theory in this section on socialization processes, rather than in the following section on cognitive processes, because it focuses on traditional learning principles of reinforcement and observation in the initial stages of gender development (Liben & Bigler, 2002).

Bussey and Bandura's (1999) description of these principles improved on early accounts in several ways. Generalized imitation of same-sex models had not been found in earlier research (Huston, 1983; Maccoby & Jacklin, 1974), and Bussey and Bandura showed the importance of the conditions under which children imitate behavior. For example, children may not imitate a single same-sex model, but they are likely to learn from multiple models engaged in the same activity.

Moreover, in social cognitive theory, observational learning is not confined to imitation of same-sex models. Instead, children learn abstract rules and styles of modeled behaviors. By attending to models of both sexes, children construct notions of "appropriate" appearance, occupations, and behavior for each sex, and use these stereotypes to develop complex concepts about gender-appropriate behavior. Thus, a boy may develop a unique style of rough-and-tumble play based on observations of multiple boys engaging in different games and girls not participating. Further, children's performance of these learned behaviors depends on incentives and sanctions associated with the outcomes of engaging in these behaviors. Through such experiences, children develop outcome expectancies and self-efficacy beliefs that become linked to gender-related behaviors, which serve to motivate and regulate gender role conduct. Although such regulatory processes are originally environmentally determined, Bussey and Bandura (1999) describe a period in early development when they become internalized, as children administer self-praise or self-sanctions in relation to a set of personal standards for gender conduct.

Finally, these environmental events are not viewed as the only source of gender learning in social cognitive theory. Instead, a triadic reciprocal model of causation is proposed, in which personal (i.e., cognitive, affective, and biological factors), behavioral, and environmental factors interact to determine gender-related conduct (see Bandura, 1986; Bussey & Bandura, 1999, for details).

In the following sections, we review the evidence regarding the impact on gender development of social ex-

periences/socialization processes in the family, among peers, at school, and via the media. These studies speak to the general social learning principles of reinforcement and observational learning, though few have examined the shift from external to internal regulation. The only study directly examining this issue suggested that children learn to guide their own gender-linked conduct with self-evaluative reactions between 3 to 4 years of age (Bussey & Bandura, 1992), but the lack of longitudinal data and other limitations (Martin et al., 2002) preclude definitive conclusions.

### *Gender Socialization in the Family*

The family provides many types of socialization experiences, including models of gender roles and differences in the ways sons and daughters are raised. The following sections outline effects of family socialization experiences on several aspects of children's gender development.

**Encouragement of Gender-Typed Activities and Interests.** Caregivers influence gender development by providing boys and girls with distinct social contexts (e.g., toys and room furnishings; Pomerleau, Bolduc, Malcuit, & Cossette, 1990; Rheingold & Cook, 1975). Gender-typed environments may subtly channel children's preferences and engagement in activities.

Meta-analysis of parents' differential treatment of boys and girls (Lytton & Romney, 1991) showed the clearest effect for encouragement of gender-typed activities (versus areas such as personality traits). For example, parents offer gender-stereotypic toys to children during free play, and they are more responsive when children are engaged in same-gender play than when they are engaged in other-gender play. The effect was moderate ( $d = .43$ ), somewhat stronger for fathers than for mothers, and decreased with the child's age. Recent research on this pattern (e.g., Caldera & Sciaraffa, 1998) extended it to cultures other than middle-class Caucasian (e.g., Raffaelli & Ontai, 2004) and revealed other means of parental encouragement of gender-typed play (Leaper, 2002). For example, communication patterns between mothers and their preschool children depended on whether children were engaged in gender-typical or gender-atypical play (Leaper, Leve, Strasser, & Schwartz, 1995). Nevertheless, other research suggests that parents often treat young children in non-stereotypic ways, such as buying gender neutral toys for

children when they are not requested by the child (e.g., Fisher-Thompson, 1993). Thus, contemporary efforts to foster sex-differentiated play may often be subtle or limited, and many parents may make conscious efforts to encourage egalitarian behaviors.

What is the effect of encouraging gender-typed play? In our last review (Ruble & Martin, 1998), we concluded that parents of very young children appear to promote precocious learning of gender distinctions when they encourage gender-typed play. Encouragement of particular activities may also influence children's learning of cognitive and social skills (Caldera et al., 1999). Boys' toys, such as blocks, model building, and manipulative toys, encourage the development of visual/spatial skills, problem solving, independent learning, self-confidence, and creativity, whereas dolls and domestic items provide girls with practice in learning rules, imitating behaviors, using adults as sources of help, and solving familiar problems (Martin & Dinella, 2002). Parents may also provide daughters and sons differential experiences that foster different social cognitive skills (Leaper, 2002). For example, parents' greater focus on explanations of scientific content in museums for boys than for girls may foster boys' greater interest in and knowledge about science (Crowley, Callanan, Tenenbaum, & Allen, 2001). In addition, parents' assignment of household chores along gender stereotyped lines (Antill et al., 1996) may have implications beyond learning particular skills. For example, children's involvement in family care work has been associated positively with prosocial concerns (Grusec, Goodnow, & Cohen, 1996).

In our last review (Ruble & Martin, 1998), we indicated that little is known about the role of parental encouragement of gender-typed play on subsequent play preferences and behaviors. That is still the case; it is still not clear how important parent socialization is to the emergence of individual differences in young children's preferences and displays of relatively female- or male-typical behavior. Some research has found significant but weak correlations between parent behaviors and children's preferences and behaviors, such as a relation between encouragement of physical behaviors by parents and children's physical play with peers (Lindsey & Mize, 2001). As Eisenberg, Wolchik, Hernandez, and Pasternack (1985) suggested, an important "tool" for gender socialization is channeling or shaping, as when socializing agents structure the environment in a way that limits choices, such as providing only dolls for girls

and trucks for boys. Given this kind of control, parents may not need to differentially encourage certain kinds of play during actual interactions, because the situation dictates the desired behavior.

**Encouragement of Gender-Typed Personal-Social Attributes.** Huston (1983) concluded that parental socialization practices influence the development of gender-typed personality characteristics in children. Meta-analysis (Lytton & Romney, 1991), however, failed to find significant effects for amount of interaction, encouragement of achievement, warmth and responsiveness, encouragement of dependency, restrictiveness/low encouragement of independence, disciplinary strictness, or clarity of communication/use of reasoning. But some limitations in the analysis suggest that it is premature to conclude that the only way parents treat boys and girls differently is by encouraging gender-typed behavior, especially because conclusions depend on how studies are combined to compute effect sizes. For most domains, studies showed effects in both directions, but reasons for heterogeneity were not explored. Moreover, a focus on broad socialization domains, such as warmth or restrictiveness, may mask significant specific effects, such as the extent of supportive versus directive speech (McHale et al., 2003). Broad groupings may also obscure effects when socialization practices in different domains have similar effects. For instance, sex differences in self-evaluative processes may be linked to seemingly quite distinct socialization practices (Leaper, 2002) such as differential control versus autonomy-granting in the home (e.g., Pomerantz & Ruble, 1998) and greater encouragement of empathy and feelings of responsibility in girls than in boys (e.g., Zahn-Waxler, Cole, & Barrett, 1991). Because such socialization processes cut across the different domains, it would be difficult to identify them in meta-analysis.

Recent research suggests promising approaches to examining when and how boys and girls are treated differently in the family. One important new direction focuses on context and the recognition that parental socialization is embedded in a larger family system (McHale et al., 2003). For example, families' sensitivity to gender-related differential treatment may be exacerbated when there are both boys and girls in the house. Consistent with this idea, parents respond more differentially to boys and girls in mixed-sex than same-sex sibling dyads (McHale et al., 2003). A particularly interesting finding

is that siblings from mixed-sex dyads with a traditional father exhibited the most sex-typed leisure activities and parent-child activities (McHale et al., 1999).

A second new direction focuses on the subtleties of gender socialization practices, suggesting that they may be implicit rather than explicit (Gelman, Taylor, & Nguyen, 2004). For example, microanalysis of everyday social interactions among the Kaluli showed how mothers use language and games to teach children adult gender roles and characteristics, even though direct reference to gender only occurs when norms are violated (Schieffelin, 1990). Recent research has identified a number of subtleties in gender-related language and communication. Pomerantz and Ruble (1998) found that although overall communication of control in the home did not differ for girls and boys, control communications were more often accompanied by autonomy granting messages for boys than for girls. In an analysis of mothers' speech patterns during reading of stories, mothers explicitly espoused egalitarian views but implicitly made gender concepts salient, for example, through labeling of gender and contrasting male and female gender categories (Gelman et al., 2004).

Although sex-differential socialization practices may be subtle, complex, and context-dependent, parents do show different treatment of sons and daughters in some very important ways that are broader than the assignments of chores or encouragement of activities or traits (Leaper, 2002). For example, mothers' tendencies to be more talkative with daughters than sons may contribute to sex-differentiated language learning (Leaper, Anderson, & Sanders, 1998). Parents also vary the nature and frequency of their discussion of emotions with young sons and daughters (e.g., Fivush, Brotman, Buckner, & Goodman, 2000). Such gender-differentiated patterns of parent-child interaction in the domain of emotions may contribute to boys learning to control their emotions and girls learning to express them (Eisenberg, Cumberland, & Spinrad, 1998).

Parents also hold stereotypic beliefs that boys and girls have different attributes and skills, even when they are not different. For example, mothers of 11-month-olds underestimated girls' motor skills and overestimated boys' skills, but tests showed no sex differences in motor performance (Mondschein, Adolph, & Tamis-LeMonda, 2002). In a different domain, parents expected sons to find science easier and more interesting than daughters, despite a lack of difference in performance (Tenenbaum & Leaper, 2003). Such beliefs and

expectations appear to influence adults' perceptions and behaviors toward their children, and even the children's own perceptions and behaviors. In an impressive program of research, Eccles and her colleagues (e.g., Fredricks & Eccles, 2002) found that parents who hold stronger stereotypes regarding the capabilities of boys and girls in English, math, and sports had differential expectations regarding their own children's abilities in these subjects, which were in turn related to the children's performance and self-perceptions of competence, even when actual ability levels were controlled. Such relations appear to be mediated, in part, by parents' tendencies to provide different experiences for sons and daughters, such as enrolling sons more often in sports programs.

Finally, early studies suggested that differential treatment may also occur through reciprocal role enactment processes in which fathers encourage femininity in daughters and mothers encourage masculinity in sons (Huston, 1983; Ruble & Martin, 1998). Parents may also feel a greater commonality and responsibility for socializing same-sex children, and thereby exert closer control over them. Because most children spend more time with female than male caregivers, such responses may represent a significant type of differential treatment, though it has been relatively understudied.

**Role Models in the Home.** In what ways do parents act as role models, thereby influencing their children's attitudes and behaviors? Maternal employment has been associated with less stereotyped concepts and beliefs in both boys and girls and less gender-typed preferences and behaviors in girls (Ruble & Martin, 1998). Relations between maternal employment and egalitarian beliefs and behaviors may reflect access to nontraditional role models, but other variables associated with maternal employment are probably also involved, such as nontraditional attitudes in the home or exposure to different kinds of information outside the home (L. O. Hoffman, 1989; McHale et al., 2003).

Despite the many processes that might lead maternal employment to be associated with nontraditional beliefs, findings are inconsistent. Many other factors likely moderate the relation between maternal employment and children's gender traditionality, such as mothers' reasons for working (Katz & Boswell, 1986) and father's involvement (Grych & Clark, 1999). Furthermore, maternal employment may reflect socioeconomic status, which is itself related to nontraditional gender concepts.

When demographic variables were controlled in one study, there were few effects of maternal employment on gender concepts and preferences (Serbin et al., 1993). Failures to find effects of maternal employment in recent research may also be due to the prevalence of maternal employment, which both reduces variability and exposes children to women in the workplace, regardless of whether their own mother works outside the home.

A few studies have examined effects of other nontraditional family roles on gender development. An egalitarian division of labor in the home (or father involvement) relates to many aspects of children's gender development, such as less traditional occupational and peer preferences (Serbin et al., 1993), and less traditional gender role attitudes and behaviors (McHale et al., 2003), although such effects are not consistently found (e.g., Weisner, Garnier, & Loucky, 1994).

**Parental Attitudes and Values.** To what extent are children's gender concepts related to general measures of gender orientation in the home, such as parents' perceptions of their own attributes, attitudes about equality, or nonegalitarian lifestyles? Early research suggested that caregivers who view themselves in traditional terms or who hold traditional attitudes foster the learning of gender distinctions in their children, such as earlier learning of gender labels and stereotype knowledge (Ruble & Martin, 1998). Some recent research has failed to confirm this (O'Brien et al., 2000), perhaps because the children were beyond toddler age.

Parental attitudes have also been associated with children's gender-typing, including the distribution of gender-typed chores to sons and daughters (e.g., Blair, 1992) and children's own gender attitudes (e.g., Mchale et al., 1999). Such relations are not always consistent across different measures of gender-typing, even in the same study, and are often moderated by other factors such as birth order (McHale et al., 1999). For example, meta-analysis of the relation between parents' gender schemas and child outcomes (Tenenbaum & Leaper, 2002) showed that effects were large for parent-daughter pairs and for parents of older children and adolescents.

Research would benefit from an approach recognizing cultural and historical variations in gendered attitudes (Leaper, 2002; Mchale et al., 2003). For example, adult African Americans (especially women) are likely to reject traditional gender divisions (Kane, 2000), many Latin cultures are marked by strong gender role divisions (Raffaelli & Ontai, 2004), and data from the

National Opinion Research Center's General Social Surveys for 1974 to 1994 suggest a shift toward egalitarian gender role attitudes in the United States (R. J. Harris & Firestone, 1998).

**Alternative Family Structures: Single Parenting and Gay and Lesbian Parenting.** Nontraditional families are interesting because role modeling and differential reinforcement are likely to differ from those in two-parent heterosexual families. For example, single parents may have less gendered roles than those in two-parent families. Because mothers usually have custody, children receive less exposure to male role models at home. To the extent that fathers take responsibility for masculinizing sons (Huston, 1983; Mchale et al., 2003), father absence should be associated with less traditional gender-typing in boys. Early studies (Huston, 1983) including meta-analysis (Stevenson & Black, 1988) showed very small effects of paternal absence on gender development, so perhaps it is not surprising that recent research is mixed (e.g., Stevens, Golombok, Beveridge & Avon Longitudinal Study of Parents and Children Study Team, 2002). Effects may be subtle (Leaper et al., 1995), occur only for cognitive variables, such as stereotypic knowledge (Serbin et al., 1993), or vary across behavior and child age and sex (e.g., older father-absent boys are more stereotypical in overt behavior, particularly aggression; effects are generally lacking in girls, except perhaps on femininity in adolescence).

These effects are important theoretically. For example, nontraditional gender role attitudes of African American children may relate to the prevalence of children reared by a working, single mother (Leaper, 2002). Further, findings that boys but not girls are affected by paternal absence support theories emphasizing identification and modeling. Minimal effects for girls, however, are inconsistent with hypotheses about reciprocal role socialization processes (e.g., E. Williams, Radin, & Allegro, 1992). Perhaps these processes are important in adolescence and account for earlier findings (Huston, 1983) that father absence is associated with difficult heterosexual relationships in adolescent girls.

Not surprisingly, other types of nontraditional family structures are also associated with less traditional gender-typing in children. For example, girls raised by lesbian couples show less female-typical clothing, activity, and occupational preferences relative to girls raised by heterosexual couples (Stacey & Biblarz, 2001), although effects are small and children from these families are

within conventional gender norms (Patterson, 2000). Research efforts should be directed to specific processes in the home (e.g., division of labor; parental attitudes) rather than the family structure itself (McHale et al., 2003).

**Sibling Effects.** Do children learn gender-related attributes and interests from their siblings? Early research showed that children with few or no siblings are more likely to have gender egalitarian beliefs, suggesting that siblings promote gender-typing (Ruble & Martin, 1998). Recent research suggests stronger socialization effects of siblings than of parents (McHale et al., 2003), but sibling effects are inconsistent, depending on age, birth order, and whether they are the same sex (Crouter et al., 1995; Mchale et al., 2003). Although sibling relationships have generally been conceptualized in terms of modeling, they may also be characterized by needs to individuate, especially in adolescence (McHale, Updegraff, Helms-Erikson, & Crouter, 2001).

### *Gender Socialization at School*

Schools provide a wide array of gender-related messages to children. Their structures provide gender messages because men tend to be in positions of power and women are teachers of younger children. Teachers treat boys and girls differently and hold differential expectations of their abilities. Classrooms provide children with opportunities to learn about the consequences of behavior through observing peers.

**Differential Treatment.** Teachers interact differently with girls and boys at every level of schooling. Teachers of infants and toddlers may shape behavior by reinforcing stereotypic expectations about girls' and boys' behavior even when no sex differences are evident. Preschool teachers encourage gender-appropriate play and discourage gender-inappropriate play. Throughout the school years, teachers not only interact and attend more to boys than to girls but also interrupt them less (see Ruble & Martin, 1998). Effects vary across grade, with teachers in lower grades showing more sex-differentiated responses than do high school teachers, except that high school boys continue to receive more criticism from teachers than do girls. In high school, teacher responsiveness depends on the sex of the teacher and the course subject (Hopf & Hatzichristou, 1999).

For instance, female mathematics teachers and language teachers of both sexes interacted more with male than female students (Duffy, Warren, & Walsh, 2002).

An interesting issue is whether teacher responsiveness reflects bias or students' willingness to volunteer answers. Elementary school teachers called on boys more than girls, but girls and boys were equally likely to be called on when they volunteered (Altermatt, Jovanovic, & Perry, 1998), whereas high school teachers' greater interactions with male students were not driven by boys' verbal comments to teachers (Duffy et al., 2002).

Teachers hold differentiated views of girls and boys. They believe that elementary school boys are better than girls in science and math (e.g., Tiedemann, 2000). They also view girls' and boys' classroom behavior differently; for instance, lying and cheating are seen to be more undesirable in girls than boys, and hyperactivity and quarrelsomeness are more serious for boys than girls (Borg, 1998). However, in naturalistic settings, teachers form relatively accurate perceptions of students based on children's characteristics (e.g., achievement and motivation) and only occasionally rely on stereotypes about sex (Madon et al., 1998). Much attention has been paid to whether teachers develop self-fulfilling prophecies of students' abilities and whether these beliefs account for student success. Overall, these effects are small, but may endure (A. E. Smith, Jussim, & Eccles, 1999). Effects may be more pronounced for some children than others; for instance, girls in mathematics classes may be more negatively influenced by low teacher expectations than girls in female-stereotypic classes (McKown & Weinstein, 2002).

Finally, school practices may foster perceptions of sex differences. Boys and girls may be kept in segregated groups for even minor activities such as standing in line. Differing contexts and activities may influence behavior. The highly structured activities of girls may elicit higher rates of feminine-typed social behaviors, such as asking for help, whereas the low-structured activities of boys may elicit higher rates of masculine-typed behaviors, such as leadership attempts toward peers; alternatively, children may engage in structures that allow them to display their preferred behaviors (Ruble & Martin, 1998).

**Role Models in School.** Schools provide children with gender-related information through roles played by men and women. Men are disproportionately repre-

sented in positions of power and administration, whereas women are often teachers, particularly in the early grades. Only in older grades are children likely to have male teachers, and these are often in male-typical classes such as mathematics and science.

There are two main issues relevant to the impact of role models on gender development. First, does exposure to male teachers affect gender concepts? The dearth of male teachers in elementary school and its implications for gender-typing has generated considerable debate, but little research has directly examined this question (Hopf & Hatzichristou, 1999). Some data suggest that male teachers foster nontraditional gender beliefs and preferences and nontraditional views of teachers perhaps because they are in female-typical roles (Ruble & Martin, 1998).

Second, is same-sex education better than coed-education? The evidence is mixed. Some evidence suggest that same-sex education has a positive effect on females' achievement (e.g., Lee & Bryk, 1986; Mael, 1998), whereas other recent studies do not show that these classes are better for girls' or boys' achievement or in changing gender conceptions (Harker, 2000; Signorella, Frieze, & Hershey, 1996; Warrington & Younger, 2003).

### *Peers*

Classic studies in the 1970s and 1980s explored peers' roles in socializing gender development through reinforcement and role modeling. Although these processes continue to be emphasized as mechanisms involved in peer socialization, another approach has become prominent—children are broadly socialized through exposure to same-sex peers. This “separate cultures” perspective presumes that children spend a significant amount of time with their own sex and thus selectively learn the behaviors and interaction styles associated with their own sex and not much about other-sex interactions and play styles (Leaper, 1994; Maccoby, 1998; Thorne, 1986).

**Differential Treatment.** Most studies of peer reinforcement of gender-appropriate behavior were conducted by Fagot and colleagues during the 1970s and 1980s (e.g., Fagot, 1977), and there are few recent studies. These classic studies showed that, by age 3, children respond differentially to gender-typed behavior in others (Huston, 1983; Ruble & Martin, 1998). Peers responded to boys' assertive behavior more than to girls'

(Fagot & Hagan, 1985) and were more negative to boys who engaged in female-typical behaviors, especially those who did not engage in male-typical behaviors (Fagot, 1984). Recent research on differential treatment, rather than examining reinforcement, focuses on rejection or dislike. Both sexes dislike others who are aggressive, but girls are more negative about externalizing behavior in peers, and boys are more negative about anxious and depressed behaviors, suggesting that both sexes are more tolerant of gender-typed behavior (Waas & Graczyk, 1999). Children of both sexes exhibiting extreme gender-nonnormative behaviors are teased and disliked by peers, with boys receiving more teasing for their behavior than girls (Zucker & Bradley, 1995).

**Peer Models.** Although peers are presumed to socialize gender development by serving as role models, this has not been well studied. Early studies demonstrated that children learn standards for gender-appropriate behavior through observation, as discussed earlier. It is less clear whether peer modeling of gender-inconsistent behavior can promote change. Simply observing peer models engage in gender-inconsistent behavior did not change young children's behavior unless the model's behavior was reinforced (Katz & Walsh, 1991). Under certain circumstances, other-sex role models can dissuade children from “own-sex appropriate” preferences, but children also consider the perceived appropriateness of the activities encouraged (Harrison & O'Neill, 2000).

Children and adolescents may also try to live up to images of what behavior is “cool” or leads to popularity and high status. Preadolescent boys achieve status via athletic ability, toughness, and social skills, whereas girls' status relates to physical appearance, social skills, and parents' socioeconomic status. Characteristics valued by high school students vary by sex and ethnicity: For Caucasian adolescents, both sexes value peers who are high achievers; for African American and Latino adolescents, girls value peers who are high achievers but boys devalue achievers (Graham, Taylor, & Hudley, 1998).

**Socialization in Sex-Segregated Play.** Increasing recognition has been given to peers' role in gender development because of the opportunities they provide to learn interactional styles and behaviors (see Ladd, 2005; Leaper, 1994; Maccoby, 1998 for reviews). In particular, emphasis has been given to the role of sex-segregated

groups and how this produces “separate cultures” (Maccoby, 1998; Thorne, 1986) because children’s time with same-sex peers exposes them more to same-sex than other-sex behaviors and interaction styles, narrowing their behavioral repertoire. “The essence of these cultures is a set of socially shared cognitions, including common knowledge and mutually congruent expectations, and common interests in specific themes and scripts that distinguish the two sexes” (Maccoby, 2002, p. 57). Although this perspective has gained broad support, it has also been questioned for its ability to adequately capture the complexity of children’s social interactions, particularly influences of social contexts, and variations in play partners (see Thorne, 1993; Underwood, 2003; Zabatany, McDougall, & Hymel, 2000).

What is the evidence for the power of peers on children’s gender development? Although not all the evidence is consistent on these points, sex segregation in certain settings with older children may lessen gender-stereotypes; for example, there is some evidence that all-female schools and math classes promote nontraditional attitudes (e.g., Lee & Bryk, 1986), allow greater exposure to successful role models, and reduce differential teacher responsiveness and peer pressures compared to mixed-sex groupings (Ruble & Martin, 1998). Sex segregation in play situations with younger children shows a different pattern. With same-sex peers, children practice gender-typed play with toys and learn behavioral patterns that facilitate interaction with their own sex and limit interaction with the other sex (Leaper, 1994; Maccoby, 1998). A recent study (Martin & Fabes, 2001) suggests a *social dosage effect* in children’s socialization by peers, in which preschool children with higher levels of same-sex play early in the school year increased in gender-typed behaviors later in the school year more than children who had lower levels of same-sex play, and these effects were beyond those that initially drew children into sex-segregated groups. Boys increased in rough-and-tumble play, aggression, gender-typed activities, and playing away from teachers; girls decreased activity and aggression and increased gender-typed play and play near adults. In young children, sex-segregated interactions appear to have the potential to move the behavior of girls and boys in gender-typed directions even with relatively limited exposure.

Sex-segregated play also influences school readiness (Fabes, Martin, Hanish, Anders, & Madden-Derdich, 2003; Martin & Dinella, 2002) and can facilitate or ex-

acerbate existing behavioral tendencies. For example, highly arousable children who play with same-sex peers show changes in behavior problems—increased for boys and decreased for girls. Playing with other highly arousable boys does not appear to help boys regulate their behavior, but girls’ calm play may help arousable girls learn control (Fabes et al., 1997). Although it is difficult to disentangle the consequences of peer socialization from the selection factors that draw that children together, analyses suggest a transactional pattern at work (Hanish, Martin, Fabes, Leonard, & Herzog, 2005; Martin, Fabes, Hanish, Leonard, & Danella, 2006).

Many interesting questions about peer socialization remain unanswered. A particularly important question concerns the nature of the processes that enable peers to influence children’s gender development. Addressing this issue requires identification of the varied nature of peer relationships and the effects of such variations (Gest, Graham-Bermann, & Hartup, 2001). Future research also should identify the situations and processes that lead to different outcomes (e.g., more versus less stereotyping) associated with sex-segregated environments.

### *Observational Learning from the Media*

Children spend much of their free time watching television, so it is not surprising that media effects are a central issue in gender development. Exposure to popular media has greatly expanded—there are hundreds of cable channels, many more music channels, and increased access through DVDs, TiVo, and videos. Other powerful forms of media, such as computers and the Internet, also provide children with extensive exposure to messages about gender (Roberts, Foehr, Rideout, & Brodie, 1999; Subrahmanyam, Kraut, Greenfield, & Gross, 2001; Vandewater, Shim, & Caplovitz, 2004). Correlations have been demonstrated between exposure to media and many types of behavior (e.g., drug use, sexual behavior, and aggression), leading researchers to argue for powerful and pervasive media influences on child development (Ward, 2003).

Both sexes spend much of their time watching television, and boys do so more than girls throughout childhood (Huston et al., 1999) but not in adolescence (Huston & Wright, 1998). Boys also spend more time than girls playing video games, watching sports, cartoons, action-adventure, and fantasy programming, and using computers, whereas girls spend more time watching relationship and comedy programming, with the dif-

ferences increasing across childhood (Huston et al., 1999; Lemish, Liebes, & Seidmann, 2001; Subrahmanyam et al., 2001; Wright et al., 2001) and in adolescence (Roberts & Foehr, 2004). Children are aware of sex differences in entertainment preferences: Three- to 9-year-olds recognize that action adventure programming should be appealing to boys more than girls (Oliver & Green, 2001).

Despite social changes of the late 1990s, the sexes continue to be portrayed in stereotypic ways, with some improvements (see Huston & Wright, 1998). Messages transmitted through the media are still highly stereotypic, teaching about and reinforcing traditional gender roles (Signorielli, 2001).

There are two broad concerns about media portrayals of the sexes. First, underrepresentation of females suggests devaluation. Early studies showed strong bias, with more males than females presented in virtually every domain (except daytime soap operas), and females occupying about one quarter to one third of televised roles (Signorielli, 1993). Underrepresentation of females has continued (Signorielli & Bacue, 1999).

Second, the sexes are portrayed in stereotypic ways regarding occupations, personality characteristics, social relationships, appearance, dress styles, and the value and desirability of roles. Some small changes have been made, such as portraying women in somewhat more prestigious careers (Signorielli & Bacue, 1999), but there continues to be stereotyping of occupational and appearance portrayals. For example, women tend to be young, thin, provocatively dressed, and beautiful, whereas men tend to be older and muscular (Signorielli & Bacue, 1999). Men are less likely than women to be portrayed cooking, cleaning, washing dishes, and shopping (Kaufman, 1999). The personality characteristics demonstrated by the sexes also continue to be stereotypic (Signorielli, 1993) and women are presented as sex objects more than men (Coltrane & Messineo, 2000; Lin, 1998). Gender-typing of roles also has been common in commercials (Furnham, 1999).

Children's programs present a more gender-typed picture of the world than do adult programs. Males outnumber females in all types of programming, including educational ones, as much as four or five to one in cartoons (Signorielli, 2001). Characters' roles continue to be stereotyped, although less than in the past. Female cartoon characters in the 1990s were more likely to be assertive, intelligent, and independent than characters

10 to 20 years earlier, but were still shown in traditional roles (i.e., emotional, romantic, and domestic). Male characters in the 1990s were presented as being more intelligent, more technical, and more aggressive but also less boastful than earlier characters (T. L. Thompson & Zerbinos, 1995).

Children's literature contains stereotypic messages about gender roles, although less so now than in the past. Girls, however, are still depicted as dependent and needing help more often than boys. Even "nonsexist" books show females in relatively limited roles (Dickman & Murnen, 2004). Girls are now more likely to be portrayed in masculine roles but boys are seldom shown possessing feminine traits (L. Evans & Davies, 2000). Females continue to be underrepresented in illustrations even when they are evenly portrayed as main characters in picture books (Gooden & Gooden, 2001). Classic children's literature also shows children in stereotyped characters (see Ruble & Martin, 1998).

Media for adolescents depict the sexes in stereotypic ways. In music-oriented broadcasting (and accompanying advertisements), women are underrepresented, and 10 times more likely to be dressed in revealing clothing than are men (Sommers-Flanagan, Sommers-Flanagan, & Davis, 1993). Video games are violent and stereotypic, with women often portrayed as sex objects (Dietz, 1998). Teen magazines for girls are highly stereotyped, with much attention paid to physical appearance, body weight, and relationships with others; magazines for boys provide entertainment and information about hobbies and activities (Malkin, Wornian, & Chrisler, 1999).

**The Influence of Gender-Stereotypic Portrayals of the Sexes.** What role does television play in children's gender socialization? It is very difficult to study the causal influence of something so pervasive in our culture. Researchers have used correlational and longitudinal studies, and natural experiments to determine whether media influences gender-related behavior and attitudes.

Some correlational studies report that children who are heavy, consistent television viewers generally hold more stereotypic beliefs about the sexes than light viewers (e.g., Huston et al., 1992). Children as young as age 5 are aware of gender stereotypes on television and are able to predict whether males or females would be in particular roles on television (Durkin & Nugent, 1998). For adolescents, frequent exposure to sexually oriented

media (i.e., soap operas, music videos) is associated with more stereotypical and casual attitudes about sex (Ward, 2003). The major problem with such studies is determining the direction of influence. Television may be influencing beliefs or heavier viewers find television more appealing because it presents images that are consistent with their beliefs.

Meta-analyses of experimental and nonexperimental studies show an association between frequent television viewing and more stereotypic beliefs about gender roles (e.g., Morgan & Shanahan, 1997). Effect sizes are small ( $r = .10$ ) but meaningful because they are consistent and because so many people are exposed to television that it is difficult to find unexposed individuals, thereby making large effects unlikely. However, it is difficult to draw firm conclusions from the correlational studies because of the inability to determine the cause of the association.

Therefore, important data come from longitudinal studies examining relations between television viewing at one time and gender-related attitudes and behavior later in time. For example, an extensive examination of viewing habits of preschoolers and a follow-up of attitudes, behavior, and achievement in adolescence (Anderson, Huston, Schmitt, Linebarger, & Wright, 2001) suggests that messages counter to gender-typed norms have longer-term effects than gender-typed messages: Positive relations between early exposure to educational television and school achievement were more pronounced for boys than girls; negative relations between watching violence and school achievement were stronger in girls.

The most convincing evidence for television's impact comes from a natural experiment in Canada: the introduction of television into towns that had been unable to receive it. In one town, children held less traditional gender attitudes than comparison children before television was introduced; but 2 years after television was introduced, they showed sharp increases in traditional attitudes (Kimball, 1986).

**Summary.** The range of media options has expanded rapidly over the last decade. Despite changes in the representation and portrayal of the sexes, the media continue to provide a window onto a highly stereotyped world. The ways in which media messages affect children's lives have yet to be fully determined. The background "wash" of gender stereotyping messages certainly provides an overabundance of inaccurate information about the sexes. But it is not enough to know

about children's media use. We need to investigate how children understand the messages and how they use them.

### *Integration and Conclusions*

Gender socialization processes at home, at school, in interaction with peers, and through the media all contribute to gender differentiation in most areas identified in Table 14.1—concepts, preferences, behaviors, and values. Many studies fail to find expected associations, however, or find them only under some conditions. For example, studies using social learning principles to *change* stereotypic beliefs and behaviors have met with little success (Ruble & Martin, 1998). Careful theoretical analysis suggests that interventions attentive to developmental factors and using combinations of strategies may prove more successful (Bigler, 1999).

It is clear that the social world is gender-typed, but it is less clear how this influences gender development. The findings highlight the complexity of gender socialization processes and the need for fine-grained analysis to understand when and how social agents influence gender development. It is relatively rare to focus on a specific process underlying differential socialization, such as via the development of personal gender standards or different attributions for performance. Instead, most studies test a relatively simple hypothesis—that boys and girls are treated differently or exposed to models of differential behavior. Although many findings are intuitively compelling, the nature of the mediating process and its causal direction are often unclear. For example, an interesting and consistent finding is that advanced gender knowledge in young children is associated with encouragement of gender-differentiated play and traditional role modeling in the home, but it is unclear which aspects of the home environment are most important—is it differential responding, traditional attitudes, or the father's lack of involvement in activities at home? Are multiple socialization processes involved or does a single process underlie these various relations?

### **Cognitive Approaches**

Cognitive approaches to the study of gender development have received considerable attention and there is a rapidly growing body of work on how cognitions affect gender development. Although cognitive approaches share many similarities (see Martin et al., 2002, for a review), different theories focus on different sorts of

cognitions and different mechanisms linking cognitions to beliefs and behavior. We examine three cognitive theories of gender development: (1) cognitive developmental, (2) gender schemas, and (3) identification with males or females as a group. Although other theories also refer to cognitive mechanisms (e.g., Bussey & Bandura, 1999), the three theories discussed here share key fundamental assumptions, explicitly described in the integration section that follows.

### ***Cognitive Developmental Theory and the Role of Gender Constancy***

Kohlberg (1966) first posited the importance of developmental changes in children's gender understanding for organizing other aspects of gendered behavior and thinking. He proposed that gender development involves an active construction of the meaning of gender categories, initiated internally by the child rather than externally by socializing agents. This idea that children socialize themselves into gender roles was pioneering, but the mechanisms driving their socialization efforts were not articulated (Huston, 1983; Martin & Little, 1990). According to Kohlberg (1966), children's understanding that sex categorization does not change was an essential motivator for children to acquire gender roles, stating that "a child's gender identity can provide a stable organizer of the child's psychosexual attitudes only when he is categorically certain of its unchangeability" (p. 95). Once children acquire this sense of gender identity, they are presumed to be actively involved in gender self-socialization as they become increasingly motivated to behave like members of their own sex. Given Kohlberg's emphasis on understanding unchangeability, many researchers not surprisingly concluded that gender consistency—children's understanding of the permanence of sex categorization across situational changes—was the critical component for motivating children to learn and to adhere to gender roles (see Section 1A for a review of the stages of gender constancy), implying that children should show few gender-typed preferences and behaviors until they have attained this level of understanding.

**Review of the Evidence.** Over the years, cognitive developmental theory (CDT) has been reformulated in a number of ways (Ruble & Martin, 1998). For example, understanding of gender constancy is no longer expected to be antecedent to all gender knowledge and gender differentiation. Instead, constancy understand-

ing is viewed as a point of increased susceptibility to gender-relevant information as well as a period of consolidation for conclusions about gender-appropriate activities (Ruble, 1994). Thus, children's engagement in gender-typed behavior prior to age 5—an observation even Kohlberg (1966) referred to—does not by itself contradict the basic tenets of contemporary CDT. Cognitive developmental theorists recognize that biological and socialization processes may lead very young children to show gender-typed preferences and behaviors prior to understanding constancy but constancy understanding is expected to exert an effect once it emerges.

Specifically, CDT predicts higher levels of gender constancy to be associated with increased responsiveness to gender-related information and more rigid application of gender norms. Indeed, as reviewed recently (Martin et al., 2002), many studies show positive relationships between level of gender constancy and aspects of gender development: selective attention to same-sex models; same-sex imitation; same-sex activity, clothing, and peer preferences; gender stereotype knowledge; and heightened responsiveness to gender cues. As Huston (1983) noted, however, there have been many mixed or null findings; and that has been true in more recent research as well (e.g., G. D. Levy, 1998; Zucker et al., 1999). Comparisons across studies are difficult because of varying operationalizations of constancy (see 1A). For example, prior research suggests that scoring only the simple responses to constancy questions (without justifications) may overestimate children's level of understanding, thereby making it difficult to interpret failures to find predicted relations between constancy and behavior in preschool children.

Interestingly, increased responsiveness to gendered information is found more often to relate to lower levels of gender constancy such as gender stability or basic identity. Only rarely has the highest level of constancy, gender consistency, been associated with other indices of gender development (Ruble & Martin, 1998). This is important because it implies that Kohlberg was right about the motivational significance of knowledge and identification with gender categories (Maccoby, 1990), but this process may begin earlier than Kohlberg thought—prior to a full understanding of gender consistency.

Supporting this idea, two recent studies have taken a developmental approach to relations between stability understanding and gender-related outcomes. In a cross-sectional study described earlier (L. Taylor et al., 2006),

stability scores increased with age and reached ceiling at 5 years in parallel with age-related increases in gender-typed beliefs and preferences. Moreover, stability understanding mediated the relation between age and some of these outcome variables. Increases in consistency understanding were not predictive of increases in gender-typing. In a longitudinal study, stability understanding was related to levels of and increases in stereotypic knowledge and rigidity—for example, beliefs that “only” boys could play with trucks (Ruble et al., 2006).

**Evaluating Gender Constancy.** There is currently little empirical support for the idea that gender consistency is a crucial component of gender development. Instead, lower levels of gender constancy are key—namely, identity and stability. It would be valuable to pay attention to the psychological processes that underlie relations between different components of constancy and gender-related outcomes. For example, does understanding gender identity elicit the kind of group identification described by social identity and schema theorists (see later sections) or reflect the motivational attachment to one’s group suggested by Kohlberg (1966)? If so, the emphasis on consistency, due largely to its association with conservation, may have been misleading.

Does gender consistency have any important consequences for gender development? Firm conclusions are difficult to draw because of methodological limitations, but it is possible to examine competing hypotheses about the role of full constancy understanding (i.e., including consistency) in gender development. The first hypothesis is that children show strongest adherence to gender-related behaviors prior to attainment of gender consistency because they are afraid that cross-sex behaviors may transform them to the other sex. Once consistency is attained, they are free to defy gender norms (Huston, 1983). Thus, the attainment of consistency should be associated with decreased rigidity. The second hypothesis is that children show a linear increase in adherence to gender norms in relation to gender consistency (Warin, 2000) and do not become more flexible until a few years after the attainment of full constancy when stereotypes become more flexible (Ruble, 1994).

Additional findings in the study described earlier (L. Taylor et al., 2006) support the first hypothesis. Among children aged 3 to 7 years, increasing age was associated both with higher levels of consistency understanding and with higher levels of flexibility of gender-related beliefs. Moreover, consistency understanding mediated

the relation between age and some indices of flexibility. Nevertheless, as described earlier, support for the second hypothesis has been found when stability understanding, rather than consistency, represents constancy. Future research using longitudinal designs is needed to clarify these relations.

In short, there are problems with the construct of gender constancy and its presumed relation to gender-related beliefs, preferences, and behaviors. Such relations are more complex than initially hypothesized. The evidence indicates that complete understanding of constancy does not serve the initial organizing function that Kohlberg (1966) proposed but may serve other important functions, such as promoting an increase in flexibility. Lower levels of constancy—identity and sometimes stability—do show some of the predicted associations. Whether such relations are best understood as reflecting the motivational processes Kohlberg described or alternative formulations remains for future research to decide.

### *Gender Schema Theory*

Several versions of gender schema theory (GST) were proposed in the early 1980s, with one version emphasizing developmental changes (Liben & Signorella, 1980; Martin & Halverson, 1981) and another emphasizing individual differences (S. L. Bem, 1981; Marcus, Crane, Bernstein, & Siladi, 1982). Although they differ in focus, variations of GST all assume that children are actively involved in gender development.

Gender schemas are interrelated networks of mental associations representing information about the sexes. Schemas are not passive copies of the environment, but instead they are active constructions, prone to errors and distortions. Two types of schemas were initially formulated: (1) the superordinate schema containing list-like information about the sexes; and (2) the own-sex schema, a narrow schema containing detailed action plans for self-relevant information (Martin & Halverson, 1981). Gender schemas also have been conceived in other ways (Ruble & Stangor, 1986), including “lenses” that color perception and thinking (S. L. Bem, 1993) and scripts (G. D. Levy & Boston, 1994). Schemas are viewed as dynamic knowledge representations changing in response to situations and age and as having content that varies with culture and with individual social experiences and preferences.

Gender schema theory has been reviewed and updated recently (Martin et al., 2002). The major elabora-

tions involve increased clarity about self- and other-schemas (Hannover, 2000), emphasis on the interplay between gender schemas and social environments (Martin & Dinella, 2002), descriptions of the dynamic nature of gender schemas (Martin, 2000; Martin & Dinella, 2001), and descriptions of processes that influence stereotyping (Barbera, 2003) and contribute to schema maintenance (Hughes & Seta, 2003).

Schematic consistency refers to children's tendencies to bring their attention, actions, and memories in line with their gender schemas. Once they identify themselves as boys or girls, children seek details and scripts for same-sex activities, show in-group biases, and become more sensitive to sex differences. Children are motivated to behave according to gender norms as a means of defining themselves and attaining cognitive consistency. The links between gender cognitions and behavior are presumed to occur through selective attention to and memory for own-sex relevant information and through motivation to be similar to same-sex others. Gender schemas are organizers of gender development but not the sole causes of gendered behavior (Martin et al., 2002).

**Developing Gender Schemas.** The development of gender schemas involves learning actual gender-related regularities in the environment and constructing other gender-related patterns, some of which may not exist in reality. Infants are assumed to attend to statistical regularities and to form categories and concepts based on them. Evidence regarding infant and child perception and categorization confirms these ideas. Infants notice even weak covariations or statistical regularities in some domains (e.g., Saffran, Aslin, & Newport, 1996). For gender categorization, sex differences in physical appearance (e.g., height, body shape) and styles (e.g., clothing, hairstyles) likely make learning even easier and increase the salience of gender categories for processing information. Furthermore, parents, media, peers, and the culture highlight the functional utility of gender categories and transmit information about sex-related differences (e.g., "boys don't wear pink"). Research confirms that children are more likely to use categories to make judgments of others when the categories are both physically salient and functional (e.g., teachers line children up by groups; Bigler, Brown, & Markell, 2001; Bigler, Jones, & Lobliner, 1997).

Furthermore, children add to their schemas by using processes that are less veridical, for instance, by forming

illusory correlations (Susskind, 2003), exaggerating between-group differences and within-group similarities (see section on identification with social categories), and drawing inferences from limited information. Schemas also are responsive to a child's own preferences: Preferences for a particular activity may modify a child's stereotypes (Liben & Bigler, 2002; Martin, Eisenbud, & Rose, 1995).

**Individual Differences in Gender Schemas.** The content and application of gender schemas varies across situations and children. Some children will stereotype a broader range of information in their environments than others, and each child develops his or her own personal view of gender. This idea is similar to those proposed by other theorists (e.g., Egan & Perry, 2001; Perry, 2004; Spence, 1999) that each child develops an idiosyncratic set of cognitions about gender (e.g., gender relevance beliefs, Perry, 2004) that are particularly relevant for determining his or her view of gender typicality. Individuals differ in how fully developed, elaborated, and accessible their gender schemas are (Hannover, 2000; Liben & Bigler, 2002; Signorella et al., 1993), and these factors relate to how schemas influence behavior and thinking (S. L. Bem, 1981), although this line of reasoning has not been fully explored. However, both earlier (see Ruble & Martin, 1998) and recent research (Lobel et al., 1999, 2000) shows the importance of some types of individual differences in the use of gender to process information.

**Gender Schemas and Inferences.** A major contribution of GST has been in showing how gender schemas guide children's gender-based inferences and judgments. Early studies showed how children of different ages rely on gender schemas to make social judgments (see Ruble & Martin, 1998) and recent research has expanded on this work using more varied judgments and age groups. Some researchers have examined gender-related social judgments in very young children (Bauer, Liebl, & Stennes, 1998). Other researchers have examined social judgments in adolescents to determine how judgments depend on the adolescent's and the target's characteristics (Lobel et al., 1999, 2000). Giles and Heyman (2005) found that children use gender schemas to make judgments about sex differences in forms of aggression. Preschool children believed that girls were more likely to engage in relational aggression and boys in physical aggression. Interestingly, children showed

memory distortions when information was inconsistent with their stereotypic beliefs. By age 8 or 9, children show evidence of using gender schemas to make judgments about which sex will play particular musical instruments, and their own preferences are similar to their stereotypes (Harrison & O'Neill, 2000, 2003).

Several studies have explored how children use social categories (e.g., sex) to make judgments in novel and ambiguous situations. In novel situations, children use gender to make generalizations about unfamiliar characteristics (Gelman, Collman, & Maccoby, 1986). For example, when 3½-year-olds were told the preferences of a girl and a boy for nongender-typed objects (e.g., pizza), they projected these preferences to sex-unspecified others based only on their proper names (Bauer & Coyne, 1997). Children also use gender schemas to evaluate and explain behavior. For instance, when told about a boy or girl who spilled some milk, children evaluated the behavior of boys more negatively and were more likely to draw general conclusions based on the behavior of boys than when girls spilled the milk, which can be interpreted as a "boys are bad" stereotype (Giles & Heyman, 2004; Heyman, 2001; Heyman & Gelman, 2000).

**Memory and Illusory Correlations.** Early evidence supported the predictions from GST that children selectively attend to and remember schematically consistent information and supported the idea that they distort information that does not fit their schemas into schema-consistent information (Ruble & Martin, 1998). Recent work confirms and extends these findings. When 6-, 8-, and 10-year-old children appraised the risk of injury for boys and girls in various activities, boys were rated as having a lower chance of injury than girls in the same activity. Children appear to develop the belief that girls are more fragile than boys, even though evidence shows boys experience more injuries than do girls (Morrongiello, Midgett, & Stanton, 2000). Consistent with an own-sex schema bias in memory, young children (3 to 6 years) and adults remember own-sex objects better than other-sex objects (Cherney & Ryalls, 1999). Age may moderate these effects. Younger, but not older, children recalled more information from stories containing gender-consistent activities than other stories (Conkright, Flannagan, & Dykes, 2000). Furthermore, GST posits that children should show illusory correlations: They should remember that schema-consistent information occurred more frequently than schema-

inconsistent or neutral information, even when each is presented an equal number of times. Illusory correlations have been demonstrated in second grade children, although their extent depends on how frequently information is presented (Susskind, 2003).

**Gender Schemas and Behavior.** Central to GST is the idea that gender group membership organizes gender development. This idea is shared among several theoretical views, so it is discussed in the Integration of Perspectives section. Gender schema theory also assumes that superordinate schemas (i.e., stereotypes) organize and guide behavior, and this idea is similar to Kohlberg's notion that children self-socialize using the guidance of their stereotypes. Extensive summaries of the evidence regarding the cognitive underpinnings of gender development have been recently published (Martin et al., 2002), so only a brief discussion of both of these issues is presented in the Integration of Perspectives section.

### *The Role of Identification with a Social Category*

Social categorization approaches emphasize gender identification occurring at a group level. Categorization represents the cognitive mechanism that segments, classifies, and orders the environment, and the resulting social groupings provide a system of orientation for self-reference (Tajfel & Turner, 1979). Social identities are socially meaningful categories that individuals consider descriptive of themselves or their group (Thoits & Virshup, 1997). In a recent review, Ashmore, Deaux, and McLaughlin-Volpe (2004) suggested that "collective identity" describes this sense of being a member of a group, and thus we have shifted our terminology from *social identity*, as used in our last *Handbook* chapter, to *collective identity*.

Considerable effort has been devoted to showing how identification with a particular social category (involving a comparison with other social categories) promotes a sense of belonging and connectedness but also may lead to stereotyping of out-group members and prejudice and intergroup conflict (Hewstone, Rubin, & Willis, 2002; Tajfel & Turner, 1979). Despite the importance of social category beliefs, we know little about how they develop over the elementary school years (Ruble et al., 2004). We examine three elements of collective identity particularly relevant to a developmental analysis of gender: (1) the *consequences* of a sense of "we," (2) the *mul-*

*tidimensional nature* of collective identity, and (3) the *contextual* influences on collective identity.

**Consequences.** Collective identities serve several different purposes and have significant personal and interpersonal consequences (Brewer & Brown, 1998; Hewstone et al., 2002). Social identity theory (Tajfel & Turner, 1979) proposes that identification with a group and comparison across groups jointly serve individuals' striving for positive self-concept. Collective identity also affects individuals' desires to look and act in identity-consistent ways. The motivational consequences of social group membership take many forms. For example, group membership shapes personal values and interests, in turn influencing effort and performance. Individuals whose gender identity is central to their self-definitions may value tasks associated with their sex and devalue those associated with the other sex (e.g., Wigfield & Eccles, 2000). Experimental work demonstrates that simply labeling an ambiguous activity as associated with one sex affects performance (Martin & Dinella, 2002; C. F. Miller, Trautner, et al., 2006).

Social identity theory also explains behavior of high- and low-status members, and thus asymmetries in gender-typing of boys and girls. The high-status group would be expected to strive to maintain its advantage, consistent with findings that boys emphasize stereotypic differences more than do girls and are more rigidly gender-typed, as reported earlier. This is supported by an experimental study: When novel groups of unequal status were created, in-group biases developed only in members of high-status groups (Bigler et al., 2001).

Finally, the mere act of categorizing individuals into social groups changes the nature of interpersonal perceptions and behaviors (Tajfel, 1978), for example, increasing perception of between-group differences and within-group similarity and increasing in-group favoritism. Such changes occur even if the social categories are arbitrary, for example, wearing different colored shirts (Bigler et al., 1997). Does this mean that as early as 3 years of age, children exhibit gender prejudice? Recent analyses suggest that in-group favoritism does not necessarily imply out-group derogation or prejudice because much past research has confounded in-group positivity and out-group negativity (J. A. Cameron, Alvarez, Ruble, & Fuligni, 2001). Social categorization and in-group positivity are probably universal aspects of human social groups, but out-group

hostility requires social-structural and motivational conditions not inherent to collective identity formation (Brewer, 2001). For example, prejudice against women is more likely when they violate gender stereotypes or participate in male-dominated domains (Eagly & Mladinic, 1994). To illustrate, "girls' efforts to 'beat the boys' in areas where boys may be tacitly expected to do better, such as playground athletics, are likely to provoke resentment and active attempts at exclusion on the part of boys" (Lutz & Ruble, 1995, p. 144).

Gender is probably one of the earliest and most salient social categories available, so children's self-identification as members of the group of males or females is likely to affect substantially their self-concepts, preferences, and behaviors. An important issue concerns the emergence of this sense of "we boys" or "we girls" (Maccoby, 1998). Although gender labeling and identity begin before age 2 (see 1A), it seems unlikely that this initial understanding involves a sense of belonging to a group, or perceived similarity to other group members. By 2 to 3 years of age, however, children can sort pictures, including their own, according to gender category, suggesting the beginning of a sense of group identification. By 5 years, children spontaneously categorize people by gender (Bennett, Sani, Hopkins, Agostinie, & Mallucchi, 2000).

Subsequent to categorization, children should evaluate their own group positively and out-groups negatively. Research on gender-related group bias is consistent with this prediction, as reviewed earlier (6C). Whether preschoolers' in-group favoritism (e.g., liking and feeling more similar to same-sex others) directly reflects the emergence of collective identity is controversial, however, and this issue represents an important direction for future research.

Another area for research concerns the evaluations of individual boys and girls in relation to gender categories. Research with adults suggests that not all in-group members are evaluated positively: Individuals who deviate from in-group social category norms are evaluated more negatively than those who support the norms (Marques, Abrams, Paez, & Martinez-Taboada, 1998). Although it is clear that children show in-group biases from an early age, it is not clear when they adopt a discerning approach to interpersonal evaluation. At what point in development, for example, do children's evaluations depend on an individual's fit to group norms rather than just in-group/out-group membership? Research on developmental changes

in children's inferences from categorical information (being male or female) versus typicality information (masculine or feminine interests) suggests that the latter does not affect judgments about individuals until age 8 or later (see Gender Schema section).

**Multidimensional Nature.** Contemporary analyses emphasize that the significance of group identity depends on more than simple self-labeling (e.g., Ashmore et al., 2004). Thus, gender identity should be conceptualized as multidimensional, including, for example, the centrality/importance of gender to self-concept, personal evaluation of one's gender, and feelings about one-self in relation to gender (i.e., typicality, contentedness, or felt pressure for gender conformity; Egan & Perry, 2001; Ruble et al., 2004). There is little work on the emergence of these components of identity, but gender appears to be central to young children relative to other social identities (Ruble et al., 2004; L. Taylor et al., 2006). Moreover, different components have different consequences for self-esteem and interpersonal relationships. For example, social-identity theorists emphasize the process of deriving self-esteem from identification with a valued group, but children also evaluate themselves on the basis of noticing how well their self-perceived gender-typing matches gender norms (e.g., Bussey & Bandura, 1999; Egan & Perry, 2001). Recent research suggests that certain combinations of different components of identity may create problems. Specifically, children who feel gender atypical but also feel pressure for gender conformity are particularly likely to have low self-esteem. Thus, focusing on the emergence and consequences of different components of gender identity represents a promising direction for future research.

**Context.** There are several ways in which context influences collective identity related to gender. First, gender salience varies with context, for example, being the only child of a particular sex in a group (e.g., McGuire, McGuire, Child, & Fujioka, 1978). Second, when social categories are emphasized, such as when gender is used for classroom organization, children process information in terms of that category (Bigler, 1995). Experimental research on collective identity formation and consequences in middle elementary school children has been critical in understanding such processes (e.g., Bigler et al., 1997), suggesting three crucial environmental/group factors: (1) functional use

(e.g., having boys and girls line up separately to go out for recess), (2) perceptual salience (e.g., distinctive clothing and hair styles), and (3) the presence of group-to-attribute links (e.g., specific mention that boys' do X, or observation that this is the case).

Third, stereotypes are representations of social groups formed in a specific intergroup context rather than stored concepts waiting to be activated. This suggests that the exact nature of gender stereotypes depends on the specific comparison. Consistent with this view, children's descriptions of their gender in-group changed significantly with changes in frame of reference (whether they were first asked about an other-sex adult or an other-sex child; Sani & Bennett, 2001); for example, boys described boys as brave, big, and strong when the contrast was girls, but as talkative when the contrast was men (Sani, Bennett, Mullally, & MacPherson, 2003).

Finally, Maccoby (1998, 2002) has described a context-dependent collective gender identity process occurring in preschool, with gender-linked qualities constructed and maintained at the level of the group of "we girls" and "we boys" rather than at the level of the individual. For example, preschool children in the same classrooms show increasing divergence across the school year in the stories they tell and the fantasy play they enact, even though such gender differentiation may not be the same as general cultural stereotypes about boys and girls (Paley, 1984; Richner & Nicolopoulou, 2001). These observations raise a number of interesting questions. What is the connection between collective identity as a girl or boy versus gender-based group identity in school? Is there a gradual incorporation of culture-based gender identity norms into these group level norms, perhaps as children are shaped by peers perceived as gender "enforcers" or gender "police" (Martin & Fabes, 2001)? Do children who never attend preschool show less gender-typed behavior in later years? It is important to explore such questions and examine long-term consequences of group-based gender identity for individual level gender-typing.

### *Summary and Conclusions across the Three Cognitive Approaches*

These three cognitive approaches have a number of commonalities, but differ in emphases. First, they hypothesize that gender cognitions act to organize and interpret information and they provide the standards that guide

behavior, but they emphasize different cognitions. Kohlberg (1966) emphasized the importance of the stability and constancy of gender concepts, but newer formulations of CDT are similar to GST and category identification perspectives in emphasizing the significance for gender development of basic categorization as a girl or boy. Each theory also has unique perspectives. Social category perspectives focus on how individuals relate to social groups, CDT on the stability and consistency of gender understanding, and GST on the range of gender-related knowledge structures that influence gender development.

Second, central to these theories is the view that children actively seek out and construct rules about gender at an early age. Children are intrinsically motivated to build on their gender schemas and to develop gendered standards for their own behavior as they strive to understand the significance of their gender category. The active construction of gender is one of the most intriguing yet understudied aspects of cognitive theories. Cognitive theorists are interested in the processes of “gender construction” that allow for the gathering and organizing of both accurate and inaccurate information about the sexes. How do children derive faulty conclusions, distorted perceptions, inaccurate recall, and idiosyncratic norms about gender? Why are children quick to use a single sex-related pairing to develop a broad rule; for example, after seeing Mom drink coffee and Dad tea, deciding that “females drink coffee.” How does this relate to other types of cognitive overgeneralization?

Third, these cognitive approaches focus on development—the relative waxing and waning of gender knowledge and its use and implications for behavior. Children move from awareness of categorical distinctions when they learn about gender (construction/information gathering) to rigid application of those distinctions during “consolidation” (Ruble, 1994) or “schema confirmation” (Welch-Ross & Schmidt, 1996) to later flexibility in applying gender knowledge (integration and schema deployment; Trautner et al., 2005). Are these phaselike shifts in the rigidity of gender knowledge parallel to other elements of gender development (e.g., Ruble, 1994)? How do changes in broad cognitive skills play a role in gender development (Bigler, 1995)?

Concerns have been raised about the overemphasis on cognitive factors in gender development. For instance, gender identity has been argued to not be central to gender development, even for same-sex modeling (Bussey & Bandura, 1999). The two main arguments against the

importance of cognitive factors reflect some misunderstandings. First, there is a widespread but erroneous assumption that cognitions must not affect gender development if they occur later than gendered behavior (e.g., Bandura & Bussey, 2004; A. Campbell et al., 2002). But cognitive theorists do not argue that this cannot occur and, instead, focus on the organizational and motivational function of gender concepts (see Martin, Ruble, & Szkrybalo, 2004). Moreover, as discussed earlier, recent evidence from infants and toddlers suggests early development of gender cognitions (e.g., Martin, et al., 2002). It is important to examine whether and how such early gender concepts influence the emergence of early gender-typed behaviors.

Second, it is often suggested that evidence fails to show associations between gender cognitions and behavior. This evidence has been extensively reviewed (Martin et al., 2002, 2004), so we only summarize it here. Most evidence focuses on two types of gender cognitions: (1) gender identity/labeling of the sexes and (2) gender stereotypes.

Concerning the evidence linking gender identity (group membership) and behavior, few studies have examined these types of relationships. Unfortunately, most studies have used gender labeling as a proxy for gender identity understanding, but it may not be equivalent. In these studies, using young children, gender labeling is related to preferences for same-sex peers and some behaviors but shows mixed relations with toy play (Fagot, 1985; Fagot, Leinbach, & Hagan, 1986; O’Brien & Huston, 1985; Weinraub et al., 1984). In older children, relations are found between gender labeling/membership, preferences, and stereotype knowledge (Martin & Little, 1990). Limited longitudinal data provide the clearest evidence. Children who engage in early gender labeling show increased gender-typed play in the toddler years relative to those who are later labelers (Fagot & Leinbach, 1989; Zosuls et al., 2006). Thus, the data support a link between gender labeling/identity and gender-related preferences and behavior, suggesting that this form of basic gender knowledge provides an organizational structure for further gender development.

Concerning links between gender stereotypes and behavior, both correlational and experimental studies provide relevant information about the role of cognitions. A number of studies have compared, at a global level, stereotype knowledge and behavior or preferences, but these do not provide a direct assessment of whether particular stereotypes influence behavioral

choices. Only a few studies have examined direct links between children's gender stereotypes and behavior, and interpretations of findings from these studies are limited by a variety of methodological issues. Nonetheless, the studies that have used similar items for knowledge and preferences tend to find that the two are related (Aubry et al., 1999; C. F. Miller, Trautner, et al., 2006; Serbin et al., 1993). In older children and adolescents, there are links between stereotypes and interests, although the direction of causation is unclear (Liben & Bigler, 2002).

Experimental studies provide strong and consistent support for the organizational influence of gender stereotypes: Gender stereotypes influence children's behavior, motivation and interests, and memory for information (for review see Martin & Dinella, 2002; Martin et al., 2002). In these studies, children are shown novel toys given gender-typed labels ("boys like the things in this box better than girls do"), and then their behavior, and/or memory is assessed (e.g., Bradbard, Martin, Endsley, & Halverson, 1986). Consistency in findings is striking across studies—from different laboratories, using obvious and subtle labels (e.g., Davies, 1989), with children of many ages, and using ploys to reduce demand characteristics: When toys are stereotyped, either with overt or covert gender cues, children respond according to whether the toy is perceived to be appropriate or inappropriate for their own sex (Martin et al., 2002).

In sum, these three cognitive perspectives focus on the role of gender-related cognitions in organizing and motivating gender development, influencing what children attend to and remember, how they make social judgments, and how they behave. A large body of evidence supports these ideas, including studies of gender identity, stability, and the importance of gender categories in directing and organizing processing, affect, and behavior.

### An Integration of Perspectives

The three broad approaches to the understanding of gender-typing—biological, socialization, and cognitive—generally focus on specific topics and concerns unique to each approach. Biological researchers have directed attention to the pathway from sex hormones to brain structure and function to gender-related preferences and behaviors and have not considered effects of gendered environments on brain structure or hormone

levels, or of biological influences on gender-related concepts or beliefs. Social developmentalists have focused on two issues that differentiate cognitive and social-learning approaches. The first issue concerns the temporal sequencing of gender awareness and gender-typing: Do children learn the consequences of behavior and then use patterns of rewards to derive gender identity, or does the formation of gender identity and understanding of gender category drive gender-typing? The second issue is less well defined but underlies the philosophical foundation of the theories. It concerns the factors that determine self-concept: Is it reinforcement history or desire to adhere to a gendered cognitive structure? Because of this intense focus on a few issues, other interesting aspects of each theory have been relatively neglected, and the developmental focus has been primarily on the preschool years.

To understand gender-typing, we need to listen to messages from separate perspectives and to devise ways to integrate the three approaches in meaningful ways. Huston's (1983) plea for biological and social psychologically oriented researchers to combine their efforts is beginning to be realized in conversation, if not yet in data. Research findings are accumulating about the wide range of influences on particular gendered behaviors, suggesting several promising avenues for future research using multiple approaches.

Lessons can be learned from nonhuman primates. Behavioral sex differences in monkeys result from hormonally influenced predispositions to engage in certain behaviors, but the ultimate expression is shaped by the social environment in which the animal develops (Wallen, 1996). For example, sex differences in rough-and-tumble play occur in all rearing environments, with the *size* of the difference affected by the environment, whereas differences in aggressive and submissive behaviors are found only in certain rearing situations. Behaviors that show consistent sex differences across social context are most affected by prenatal androgens. Existing evidence in human children is consistent with this: Prenatal androgens have the largest effect on activities and interests, which also show large sex differences across cultures. It is important to study context in hormonally informative samples; for example, are differences in aggression between girls with and without CAH apparent primarily when aggression is spontaneous and not when it is provoked?

Children come into this world with certain predispositions that are manifested and exaggerated or sup-

pressed by the environment in which they are reared, and those with sex-atypical predispositions provide a unique opportunity to examine this developmental process with respect to gender-related behavior. Hypotheses derived from cognitive/schema and socialization theories can be tested in girls with CAH or typical girls with high levels of prenatal testosterone. Doing so makes clear that biology is a process, unfolding across development, manifested through and moderated by the social environment, thereby challenging researchers to develop hypotheses about the *ways* in which biological factors affect behavior.

Consider some outstanding questions about gender development that can be informed by such studies. What is the role of gender identity and awareness in gender-typing—how do girls with CAH develop female gender identity but interest in boys' toys? How does socialization occur—do girls with CAH model others on the basis of their female-typical gender identity or their male-typical interests? What is the basis of sex-segregation—do girls with CAH play with girls who share their identity, boys who share their interests, or children who share their play style or strategy for influencing others (which have not yet been studied in CAH)? Does the effectiveness of the environment vary with biology—do girls with CAH benefit from practice in spatial ability more than typical girls do?

The key questions about gender development—for example, how do gender identity and gendered behaviors develop and how does gender socialization operate—require creative thinking across disciplinary boundaries and perspectives. Answers require a willingness to suspend narrow conceptualizations of gender and old biases. Using multidisciplinary teams, multiple perspectives, and broader conceptualizations of underlying mechanisms and processes should enable significant strides in understanding the complexities of gender differentiation.

## CONCLUSIONS AND FUTURE DIRECTIONS

One of the difficulties in compiling research on gender is that it cuts across areas and is relevant to virtually every topic, ranging from brain sex differences to children's identification with gender in all of its complexities. Controversies frequently arise that do not occur with regularity in many other areas, such as the questioning of the research enterprise itself, confusion about

terms for major constructs, and the political implications of the findings. Despite, or perhaps because of the controversies, the study of gender attracts scientists from many disciplines, each bringing to the enterprise different interests and strategies. The pluralism of views provides many insights into the diverse issues covered in gender studies.

Several broad themes are apparent from the literature that we reviewed for this chapter. First, interest in all sorts of biological factors has marked the literature of the past 10 years. In accord with this interest are suggestions that biological factors may play a more prominent role in behavior, thinking, and gender identity than has been previously considered. Thus, this section of the chapter received a major revision in the present edition. Second, social and cognitive theories have moved more closely together but continue to disagree about some issues, and these theoretical debates drive a surprising amount of gender-typing research. In the present revision, we expanded discussion of identification with social groups as important theoretical processes to consider in future research. Third, developmental researchers have taken Huston's (1983) admonitions to heart: They have included multiple components of gender-typing in studies, are less prone to infer broadly about gender-typing from one measure, and recognize the distinctions among various content domains and constructs. Fourth, new methods have played an important role in the research that has been undertaken in the past 10 years. For instance, sophisticated testing procedures have allowed researchers to begin to understand what infants and young children know about gender.

Many new and intriguing ideas are emerging in the field that may spark interest and lead researchers to think about gender in novel and interesting ways. There is renewed interest in process and change in gender development. Social learning theorists have concentrated efforts on cognitive mechanisms underlying observational learning (Bussey & Bandura, 1999). Cognitive theorists have considered how shifts from early gender concepts to more consolidated ones influence information processing and memory (Martin et al., 2002; Ruble, 1994). There is increasing interest in the changing nature of gendered personal identities and stereotypes in context (e.g., Sani & Bennett, 2001). Gender researchers should explore in even more depth the issues of context and variability, given their importance in development. Biological perspectives also encourage the study of change because predispositions are manifested

and moderated by the organism's transactions with the environment.

The idea that gender is constructed in a social context has many interesting possibilities for future research. The idea of the social construction of gender has generally meant that we must investigate how we see others in gendered ways, using gender cues. But it also suggests that we need to examine how individuals construct their own multifaceted gender cues and how they believe these cues work in social interactions. For instance, do individuals strive for balance in their gender cues to present a particular image? Does a woman who is assertive and dominant choose to dress in a feminine way to offset perceptions of masculinity? Appearance, clothing, adornment, mannerisms all become more important to study, given that they are visible cues that are often used to read and construct gender.

Questions about mental health and self-esteem also require more research efforts. In the 1970s, mental health was thought to be associated with androgyny. Recent research has provided alternative views and suggested that different elements of gender identity relate differentially to personal and interpersonal adjustment (e.g., Egan & Perry, 2001). For example, adjustment variables were found to be positively associated with self-perceptions of gender typicality and contentedness, but negatively associated with felt pressure for gender conformity in fourth to eighth graders (Carver et al., 2003; Egan & Perry, 2001). These associations remained after controlling for children's perceptions of self-efficacy for gender-typed activities, implying that gender identity has implications for adjustment beyond gender-linked competencies. Such research represents promising new directions, taking seriously the idea of the multidimensionality of gender. Which particular domains of gender influence positive self-regard? Why are preadolescent girls more likely to show declines in self-esteem than boys? Which factors related to gender may be risk versus buffering factors?

Gender in relationships is an idea that promotes many new and interesting views. Peers' contributions to socialization have been at the forefront of recent research because sex segregation probably provides the impetus for many sex differences seen in adults (Maccoby, 1998, 2002). The role of parents in socialization continues to be of interest, but perhaps with some different emphases on subtle forms of socialization. Research suggests that children with rigid cross-gender roles may be more likely than others to show later maladjustment. Does this mean

that parents should not encourage cross-gender interests for fear of inducing psychological problems in their children? We also know surprisingly little about the effects of androgynous interests.

A final comment about current directions in the field: Despite the number of exciting new directions and increased interest in certain age periods, such as infancy, it was surprising to note the relative dearth of research on adolescents and adolescent transitions. This is puzzling, given the significance of changes during adolescence for gender development (e.g., acceptance of one's male or female body and reproductive functions, forming a sexual orientation, establishing new forms of relationships with same-sex and other-sex peers, and decisions regarding future gender roles). Although many researchers have been intrigued by notions of gender intensification during this developmental phase, empirical research, including measures suitable for research with adolescents, has been relatively rare. A few recent studies examining gender subgroups and crowd types (e.g., druggies, brains) suggests that future theorizing about gender development would benefit from greater attention to adolescence (Eccles & Barber, 1999; Eckes, Trautner, & Behrendt, 2005).

In conclusion, the study of gender is a monumental undertaking, shared by individuals from many fields. Constantinople (1979) used the metaphor about four blind men studying an elephant to describe how gender researchers have focused on individual parts of the elephant, with each one assuming that the animal was best described by the part they were studying. No one recognized the whole animal. Gender researchers must continue to be careful about building global concepts based on partial information. However, we now have some sense of the size of the animal, its capacities, and its general framework. The picture is far from complete but the process of identification has certainly continued to be intriguing.

### **THE SOCIALIZATION OF MOTIVATION: PARENTAL INFLUENCES 968**

Work on the development of children’s achievement motivation has continued to flourish since the fifth edition of this *Handbook* was published in 1998. In this chapter, we update Eccles, Wigfield, and Schiefele’s (1998) chapter on motivation from the previous edition of the *Handbook*. Motivational psychologists study what moves people to act and why people think and do what they do (Pintrich, 2003; Weiner, 1992). Motivation energizes and directs actions, and so it has great relevance to many important developmental outcomes. Achievement motivation refers more specifically to motivation relevant to performance on tasks in which standards of excellence are operative. Because much of the work on motivation in developmental and educational psychology has focused on achievement motivation, we emphasize it in this chapter.

---

We would like to thank Ellen Skinner and Nancy Eisenberg for helpful comments on an earlier version of this chapter. The work contributed to this chapter was completed when Dr. Roeser was a visiting scholar at the Steinhardt School of Education, New York University.

### **CONCLUSIONS 987**

### **REFERENCES 988**

How can we conceptualize broadly the nature of motivation, its influences on behavior, and its development? Motivation is most directly observable in the level of energy in individuals’ behaviors. Researchers studying motivation posit various sources of this energy. Historically, drives, needs, and reinforcements were proposed as the primary sources (see Eccles et al., 1998; Pintrich & Schunk, 2002; Weiner, 1992), and needs continue to be prominent in one major current motivational theory. However, much current theory and research on motivation focuses on individuals’ beliefs, values, and goals as primary influences on motivation (Eccles & Wigfield, 2002). This implies that the processes influencing motivation are cognitive, conscious, affective, and often under control of the individual. We focus on the belief, value, and goal constructs prominent in current theoretical models in this chapter.

With respect to influences on behavior, children’s motivation relates to their choices about which tasks and activities to do, the persistence with which they pursue

those activities, the intensity of their engagement in them, and their performance on them. Depending on their motivation, some individuals approach particular activities with great persistence and enthusiasm, whereas others seek to avoid these activities. Thus, motivation influences the ways in which individuals' do or do not participate in different activities. Once engaged in an activity, motivation can influence how diligently and in what ways the activity is pursued. Fundamentally, motivational theorists and researchers work to understand the motivational predictors of choice, persistence, and effort (Eccles et al., 1998).

With respect to development, there are important changes in children's motivation as they grow up. The prevailing pattern of change with respect to achievement motivation for many children is a decline over the school years. We discuss the reasons for this decline in this chapter. There are also important individual and group differences in the development of motivation. Many researchers have focused on gender differences in motivation, and there is increasing interest in cultural differences in motivation. We highlight work on both kinds of differences, with a particular emphasis on culture and motivation because much work on this topic has been done over the past decade. Although current theoretical perspectives often emphasize psychological beliefs, values, and goals as crucial to motivation, children's motivational development also is strongly influenced by different socialization agents, such as parents, teachers, and peers, and by the contexts in which they develop. We discuss these influences in this chapter. Indeed, a hallmark of much recent work on motivation is a concern for how different contexts influence motivation (Urdu, 1999).

To present the work on motivation, we organize our chapter in a similar fashion to the one published in the previous edition of this *Handbook*, with some deletions and some additions. To incorporate the new work into the chapter, we deleted or shortened the sections of the chapter focusing on the history of the field. Readers can consult that chapter (Eccles et al., 1998) or Weiner (1992) for this history. To explain the nature of motivation, we begin with a discussion of current theories. Some theories discussed in our previous chapter receive less attention this time and some more attention based on our assessment of their current influence on the field. We then discuss how children's motivation develops. We nest our discussion of group differences in motivation in this section because these differences are developmen-

tal in nature—they emerge during children's development. Next, we turn to how children's motivation is socialized in the home, school, and by peers. We conclude with a brief overall assessment of the state of theory and research in the achievement motivation field.

## CURRENT THEORETICAL PERSPECTIVES ON MOTIVATION

Current achievement motivation theories continue to emphasize children's beliefs, values, and goals as prominent influences on motivation. This means that many theorists adopt a social cognitive perspective on the nature of motivation (Eccles et al., 1998; Pintrich, 2003). Central constructs of interest to motivation theorists include (a) self-efficacy, perceptions of control, and other competence-related beliefs; (b) the goals (both specific and general) children have for learning and other activities; (c) children's interest and intrinsic motivation for learning; and (d) children's valuing of achievement. Although the study of beliefs, goals, and values remains strong, self-determination theorists continue to emphasize the role of basic psychological needs and how they influence motivation.

As Eccles et al. (1998) did we organize our discussion of motivation theories and research around three broad motivation-related questions children can ask themselves: "Can I do this task?" "Do I want to do this task and why?" and "What do I have to do to succeed on this task?" The first two questions primarily are motivational, whereas the third merges cognitive and motivational variables crucial to the regulation of achievement behavior. Some theories include constructs that deal with all of these questions, but even so we find these questions to be a useful way to organize the theories and constructs.

### Theories Concerned Primarily with the Question: "Can I Do This Task?"

Competence-related beliefs—including individuals' beliefs about their competence, self-efficacy, and expectancies for success; attributions and beliefs about intelligence; and sense of control over outcomes—relate directly to the question: "Can I do this task?" and remain prominent in theory and research on achievement motivation (e.g., Elliot & Dweck, 2005). In general,

when children answer this question affirmatively, they try harder, persist longer, perform better and are motivated to select more challenging tasks.

### *Self-Efficacy Theory*

Bandura's (1977, 1997) construct of self-efficacy is a major part of his broader social cognitive model of learning and development. Bandura defines self-efficacy as individuals' confidence in their ability to organize and execute a given course of action to solve a problem or accomplish a task. He emphasizes human agency and self-efficacy perceptions as major influences on individuals' achievement strivings, including performance, choice, and persistence. Bandura (1997) characterizes self-efficacy as a multidimensional construct that can vary in strength (i.e., positive or negative), generality (i.e., relating to many situations or only a few), and level of difficulty (i.e., feeling efficacious for all tasks or only easy tasks).

An important distinction in Bandura's (1997) model is different kinds of expectancies for success. He distinguished between two kinds of expectancy beliefs: (1) outcome expectations—beliefs that certain behaviors, like practice, will lead to certain outcomes, like improved performance; and (2) efficacy expectations—beliefs about whether one can perform the behaviors necessary to produce the outcome (e.g., I can practice sufficiently hard to win the next tennis match). Individuals can believe that a certain behavior will produce a certain outcome (i.e., outcome expectation) but may not believe they can do that behavior (i.e., efficacy expectation). Bandura therefore proposed that individuals' efficacy expectations rather than outcome expectancies are the major determinant of goal setting, activity choice, willingness to expend effort, and persistence (see Bandura, 1997).

Bandura proposed that individuals' perceived self-efficacy is determined primarily by four things: Previous performance (i.e., succeeding leads to a stronger sense of personal efficacy); vicarious learning (i.e., watching models succeed or fail on tasks); verbal encouragement by others; and one's physiological reactions (i.e., overarousal and anxiety/worry leading to a lower sense of personal efficacy). His stress on these four determinants reflects the link of this theory with both behaviorist and social learning traditions. In addition, Bandura acknowledged the influence of causal attributions on people's self-efficacy. However, Bandura argued that causal attributions only influence behavior

through their impact on efficacy beliefs. Bandura (1995) extended the self-efficacy model by discussing how collective efficacy along with individual efficacy also can be a strong influence on achievement strivings.

The self-efficacy construct has been applied to behavior in many domains, including school, health, sports, therapy, occupational choice, and even snake phobia (see Bandura, 1997, for a comprehensive review). The evidence is supportive of his theoretical predictions with respect to efficacy's influences on performance and choice. For example, high self-efficacy predict subsequent performance, course enrollment, and occupational choice (see Bandura, 1997; Pajares, 1996; Schunk & Pajares, 2002); we discuss some of the particular findings in a later section.

Bandura (1997) systematically discussed why he believes self-efficacy theory provides a fuller and richer depiction of the causal relations of self-beliefs to behavior than do other theories focused on self-referent beliefs, including theories of self-concept, locus of control, effectance motivation, control beliefs, perceived competence beliefs, and possible selves, among others. He argued that self-efficacy is defined more precisely and is more task and situation specific than many of these other beliefs and therefore should relate more strongly to behavior. However, some of the distinctions among these constructs may be less clear than Bandura proposed. For instance, researchers measuring both self-concept and self-efficacy in the same study often have found it difficult to distinguish the two constructs empirically (Skaalvik & Bong, 2003; Skaalvik & Rankin, 1996). Bong and Clark (1999) and Skaalvik and Bong (2003) provide a good discussion of conceptual and methodological similarities and differences between self-efficacy and self-concept.

Like many social cognitive-based theories, self-efficacy theory can be criticized for its overly rational and information-processing approach. How accurate are individuals at judging their efficacy, how do these calibrations vary over age, and how much are our decisions influenced by a rational judgment of our competence to do an activity? Further, the focus on one major variable as the major predictor of performance and choice perhaps is too limiting.

### *Self-Concept and Self-Worth Theories*

Harter (1998; Chapter 9, this *Handbook*, this volume) presents comprehensive reviews of the work on self-concept, and so we only include a brief discussion of it

here. Work on self-concept is relevant to this section of the chapter in two main respects. First, many of the most widely used measures of self-concept, such as those developed by Harter (1982) and Marsh (1989), assess perceived competence as the major dimension of self-concept. Thus, self-concept as measured by these instruments is beliefs about one's competence in different areas.

Second, a variety of researchers have examined the relationship between self-concept and achievement, one of the outcomes of great interest to motivation researchers. For many years, researchers debated about the causal direction between self-concept and achievement, with some proposing that growth in self-concept produces growth in achievement, and others proposing just the opposite (see Marsh, 1990b). Many of the studies that purportedly tested these relations used designs that were not adequate to test fully either position (see Marsh & Yeung, 1997, for discussion of these design problems). Recently, a number of researchers utilizing longitudinal designs found that relations between self-concept and achievement are reciprocal. These reciprocal relations have been observed in studies of children of different ages, including children as young as age 7 (Guay, Marsh, & Boivin, 2003). These findings (finally) move the field away from the seemingly intractable question of "which causes which" to the more reasonable conclusion that each variable has causal influence on the other. Such findings provide support for the important role of social cognitive and behavioral variables in the study of motivation.

Self-worth, or our overall evaluation of our worth as a person, continues to be an important variable relevant to motivation as well. Covington and his colleagues (e.g., Covington, 1992; Covington & Dray, 2002) provide the most complete motivational analysis of self-worth, arguing that individuals have a strong desire to protect their self-worth in achievement settings. Schools often focus on the demonstration of relative competence, and Covington argued that to maintain self-worth in school children must protect their competence. Children who do less well than their peers are most at risk for losing self-worth, and so they can develop strategies, such as not trying or procrastinating, as a way to try to protect their sense of competence. These strategies may provide some short-term benefits with respect to self-worth protection but, over the long term, actually work against children. Covington and his colleagues have written about ways in which school environments can be changed to lessen the emphasis on relative competence

of children, thereby allowing more children to maintain a sense of self-worth in school.

Researchers also continue to study other self-processes that guide, direct, and motivate behaviors in ways other than self-worth maintenance (e.g., Garcia & Pintrich, 1994; Markus & Wurf, 1987). For example, Markus and her colleagues discuss how "possible future selves" motivate behavior. Possible selves, the vision individuals have of themselves in the future, include both hoped-for (I will pass geometry) and feared (I will not pass geometry) components. Because possible selves are not identical to one's current self-concept, they motivate the individual by providing goals that the individual tries to attain and outcomes that the individual tries to avoid to achieve his or her image. Whether the possible self is attained depends on many things, one of which is the individual's current perceived competence.

#### *Attribution Theory and Theories about Beliefs about Intelligence and Ability*

Attribution theory concerns individuals' explanations (or attributions) for their successes and failures and how these attributions influence subsequent motivation (Graham, 1991; Weiner, 1985, 2004, 2005). Weiner and his colleagues identified the most frequently used attributions (i.e., ability, effort, task difficulty, and luck), and classified these and other attributions into the different causal dimensions of stability (i.e., stable or unstable), locus of control (i.e., internal or external), and controllability (i.e., under one's volition or not). For instance, ability is classified as internal, stable, and uncontrollable. Each of these dimensions has important psychological consequences that influence subsequent motivation and behavior. The stability dimension relates most directly to expectancies for success and failure, locus of control to affective reactions to success and failure, and controllability to help giving. For instance, attributing failure to lack of ability leads to lowered expectancies for success and negative affect like shame (Weiner, 1985; see Eccles et al., 1998, for more detailed review).

Attribution theory was quite dominant in the motivation field for many years, but its influence has waned to an extent recently. Despite this, there still is great interest in the motivation field in perceptions of ability and also of effort. Indeed, some theorists (most notably, Carol Dweck) working in the attribution tradition have become interested in individuals' beliefs about the nature of ability and the implications of these beliefs for their motivation and effort. Dweck and her colleagues

(e.g., Dweck, 2002; Dweck & Leggett, 1988) posited that children can hold one of two views of intelligence or ability. Children holding an *entity* view of intelligence believe that intelligence is a stable trait. Children holding an *incremental* view of intelligence believe that intelligence is changeable, so that it can be increased through effort. Note that this differs from the traditional attribution theory view, which is that ability is a stable characteristic. In Dweck's work there is more than one way to view one's ability.

Dweck and her colleagues (Dweck, 2002; Dweck & Leggett, 1988) have discussed how children's conceptions of ability and intelligence can have important motivational consequences. Dweck (2002) argued that children holding an entity theory of intelligence are motivated to look smart and protect their sense of ability. Children believing intelligence can change focus on learning and improvement. When children do poorly, believing that their ability has a limited capacity means that failure is more debilitating. Some children holding this view will believe they have little chance of ever doing well because their ability cannot be improved. Children holding this belief can become "learned helplessness" in achievement settings; we discuss learned helplessness later. In contrast, believing effort can improve performance in important ways can mean that children will continue to try even if they are not doing well on a given task (see Dweck & Leggett, 1988; Nicholls, 1984, 1990, for further discussion).

Dweck and Leggett (1988) tied children's beliefs about intelligence to their achievement goals, as we see in a later section. Children holding an incremental view of intelligence tend to have mastery or learning goals, whereas children holding an entity view have performance goals. Further, Dweck and Leggett broadened their analysis to other domains, contrasting the relative benefits of incremental versus entity views about social relationships and moral development. In each case, they argued that the incremental view has many benefits to children (see also Dweck, 2002).

### **Control Theories**

Building on the seminal early work of Rotter (1966) and Crandall, Katkovsky, and Crandall (1965) on internal and external locus of control, theorists have elaborated broader conceptual models of control. Connell (1985), for example, added *unknown control* as a third control belief category and argued that younger children are particularly likely to use this category. He developed and validated to a scale to assess external control (i.e.,

"powerful others"), internal control (i.e., effort and ability), and unknown control for cognitive, physical, social, and general activities. Connell and Wellborn (1991) then integrated control beliefs into the self-determination framework that proposes the fundamental psychological needs for competence, autonomy, and relatedness (see Deci & Ryan, 1985; R. M. Ryan, 1992; R. M. Ryan & Deci, 2000a, further discussion later). They linked control beliefs to competence needs: Children who believe they control their achievement outcomes should feel more competent. They hypothesized that the extent to which these needs are fulfilled is influenced by the following characteristics of their family, peer, and school contexts: (a) the amount of structure, (b) the degree of autonomy provided, and (c) the level of involvement in the children's activities.

Ellen Skinner and her colleagues (e.g., Skinner, 1995; Skinner, Chapman, & Baltes, 1988) proposed a more elaborate model of control beliefs. This model includes three critical control-related beliefs: (1) strategy beliefs, (2) control beliefs, and (3) capacity beliefs. Strategy beliefs concern the expectation that particular causes can produce certain outcomes; these causes include Weiner's (2005) various causal attributions and Connell's (1985) unknown control. Control beliefs are the expectations individuals have that they can produce desired events and prevent undesired ones. Capacity beliefs are the expectations that one has access to the means needed to produce various outcomes. Skinner (1995) proposed that control beliefs are a major determinant of actions, leading to outcomes that are interpreted by the individual and subsequently influence their control beliefs, starting the cycle again.

Skinner distinguished her position from self-efficacy theories by noting that self-efficacy theorists discuss connections between agents and means primarily as expectancies that the individual can produce some outcome; thus outcomes are contingent on one's responses. In contrast, she argued that her capacity beliefs relate to potential as well as actual means. Further, an individual can have strong capacity beliefs for different means without believing that any of the means are necessarily effective (see also R. M. Ryan, 1992).

Finally, Skinner, Connell, and their colleagues have broadened their discussion of perceived control and its influences by developing a model of the relations among context, the self, action, and outcomes (e.g., Connell, Spencer, & Aber, 1994; Skinner & Wellborn, 1994). They proposed that when contexts are set up in a way that allows the needs of competence, relatedness, and

autonomy to be supported, individuals will be engaged more fully in activities, which leads to positive developmental outcomes. Contexts that are not supportive of these needs lead to disengagement. Further, the ways in which these needs are fulfilled determine engagement in different activities. When the needs are fulfilled, children will be fully engaged. When one or more of the needs is not fulfilled, children will become disaffected. Connell et al. (1994) and Skinner and Belmont (1993) conducted studies in classroom settings that supported these linkages. We discuss the implications of these findings in the section on how school contexts influence children's motivation.

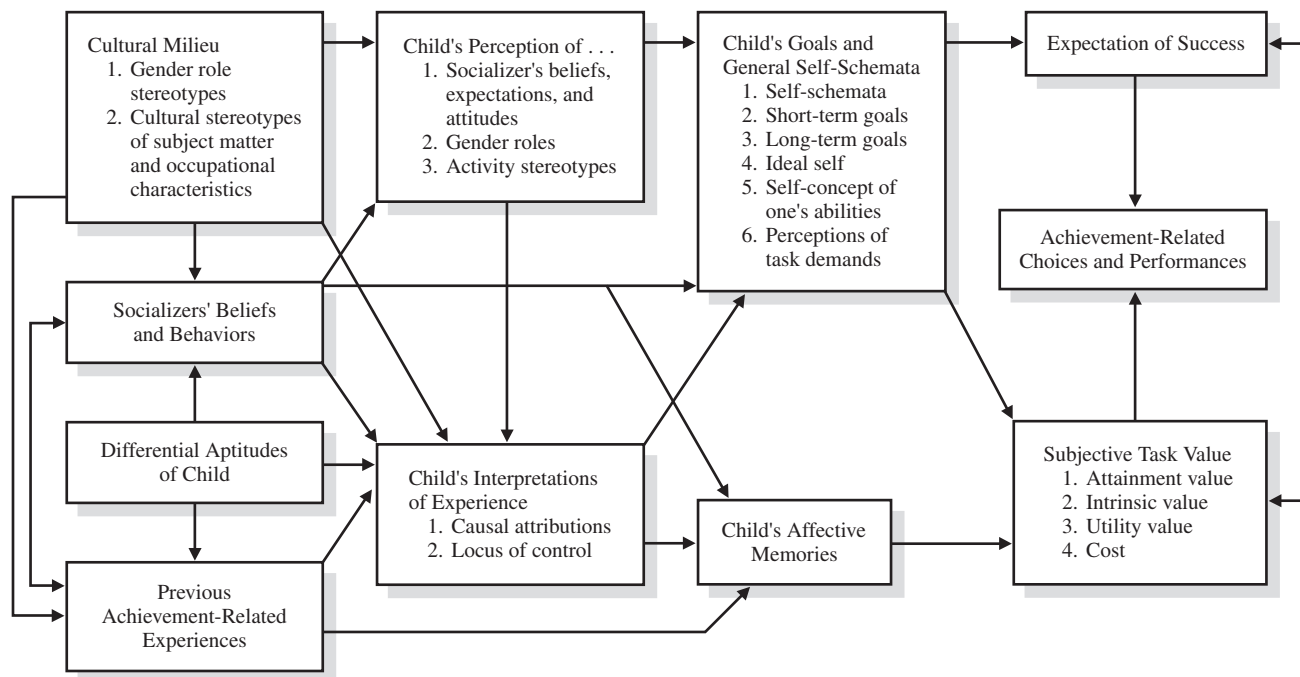

### Modern Expectancy-Value Theory

Modern expectancy-value theories (e.g., Eccles-Parsons et al., 1983; Feather, 1982; Heckhausen, 1977; Pekrun, 1993; Wigfield & Eccles, 2000, 2002b) are based in Atkinson's (1957, 1964) original expectancy-value model in that they link achievement performance, persistence, and choice most directly to individuals' expectancy-related and task-value beliefs. However, they differ from Atkinson's theory in several ways: First, both the expectancy and value components are more elaborate and are linked to a broader array of psycholog-

ical and social/cultural determinants. Second, they are grounded more in real-world achievement tasks than the laboratory tasks often used to test Atkinson's theory. We focus here on the ability and expectancy portion of Eccles and her colleagues' model; see Eccles et al. (1998) for review of some other modern expectancy-value models.

**The Eccles et al. Expectancy-Value Model.** Eccles-Parsons and her colleagues elaborated and tested one expectancy-value model of achievement-related choices (see Eccles, 1987, 1993; Eccles & Wigfield, 1995; Eccles-Parsons et al., 1983; Wigfield & Eccles, 2000, 2002b). This model focuses on the social psychological influences on choice and persistence. Choices are seen to be influenced by both negative and positive task characteristics and all choices are assumed to have costs associated with them precisely because one choice often eliminates other options. Much of their work focuses on individual differences and gender differences in decisions regarding which courses to take, what careers to seek, and what activities to pursue.

The theoretical model is depicted in Figure 15.1. Expectancies and values are assumed to directly influence performance, persistence, and task choice. Expectan-

**Figure 15.1** Eccles and colleagues' motivational model of achievement performance and choice.

cies and values are assumed to be influenced by task-specific beliefs such as perceptions of competence, perceptions of the difficulty of different tasks, and individuals' goals and self-schema. These social cognitive variables are influenced by individuals' perceptions of other peoples' attitudes and expectations for them and by their own interpretations of their previous achievement outcomes. Individuals' task-perceptions and interpretations of their past outcomes are assumed to be influenced by the socializer's behavior and beliefs and by the cultural milieu and unique historical events.

Eccles-Parsons et al. (1983) defined expectancies for success as children's beliefs about how well they will do on upcoming tasks, either in the immediate or longer-term future. These expectancy beliefs are measured in a manner analogous to measures of Bandura's (1997) personal efficacy expectations: Thus, in contrast to Bandura's claim that expectancy-value theories focus on outcome expectations, the focus in this model is on personal or efficacy expectations.

Eccles-Parsons et al. (1983) defined beliefs about ability as children's evaluations of their competence in different areas; this definition is similar to those of researchers like Covington (1992), Harter (e.g., Harter, 1982, 1990), and Marsh and his colleagues (e.g., Marsh, 1990a). In measuring ability beliefs, Eccles and her colleagues measure individuals' beliefs about how good they are at a certain activity, how good they are relative to other individuals, and how good they are relative to their performance on other activities. This approach is somewhat different from the way in which self-efficacy often is measured. Many self-efficacy measures do not include the comparative items but instead focus solely on individuals' judgments of their own capabilities (Bandura, 1997; Pajares, 1996).

In this model, ability beliefs and expectancies for success are distinguished theoretically in that ability beliefs are seen as beliefs about competence in a given domain, in contrast to one's expectancies for success on a specific upcoming task. However, their empirical work has shown that children and adolescents do not distinguish between these two different levels of beliefs (e.g., Eccles & Wigfield, 1995; Eccles, Wigfield, Harold, & Blumenfeld, 1993). Even though these constructs can be theoretically distinguished from each other, in real-world achievement situations they are highly related and thus empirically indistinguishable. Eccles and her colleagues have found that children's expectancy-related beliefs have direct effects on their subsequent perfor-

mance and indirect effects on their intentions to continue doing activities and actual choices of doing so (e.g., Meece, Wigfield, & Eccles, 1990).

In sum, a variety of theories continue to focus on competence-related beliefs as having a major impact on motivation. As we have seen, there are differences in how the competence and control constructs are defined and measured in these theoretical models. These distinctions among the various constructs are important theoretically, but, empirically and practically, the constructs are highly related. A further proliferation of these constructs does not seem necessary, and perhaps by examining more closely relations among them we can determine which of them is the most viable.

### **Theories Concerned with the Question: "Do I Want to Do This Task and Why?"**

Theories dealing with efficacy, expectancy, and control beliefs provide powerful explanations of individuals' performance on different kinds of achievement tasks. However, these theories do not systematically address another important motivational question: "Do I *want* to do the task?" Even if people are certain they can do a task, they may not want to engage in it, and so they may not be strongly motivated to approach it. Further, individuals often have different purposes or goals for doing different activities, which also can impact their motivation for doing the task. The theories presented next focus on these kinds of issues.

### ***Modern Expectancy-Value Theories: The Importance of Task Value***

We discussed in the previous section the expectancy and competence belief portions of expectancy-value models. Here we focus on the task value part of the model. Eccles and her colleagues have done much of this work. However, it is important to acknowledge Feather's (1982, 1988, 1992) contributions (see Eccles et al., 1998, for more detailed discussion of his work). Feather looked at broader values and task-specific values in several studies of students' choices of college majors and activities. Finding values to be strongly predictive of these choices, he also found that students' expectancies for success and values were positively rather than inversely related.

**Eccles, Wigfield, and Colleagues' Work on Subjective Task Values.** Eccles-Parsons and her

colleagues (1983) defined four motivational components of task value: (1) attainment value, (2) intrinsic value, (3) utility value, and (4) cost. They defined attainment value as the personal importance of doing well on the task, and also linked this aspect of task value to the relevance of engaging in a task for confirming or disconfirming salient aspects of one's self-schema, such as perceived gender role, ethnic identity, or other salient aspect of self.

Intrinsic value is the enjoyment the individual gets from performing the activity, or the subjective interest the individual has in the subject. This component of value is similar in certain respects to the construct of intrinsic motivation as defined by Harter (1981), and by Deci and his colleagues (e.g., Deci & Ryan, 1985; R. M. Ryan & Deci, 2000a), and to the constructs of interest and flow as defined by Csikszentmihalyi (1988), Renninger (1990), and Schiefele (1991). However, like the debates about the different competence-related belief constructs, there have been discussions in the literature about the differences among these related constructs as well.

Utility value is determined by how well a task relates to current and future goals, such as career goals. A task can have positive value to a person because it facilitates important future goals, even if he or she is not interested in the task for its own sake. For instance, students often take classes that they do not particularly enjoy but that they need to take to pursue other interests, to please their parents, or to be with their friends. In one sense, this component captures the more extrinsic reasons for engaging in a task. But it also relates directly to individuals' internalized short- and long-term goals.

Finally, Eccles and her colleagues identified "cost" as a critical component of value (Eccles, 1987; Eccles-Parsons et al., 1983). Cost is conceptualized as the negative aspects of engaging in the task, such as performance anxiety and fear of failure or of success and the amount of effort needed to succeed. It also is defined by the lost opportunities that result from making one choice rather than another. When a child chooses to do her homework this may mean she will not have time to instant message her friends, truly a major cost for some children. This aspect of task values has been less studied than the others, even though it likely plays an important role in individuals' choices. Indeed, Battle and Wigfield (2003) found that the perceived psychological costs of attending graduate school were a negative predictor of college students' intentions to enroll in graduate school.

Eccles and her colleagues and others (e.g., Bong, 2001) have assessed the links of expectancies and values to performance and choice (see Wigfield & Eccles, 2002b, for review). They have shown that ability self-concepts and expectancies for success directly predict performance in mathematics, English, computer activities, and sport activities, even when previous performance is controlled. Children's task values predict course plans and enrollment decisions more strongly than do expectancy-related beliefs. Eccles (1994) found that both expectancies and values predict career choices. These results illustrate the importance of looking not only at competence and expectancy beliefs but also at achievement values in understanding individuals' performance and choice.

**Valuing Particular Learning Activities Now and in the Future.** Brophy (1999) edited a special issue of the journal *Educational Psychologist* devoted to the value aspects of learning. In his article in this issue, he noted that we still know relatively little about how children's values and interests for particular learning activities develop and how different learning opportunities influence children's valuing of them. He made the intriguing proposal that we should think of a motivational zone of proximal development (ZPD) along with a cognitive ZPD as we consider ways to enhance children's learning and motivation. When learning activities are in a child's motivational ZPD they can come to appreciate the importance of the activity and will be more likely to engage in it. If a learning activity is too far above a student's motivational ZPD the student will be less likely to engage in the activity, or appreciate its importance. Brophy also proposed that the cognitive and motivational ZPD's may interact to influence students' learning and engagement, and he discussed ways in which children's valuing of learning can be fostered. We return to these ideas in a later section.

Husman, Lens, and their colleagues have discussed another important values-related construct, future time perspective (FTP; Husman & Lens, 1999; Kaufman & Husman, 2004; Lens, 1986), building on earlier work on the role of the future in motivation by theorists such as Raynor (1982). They noted that much of the work in the motivation field focuses on motivation for immediate tasks and activities. This motivation obviously is important for students' engagement in learning, but students also know that a major purpose of education is to prepare them for the future. Therefore, if students

believe that current educational activities are useful to them in the long run, they are more likely to be motivated to achieve. Husman, Lens, and their colleagues have done a series of studies on FTP, showing that when students see the value of educational activities to their future success they are more positively motivated, self-regulated, and achieve higher grade point averages (GPAs). They refer to the *instrumentality* of these activities to the future as the key predictive variable. With respect to Eccles and colleagues' definitions of aspects of task value, it appears that FTP focuses on the utility and (possibly) the attainment aspects rather than the interest aspect. However, Husman (1998) has shown some relations of future instrumentality to intrinsic motivation.

In sum, expectancy-value models continue to be prominent. We noted in our previous chapter that research has focused to a much greater extent on expectancy-related rather than value aspects of this model. That picture has changed some over the past several years. Yet, more work is needed on the nature of children's achievement values and how they develop. We also need more work on how the links of expectancies and values to performance and choice change across ages (see Eccles, 1993; Wigfield, 1994) and on the links between expectancies and values (see Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002). Both Eccles (1984) and Bandura (1997) propose a positive association between expectancy related beliefs and task values, and research supports this (e.g., Wigfield et al., 1997). The role of FTP in expectancy-value models also deserves continued study.

Like self-efficacy theory, modern expectancy-value theory can be criticized for emphasizing overly rational cognitive processes leading to motivation and behavior. Such criticisms are likely to be particularly apropos when these models are considered from a developmental perspective (see Wigfield, 1994). However, the impressive body of research showing the relations of expectancy and values to different kinds of performance and choice supports the continuing viability of these models. Furthermore, as conceptualized by Eccles and her colleagues, values are linked to more stable self-schema and identity constructs and choice is not necessarily the result of conscious, rational, decision-making processes (see Eccles, 1987; Eccles & Harold, 1992). By including affective memories, culturally based stereotypes, and identity-related constructs and processes as part of the theoretical system, Eccles and her colleagues

have allowed for less rational and conscious processes in motivated behavioral choices.

### *Intrinsic Motivation Theories*

There is a fundamental distinction in the motivation literature between *intrinsic* motivation and *extrinsic* motivation. When individuals are intrinsically motivated, they do activities for their own sake and out of interest in the activity. When extrinsically motivated, individuals do activities for instrumental or other reasons, such as receiving a reward (see Sansone & Harackiewicz, 2000b). There is continuing debate about the pros and cons of intrinsic and extrinsic motivation, and a growing consensus that these two constructs should not be treated as polar opposites. Rather, they often both operate in different situations, and may even form a continuum.

Much of the work on intrinsic motivation stemmed from White's (1959) seminal article on effectance motivation: He argued persuasively that both people and at least some animals are motivated by curiosity and interest in developing their competence rather than just by rewards or the satisfaction of basic bodily needs. This influential article had a strong influence on the views of Edward Deci and Richard Ryan, whose self-determination theory of intrinsic motivation is the main focus in this section.

**Self-Determination Theory.** Deci, Ryan, and their colleagues' self-determination theory (SDT) is an organismic theory of development that has a particular focus on the role of motivation in development and learning (e.g., Deci & Ryan, 1985, 2002b; Deci, Vallerand, Pelletier, & Ryan, 1991; R. M. Ryan & Deci, 2000a). Broadly, self-determined behavior is behavior that originates from the self and that results from the individual utilizing his or her volition. Deci, Ryan, and their colleagues suggest that when individuals' behavior is self-determined they are psychologically healthier and tend to be intrinsically motivated. Indeed, they make a specific link between intrinsic motivation and self-determination, arguing that intrinsic motivation is only possible when individuals freely choose their own actions—they are self-determined.

Deci, Ryan, and their colleagues propose that there are three basic or fundamental human psychological needs: (1) the need for competence, (2) the need for autonomy, and (3) the need for relatedness (Deci & Ryan, 2002b; R. M. Ryan & Deci, 2002). For healthy development to occur, these needs must be met. Further, these

needs are a basis for motivation. For instance, the need for competence is the major reason why people seek out optimal stimulation and challenging activities. The need for autonomy refers most directly to volition and self-determination; Deci and Ryan argue that this sense of volition is necessary for optimum motivation. R. M. Ryan (1992) discussed the importance of distinguishing between competence and autonomy. He argued that models that focus primarily on competence, like self-efficacy theory, do not make this distinction clear enough. Individuals can act competently and demonstrate their competence but still be doing so under the control of others. R. M. Ryan compared such actions to those of a robot, rather than a self-determined individual, and argued that intrinsic motivation only occurs when individuals are both autonomous and competent. The proposal that autonomy is a basic human need has led to much interesting research on topics such as choice and how providing children and adults with choice influences their intrinsic motivation.

Relatedness refers to the need to be connected with others. This need was added to the theory after the other two, and reflects Deci and Ryan's beliefs that individuals must have strong connections to others for optimum development to occur. In their view, the need for autonomy does not imply total independence; connections with others also are important to optimum development.

Deci, Ryan, and colleagues go beyond the extrinsic-intrinsic motivation dichotomy in their discussion of *internalization*, which is the process of transferring the regulation of behavior from outside to inside the individual (see Deci, Koestner, & Ryan, 1999; Grolnick, Gurland, Jacob, & Decourcey, 2002). They developed a taxonomy to describe different types of motivation involved in the process of going from external to more internalized regulation of motivation. This taxonomy forms a continuum. At one extreme is *amotivation*, which as the name implies means an absence of motivation to act. Next are several types of extrinsic motivation that range from least to most autonomous. In order, these are:

- *External*: Regulation coming from outside the individual
- *Introjected*: Internal regulation based on feelings that he or she should or has to do the behavior
- *Identified*: Internal regulation of behavior that is based on the utility of that behavior (e.g., studying hard to get grades to get into college)
- *Integrated*: Regulation based on what the individual thinks is valuable and important to the self

Each of these levels also is associated with different kinds of motivation. For instance, extrinsic rewards are most salient for external regulation, and at each subsequent level motivation become more internalized.

Deci, Ryan, and their colleagues have developed scales to measure these different levels of regulation. They have tested their continuum idea by looking at how related the different kinds of motivation are. For instance, R. M. Ryan and Connell (1989) assessed children's external, introjected, identified, and intrinsic reasons for doing schoolwork, and found that these correlations formed a simplex pattern (see also Vallerand et al., 1993). The levels of regulation closer to one another in the continuum were more highly related than those further apart, which they took as evidence for their placement on the continuum. Further, they found that the more extrinsically motivated the students were, the less invested they were in their schoolwork.

One major focus of Deci, Ryan, and their colleagues' research and theorizing has been how extrinsic rewards can undermine intrinsically motivated behavior. They call this portion of their theory cognitive evaluation theory. They and others (e.g., Lepper & Green, 1978) described different conditions under which rewards can be undermining; the most notable is when rewards are controlling, which reduces the individual's perceptions of autonomy over their own learning. When rewards provide individuals with information about how they are doing rather than focus on controlling them, the undermining effects do not occur. In 1994, Cameron and Pierce published a meta-analysis of this research in which they questioned the strength of these undermining effects, arguing that they occurred only in very limited circumstances if at all. This article led to a series of commentaries and reactions and further meta-analyses of the findings regarding the undermining effects of rewards on intrinsically motivated behavior, with many claims and counter-claims about the adequacy of the meta-analytic techniques used and ways of parsing the findings (see Deci et al., 1999; Lepper & Henderlong, 2000; R. M. Ryan & Deci, 2000b; Sansone & Harackiewicz, 2000b, for a summary of this debate). We believe that Deci, Ryan, and their colleagues have replied effectively to Cameron and Pierce's various arguments against the undermining effects of extrinsic motivation. Yet, this debate was useful because it served to clarify the conditions under which extrinsic motivators do undermine intrinsically motivated behaviors and so moved the field ahead in important ways.

SDT has been a dominant theoretical model and one that has generated a great deal of research. It is a broad model that encompasses a variety of constructs and that integrates many important issues with respect to the development of motivation. The theory, however, has been the subject of some criticism. A number of questions have been raised about Deci and Ryan's contention that there are three basic psychological needs (see Pintrich, 2003). Other questions have been raised about the universality of these needs and whether they operate similarly in different cultures. For instance, in cultures defined as less individualistic and more collectivist does the need for autonomy take on the same importance? This question currently is the focus of a great deal of research (Reeve, Deci, & Ryan, 2004). There also has been debate in SDT on the role of choice in helping children fulfill their need for autonomy (Reeve, Nix, & Hamm, 2003). Finally, although the continuum from extrinsic to intrinsic motivation is intriguing, there is some concern that intrinsic motivation as defined in this way only describes a very limited set of activities that people do during their daily lives. This perhaps constrains intrinsic motivation too much.

**Flow Theory.** Csikszentmihalyi (1988) discusses intrinsically motivated behavior in terms of the immediate subjective experience that occurs when people are engaged in the activity. Interviews with climbers, dancers, chess players, basketball players, and composers revealed that these activities yield a specific form of experience—labeled flow—characterized by: (a) holistic feelings of being immersed in, and of being carried by, an activity; (b) merging of action and awareness; (c) focus of attention on a limited stimulus field; (d) lack of self-consciousness; and (e) feeling in control of one's actions and the environment. Flow is only possible when people feel that the opportunities for action in a given situation match their ability to master the challenges. The challenge of an activity may be something concrete or physical, like the peak of a mountain to be scaled, or it can be something abstract and symbolic, like a set of musical notes to be performed, a story to be written, or a puzzle to be solved. Further research has shown that both the challenges and skills must be relatively high before a flow experience becomes possible (Massimini & Carli, 1988).

At first sight, the theories of Deci and Ryan and Csikszentmihalyi seem to be very different. Deci and Ryan (1985, 2002b) explain intrinsic motivation by as-

suming innate, basic needs, whereas Csikszentmihalyi stresses subjective experience. We suggest that this difference reflects two sides of the same coin. As K. Schneider (1996) has argued, a person has to distinguish between immediate reasons (e.g., enjoyment) and ultimate reasons of behavior (e.g., survival). Intrinsically motivated behavior can be conducive to ultimate goals even though the actor is only motivated by immediate incentives. A typical case is exploratory or play behavior. Both types of behavior help to increase an individual's competence, but they are usually performed because they are exciting, pleasurable, or enjoyable. This distinction between immediate and ultimate causes of behavior makes it possible to reconcile the positions of Deci and Ryan and Csikszentmihalyi. Deci and Ryan (1985) focus on ultimate reasons of behavior, whereas Csikszentmihalyi (1988) focuses mainly on immediate reasons. Csikszentmihalyi and Massimini (1985) have suggested that the experience of flow is a reward that ensures that individuals will seek to increase their competence. According to Csikszentmihalyi, the repeated experience of flow is only possible when individuals seek out increasingly challenging tasks and expand their competencies to meet these challenges. Thus, the experience of flow should reinforce behaviors underlying development.

**Individual Difference Theories of Intrinsic Motivation.** Until recently, intrinsic motivation researchers like Deci and Ryan and Csikszentmihalyi have dealt with conditions, components, and consequences of intrinsic motivation without making a distinction between intrinsic motivation as a state versus intrinsic motivation as a traitlike characteristic. However, interest in traitlike individual differences in intrinsic motivation has increased recently, particularly among educational psychologists (see Gottfried, 1985, 1990; Gottfried, Fleming, & Gottfried, 2001; Harter, 1981; Nicholls, 1984, 1989; Schiefele, 1996a, 1996b; Schiefele & Schreyer, 1994). These researchers define this enduring intrinsic motivational orientation by three components: (1) preference for hard or challenging tasks, (2) learning that is driven by curiosity or interest, and (3) striving for competence and mastery. The second component is most central to the idea of intrinsic motivation. Both preference for hard tasks and striving for competence can be linked to either extrinsic or more general need achievement motivation. Nonetheless, empirical findings suggest that the three components are highly correlated. In addition, evidence suggests that

high levels of traitlike intrinsic motivation facilitate positive emotional experience and well-being (Matsumoto & Sanders, 1988; R. M. Ryan & Deci, 2000a), self-esteem (R. M. Ryan, Connell, & Deci, 1985), high academic achievement (Cordova & Lepper, 1996; Schiefele & Schreyer, 1994), creativity (e.g., Hennessey, 2000), self-regulation, and persistence (Cordova & Lepper, 1996; Pelletier, Fortier, Vallerand, & Brière, 2001; Pintrich & Schrauben, 1992; Schiefele & Schreyer, 1994). As a consequence, many have suggested that the development of an intrinsic motivational orientation should be fostered in the home and the classroom (e.g., Brophy, 1999; Dewey, 1913; Lepper & Chabay, 1985).

### *Interest Theories*

Closely related to the notion of intrinsic motivation is work on the concept of “interest” (P. A. Alexander, Kulikowich, & Jetton, 1994; Hidi, 2001; Krapp, 2002; Renninger, 2000; Renninger, Hidi, & Krapp, 1992; Schiefele, 1991, 2001; Tobias, 1994). Hidi and Harackiewicz (2000) propose that interest is more specific than intrinsic motivation, which is a broader motivational characteristic (see also Deci, 1992, 1998). Researchers studying interest differentiate between individual and situational interest. Individual interest is a relatively stable evaluative orientation toward certain domains; situational interest is an emotional state aroused by specific features of an activity or a task. Two aspects or components of individual interest are distinguishable (Schiefele, 1996a, 2001): (1) feeling-related valences and (2) value-related valences. Feeling-related valences refer to the feelings that are associated with an object or an activity itself—feelings like involvement, stimulation, or flow. Value-related valences refer to the attribution of personal significance or importance to an object. In addition, both feeling-related and value-related valences are directly related to the object rather than to the relation of this object to other objects or events. For example, if students associate mathematics with high personal significance because mathematics can help them get prestigious jobs, we would not speak of interest. Although feeling-related and value-related valences are highly correlated (Schiefele, 1996a), it is useful to differentiate between them because some individual interests are likely based primarily on feelings, whereas others’ interests are more likely to be based on personal significance (see Eccles, 1984; Wigfield & Eccles, 1992). Further research is necessary to validate this assumption.

Much of the research on individual interest has focused on its relation to the quality of learning (see P. A. Alexander et al., 1994; Hidi, 2001; Renninger, Ewen, & Lasher, 2002; Schiefele, 1996a, 1996b, 1999). In general, there are significant but moderate relations between interest and text learning. Importantly, interest is more strongly related to indicators of deep-level learning (e.g., recall of main ideas, coherence of recall, responding to deeper comprehension questions, and representation of meaning) than to surface-level learning (e.g., responding to simple questions or verbatim representation of text; Schiefele, 1996b, 1999; Schiefele & Krapp, 1996). Findings by Ainley, Hidi, and Berndorff (2002) and Hidi (2001) suggest that attentional processes, affect, and persistence mediate the effects of interest on text learning.

There is also ample evidence that subject matter interest is positively related to school achievement (cf. Schiefele, Krapp, & Winteler, 1992). Recent studies suggest that interest particularly predicts achievement when there is a context that allows for choice. Specifically, Köller, Baumert, and Schnabel (2001) found that interest in mathematics predicts achievement only at higher grade levels when students have a choice between more or less advanced courses. The “effect” of interest on achievement was partly mediated by choice of course level. However, there was also a direct path from interest to achievement even when controlling for prior achievement.

Most of the research on situational interest has focused on the characteristics of academic tasks that create interest (e.g., Hidi, 2001; Schraw & Lehman, 2001). Among others, the following text features were found to arouse situational interest: personal relevance, novelty, vividness, and comprehensibility (Chen, Darst, & Pangrazi, 2001; Schraw, Bruning, & Svoboda, 1995; Wade, Buxton, & Kelly, 1999). Empirical evidence has provided strong support for the relation between situational interest and text comprehension and recall (see reviews by Hidi, 2001; Schiefele, 1996a, 1999; Wade, 1992).

### *Goal Theories*

Work on achievement goals and goal orientations has flourished since the publication of our previous chapter. This work can be organized into three relatively distinct areas (see Pintrich, 2000a). One group of researchers has focused on the properties of goals for specific learning activities. These researchers (e.g., Bandura, 1986; Schunk, 1991) focus on goals’ proximity, specificity,

and level of challenge and have shown that specific, proximal, and somewhat challenging goals promote both self-efficacy and improved performance. A second group of researchers defined and investigated broader goal orientations students have toward their learning, focusing primarily on three broad orientations: (1) a mastery or learning orientation, (2) an ego or performance orientation, and (3) a work-avoidant orientation. These orientations refer to broader approaches children take to their learning, rather than goals for specific activities, although goal orientations can also influence the approach one takes to a specific task. A third group focuses on the content of children's goals, proposing that there are many different kinds of goals individuals can have in achievement settings, including both academic and social goals (e.g., Ford, 1992; Wentzel, 1991b). We focus in this section on the work of the latter two groups.

**Goal Orientation Theory.** Researchers (e.g., Ames, 1992; Blumenfeld, 1992; Butler, 1993; Dweck & Leggett, 1988; Maehr & Midgley, 1996; Nicholls, 1984) initially distinguished two broad goal orientations that students can have toward their learning. First, the *learning*, *task-involved*, or *mastery* goal orientation means that the child is focused on improving their skills, mastering material, and learning new things. Questions such as "How can I do this task?" and "What will I learn?" reflect task-involved goals. Second, the *performance* or *ego* orientation means that the child focuses on maximizing favorable evaluations of their competence and minimizing negative evaluations of competence. In addition, Nicholls and his colleagues (e.g., Nicholls, Cobb, Yackel, Wood, & Wheatley, 1990) and Meece (1991, 1994) have described a *work-avoidant* goal orientation, which means that the child does not wish to engage in academic activities.

The different terms used to label these goal orientations occurred because different researchers were working on them simultaneously, with each having a somewhat distinctive view of each orientation (see Pintrich, 2000a; Thorkildsen & Nicholls, 1998, for discussion of the intellectual roots of different researchers' definitions of these goal orientations). For instance, Dweck and Leggett (1988) proposed that children's goal orientations stem from their theories of intelligence that were described earlier. Children believing intelligence is malleable tend to hold a learning (mastery) goal orientation, and children adopting

the entity view take on performance goals. By contrast, Ames (1992) focused primarily on classroom antecedents of these goal orientations, rather than characteristics of children, which implies that goal orientations are more a product of context rather than the person and so may vary more widely across different achievement situations. We acknowledge that the different terminology used by these theorists reflects some important distinctions in the conceptualization of these goal orientations, but also believe that the similarities are stronger than the distinctions between them (see Midgley, Kaplan, & Middleton, 2001; Pintrich, 2000a, for a similar conclusion). We will use the terms *mastery* and *performance* goal orientations in this chapter.

One of the newer directions in goal orientation theory is further differentiation of these two broad goal orientations into approach and avoidance components (Elliot, 1999, 2005). This occurred first for the performance goal orientation, beginning with work by Elliot and Harackiewicz (1996) and Skaalvik (1997), among others. These further distinctions emerged for two main reasons. Empirically, findings concerning the outcomes of having a performance goal orientation were somewhat contradictory, leading researchers to wonder why this occurred. Theoretically, Elliot and Harackiewicz noted that traditional achievement motivation theories, such as Atkinson's (1957) expectancy-value model, included both approach and avoidance motives. By contrast, most modern theories focus primarily on the approach aspect, thus overlooking the importance of avoidance motivation.

Therefore, Elliot and Harackiewicz (1996) proposed approach and avoidance aspects of performance goals, as did Skaalvik (1997). Performance-approach goals refer to the students' desire to demonstrate competence and outperform others. Performance-avoidance goals involve the desire to avoid looking incompetent. Researchers began to disentangle the effects of these two kinds of performance orientations. As we see later, there is evidence that performance-approach goals can have a positive impact on different outcomes, such as grades, whereas the impact of performance-avoidance goals is nearly always negative.

Elliot (1999; Elliott & McGregor, 2001) and Pintrich (2000c) proposed that the mastery goal orientation also may be divided into approach and avoid components. Elliot and McGregor stated that the assumption was made that mastery goals always referred to approach situations,

rather than avoidance situations, which they believe does not provide a full characterization of situations to which mastery goals apply. They argued that mastery-avoidance goals include such things as working to avoid misunderstanding or the use of standards to not be wrong when doing an achievement activity. As Elliot and McGregor and Pintrich both note, perfectionists may be characterized as holding mastery-avoidance goals. Elliot and McGregor (2001) developed items to assess mastery-avoidance goals and found (in a study of college students) that these items factored separately from items measuring the other three kinds of goal orientations. The antecedents (as perceived by the participants) of mastery-avoidance goals were not as positive as antecedents of mastery-approach goals. These results are intriguing, but much more work is needed to establish the meaningfulness of this new category.

There is a growing body of research documenting the consequences of adopting one or the other of these goal orientations. Researchers have used a variety of methodologies in this work—including classroom observations (Ames & Archer, 1988), interviews (Dowson & McInerney, 2003), and questionnaire-based studies—often using Midgley and her colleagues' Patterns of Adaptive Learning Scale (PALS; Midgley et al., 1998). Experimental manipulations of students' goal orientations also have been done, by introducing achievement tasks in a way that fosters either mastery or performance goals (e.g., Graham & Golan, 1991). The results concerning mastery orientation are quite consistent and positive (see E. M. Anderman, Austin, & Johnson, 2002; Pintrich, 2000a, 2000c; Urdan, 1997, for review). When children are mastery oriented, they are more highly engaged in learning, use deeper cognitive strategies, and are intrinsically motivated to learn. Elliot and McGregor (2001) found that mastery-avoidance goals are associated with a mixture of outcomes, including subsequent test anxiety, mastery-approach goals, and performance-approach goals. Based on this and other work, researchers have proposed that schools should work to foster mastery goal orientations rather than performance goal orientations, and school reform efforts to do just that have been undertaken (e.g., Maehr & Midgley, 1996). We discuss some of this work in a later section of this chapter.

As noted earlier, the research on performance goals is somewhat less consistent, in part because of the methodological confounding of performance-avoidance and performance-approach goals. When these two as-

pects of performance goals are unconfounded, researchers find that performance-avoidance goals have negative consequences for students' motivation and learning (e.g., Elliot & Harackiewicz, 1996; Middleton & Midgley, 1997; Skaalvik, 1997). Performance-approach goals relate positively to academic self-concept, task value, and performance (at least in college students) but not to intrinsic motivation to learn (see Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002, for review).

The distinction between performance-approach and performance-avoidance goals, and evidence showing that performance-approach goals relate to positive motivational and achievement outcomes, led Harackiewicz, Barron, and Elliot (1998) and Pintrich (2000a, 2000c) to call for a revision of goal theory that acknowledges the positive effects of performance-approach goals, and also the need to look at how different goals relate to different outcomes. Traditional (or *normative* to use the term adopted by Harackiewicz et al.) goal theory argues for the benefits of mastery goals and the costs of performance goals. Pintrich (2000b) studied eighth grade students' goal orientations, and identified four groups of children crossing high and low mastery and performance goal orientations. He found that students with a combination of high mastery and high performance-approach goal orientations were similar with respect to a variety of motivational outcomes to a group of students who were high in mastery but low in performance goal orientations. This finding does not support the normative theory view that only mastery goal orientations lead to positive developmental outcomes and was one impetus for the call for a revised goal orientation theory.

Midgley et al. (2001) disputed these claims, arguing that the costs of performance-avoidance goals are clearly documented and that the benefits of performance-approach goals are not as clearly established in the literature. They also noted that performance-approach goals may benefit some students (e.g., boys, older students) rather than others (e.g., girls, younger students), and that we do not yet have enough information about how performance-approach goals operate in other groups of children. They also pointed out that benefits of performance goals identified by researchers may be in part due to the focus of our educational system on standards, assessments, and performance rather than effort and improvement, which they argue is a better approach to schooling.

In response, Harackiewicz et al. (2002) argued that the evidence for the positive effects of performance-approach goals is clearer than Midgley et al. (2001) stated that it was, and they continued to propose the multiple goal perspective (that both mastery and performance goals can benefit different educational outcomes) is the more viable approach to goal orientation theory. They noted a number of areas of research that now are needed to assess each of these perspectives. In a final response, Kaplan and Middleton (2002) took a broader perspective and focused on what the purposes of schooling should be. In their view, the purposes of schooling should be knowledge growth and the fostering of a love of learning, rather than performance per se, and thus for them a mastery orientation continues to be more desirable, even if performance-approach goals relate to some positive educational outcomes in our current educational system (see also Roeser, 2004a, for further elaboration of these ideas). So this debate appears to be at different levels. At one level is the concern for how the specific goal orientations relate to different kinds of outcomes in our current educational system. The second level concerns what that system should focus on rather than an acceptance of the current system and its strong performance emphasis.

This healthy debate among goal orientation theorists should move the field ahead, as more research is done to look at the benefits and costs of different kinds of goal orientations, and as we consider further the nature and purposes of schooling and their influence on the development of students' goals and motivation. We believe the move beyond the perhaps too simplistic two-goal orientation theory is welcome, but acknowledge that more work is needed both on performance-approach and (especially) mastery-avoidance goals to evaluate their effects, and in the case of mastery-avoidance goals, to document their existence. Work on achievement goal orientations also needs to look more carefully at how different achievement domains (e.g., math, science, English) might impact achievement goal orientations and their effects (see Meece, 1991, 1994). Finally, Brophy (2005) noted recently that goal orientation theorists need to investigate further the frequency of occurrence of performance goals in school situations, arguing that students may not spontaneously generate such goals very frequently.

**The Goal Content Approach: Academic and Social Goals.** Building on Ford's (1992) work defining a

taxonomy of human goals, Wentzel has examined the multiple goals of children in achievement settings (see Wentzel, 1991b, 1993, 2002b, for review of this work). Her view on goals differs from the goal orientation theorists in that she focuses on the *content* of children's goals to guide and direct behavior, rather than the criteria a person uses to define success or failure (i.e., mastery versus performance). In this sense, these goals are like the goals and self-schema that relate to attainment value hierarchies in the Eccles-Parsons et al. (1983) expectancy value. However, she does view these goals as contributing to children's competence in particular situations. Wentzel primarily has focused on academic and social goals and their relations to a variety of outcomes.

Wentzel has demonstrated that both social and academic goals relate to adolescents' school performance and behavior (Wentzel, 2002b). For instance, she found that the goals related to school achievement include seeing oneself as successful, dependable, wanting to learn new things, and wanting to get things done. Higher achieving students have higher levels of both social responsibility and achievement goals than lower achieving students. Similarly, Wentzel (1994) documented the association among middle school children's prosocial goals of helping others, academic prosocial goals like sharing learning with classmates, peer social responsibility goals like following through on promises made to peers, and academic social responsibility goals like doing what the teacher says to do. Prosocial goals (particularly academic prosocial goals) related positively to peer acceptance. She also found positive relations between prosocial goals and children's grades and even IQ scores (Wentzel, 1989, 1996).

Although it appears valuable to have multiple goals, Wentzel (2002b) discussed the difficulty some children may have coordinating these multiple goals. Can students manage a variety of social and academic goals? This question also applies to the multiple goal perspective in goal orientation theory. Having multiple goals may be especially challenging for younger children, whose resources to manage such goals may be limited.

Building in part on Wentzel's work, researchers increasingly are interested in how social relations and the social context influences students' goals and other aspects of motivation (e.g., L. H. Anderman, 1999; Patrick, 1997; A. M. Ryan, 2001). L. H. Anderman (1999) proposed a number of mechanisms by which students' social experiences in school relate to their motivation. These include the extent to which students feel a

part of the school or at least some activities in the school, how much they endorse social responsibility goals, and the kinds of relationships they have with peers. We return to some of these points later.

### Summary

Work on interest, intrinsic motivation, values, and goals continues to thrive, and the knowledge base in these areas is beginning to rival that on competence-related beliefs, although it still lags behind to a degree. We need additional work on the relations among these various constructs and a closer look at the developmental trajectories that they take.

### Theories Concerned with the Question: “What Do I Have to Do to Succeed on This Task?”

We discussed in the previous version of our chapter that researchers were becoming increasingly interested in linkages between motivation, self-regulation, and cognitive processes. This work has grown over the past several years. In this section, we discuss work on the following topics: (a) motivation and the regulation of behavior; (b) motivation and volition; (c) relations of motivation to cognitive processes and conceptual change; and (d) academic help seeking.

### Social Cognitive Theories of Self-Regulation and Motivation

Reviewing the extensive literature on the self-regulation of behavior is beyond the scope of the chapter (see Boekarts, Pintrich, & Zeidner, 2000, for a comprehensive review of models of self-regulation from a variety of different fields in psychology). These models take a variety of different conceptual and methodological approaches. There are two approaches to self-regulation that relate most directly to our focus on the development of motivation in this chapter. First is self-determination theory; we mention it only briefly here because it was discussed earlier. This theory proposes that individuals are intrinsically motivated when they are self-determined or are the source of their own behavior (Deci & Ryan, 2002b; R. M. Ryan & Deci, 2002). R. M. Ryan and Deci discuss the internalization process, which essentially involves the individual taking greater control over her own behavior, leading to greater intrinsic motivation. Grolnick et al. (2002) review the development of self-determination and how it is influenced by experiences at home and in school; we discuss some

of this work in the Socialization of Motivation section of this chapter.

A second approach to self-regulation particularly relevant to this chapter is the social cognitive perspective, and there are several models in this tradition. We focus on the recent work of Pintrich, Schunk, Zimmerman, and their colleagues because they directly link motivation to self-regulation; see Schunk and Zimmerman (1994) and Eccles et al. (1998) for review of earlier work on self-regulation.

Zimmerman (1989) described self-regulated students as being metacognitively, motivationally, and behaviorally active in their own learning processes and in achieving their own goals and active in their use of cognitive strategies for learning; thus motivation plays an important part in self-regulation. Recent social cognitive models of self-regulation (e.g., Pintrich, 2000c; Schunk & Ertmer, 2000; Zimmerman, 2000) divide the regulation of behavior into three phases: (1) forethought, (2) performance and volitional control, and (3) self-reflection. We focus on how motivation relates to each of these phases. *Forethought* involves planning one's behavior, and Zimmerman stated that there are two major aspects of forethought: (1) analyzing the task or activity that needs to be done and (2) motivating oneself to undertake the activity. Zimmerman focused on goal setting, self-efficacy, and interest and value as the key aspects of motivation during this phase. When students are efficacious about their ability to regulate their behavior, set goals and commit to them, and value what they are doing, they will be more likely to begin an activity. Zimmerman also noted that having a mastery goal orientation might facilitate task engagement and self-regulation of achievement behaviors.

*Performance* refers to self-regulation as the individual actually is doing the activity. What is crucial for the regulation of performance is focusing attention on the activity and monitoring how one is doing, through processes of self-observation. Schunk and Ertmer (2000) also noted that maintaining self-efficacy and monitoring progress toward the achievement of goals are important motivational aspects of the performance process. During *self-reflection and reaction*, individuals interpret the outcomes of their activities by making attributions for their success and failure and by evaluating whether they achieved their goals. Affective reactions are likely here as well. When individuals achieve the expected outcome they experience satisfaction; when they don't, various negative affective reactions can occur (see Pintrich, 2000c).

Wigfield and Eccles (2002b) discussed the particular roles achievement values may take in different aspects of the regulation of behavior. They argued that the social cognitive models of self-regulation focus primarily on self-efficacy and goals as the motivational factors influencing self-regulation, although some attention has been paid to values. Schunk and Ertmer (2000) discussed how the value of an activity is an important part of the forethought or preengagement phase of self-regulation; when activities are valued, students will devote more time both to planning for them and doing them. Rheinberg, Vollmeyer, and Rollett (2000) specified different questions individuals pose to themselves concerning potential links of their actions to desired outcomes. One of the questions is a “values” question: Are the consequences of the action important enough to me? If the answer is yes, the individual more likely will undertake the action; if no, engagement is less likely. Wigfield and Eccles discussed two additional roles values may play in the regulation of behavior. Values may help individuals determine which of different (and potentially conflicting) goals to pursue. During the self-reflection phase, after an activity is completed, students’ valuing of the activity likely influences their likelihood to continue to engage in the activity.

Wolters (2003) discussed the importance of regulating one’s motivation along with regulating one’s behavior and cognition (see also Pintrich, 2000c). He posited that motivational regulation is one part of the broader self-regulatory process. The regulatory aspect in this instance refers to individuals’ cognitive awareness of and control over their own motivation, but Wolters noted that motivation regulation and motivation itself likely are strongly related. He argued further that the regulation of motivation might be most needed when individuals encounter obstacles as they are attempting to do various achievement activities, even activities that they initially were quite motivated to do. Wolters discussed a variety of motivation regulation strategies. These include creating consequences for one’s own behavior (when I finish my homework, I can play the videogame I want to play), attempting to modify activities one is doing to make them more interesting, and engaging in goal-oriented self talk (reminding oneself of the purposes for which the activity was undertaken in the first place), among others, including managing one’s efficacy perceptions and controlling the kinds of attributions for success and failure that are made. One interesting regulatory strategy is self-handicapping, which involves things like waiting until the last minute to study for a

test, and setting up other obstacles to performance. Although this regulatory strategy may provide students with good excuses for not doing well, its potential costs likely outweigh its benefits. Another potentially less positive strategy is called defensive pessimism in which individuals believe that they are unprepared and will do poorly on an exam or assignment, which spurs them to work harder. Defensive pessimists often perform well, but the desirability of this strategy is questionable.

In sum, social cognitive models of self-regulation consider many of the aspects of motivation that we are reviewing in this chapter, including self-efficacy, goals, achievement values, and interest. Researchers are beginning to focus on the regulation of motivation and how it fits into the broader models of self-regulation of achievement behaviors. Self-regulation of behavior and motivation processes require relatively sophisticated cognitive processes, which can be problematic for young children (see Pintrich & Zusho, 2002; Wigfield & Eccles, 2002b; Zimmerman, 2000, for a discussion of the development of self-regulatory processes). We return to this issue later.

### *Theories of Motivation and Volition*

The term *volition* refers to both the strength of will needed to complete a task and diligence of pursuit (Corno, 1993, 2004; Kuhl, 2000). Zimmerman (2000) and other theorists proposing social cognitive models of self-regulation include volition as part of the regulation of achievement behavior, but Corno argued that volition is a broader concept than self-regulation because volition includes personality characteristics, aptitudes, and other cognitive processes (see also Corno & Kanfer, 1993). Researchers studying volition also argue for a clear distinction between motivation and volition; motivation brings the individual to an activity, but volitional processes carry him or her through the activity (see Corno, 2004).

Kuhl (1987) proposed several specific volitional strategies to explain persistence in the face of distractions and other opportunities; including cognitive, emotional, motivational, and environmental control strategies (see Eccles et al., 1998, for review of these strategies). Corno (1993) provided several examples of the volitional challenges students face, including coordinating multiple demands and desires like doing homework, watching TV, or calling a friend; dealing with the many distractions in any particular context like a classroom; and clarifying often vaguely specified goals and assignments.

There currently is some debate between volitional theorists and social cognitive self-regulation theorists (see Corno, 2004; Wolters, 2003; Zimmerman & Schunk, 2002). The social cognitive theorists argue that the “hard” distinction between motivation as the intention to act and volition as the control of action is drawn too strongly by volitional theorists. Wolters (2003) notes that the regulation of motivation can occur both in the phase leading up to action and the action phase itself, and so sees regulatory process as integrated across both. Corno (2004) continued to argue for the motivation-volition distinction but stated that volition can involve reassessing motivational goals as well.

### *Theories Linking Motivation and Cognition*

Motivation researchers increasingly are interested in how motivation and cognition influence one another (see Eccles et al., 1998, for work done on this topic in the 1980s and early 1990s). In a seminal article, Pintrich, Marx, and Boyle (1993) discussed links of motivation and cognition, with specific reference to conceptual change. They argued that traditional “cold” cognitive psychological models of conceptual change, which focus on conceptual change resulting from dissatisfaction with one’s current conceptions, and the intelligibility, plausibility, and fruitfulness of the new conception, do not consider the motivational and contextual factors that influence conceptual development. They identified a variety of contextual and motivational factors that can influence this process (see also Pintrich & Schrauben, 1992); we briefly note some of the motivation factors here.

Pintrich et al. (1993) focused on goal orientation, interest and value, and self-efficacy as motivational factors influencing conceptual change. They reviewed work showing that mastery goal orientations relate to deeper cognitive processing and more sophisticated cognitive strategy use. As discussed earlier, students’ valuing of achievement relates to their choices of activities, and when they are interested in an activity deeper cognitive processing occurs. Similarly, students with higher self-efficacy use more elaborate and better cognitive strategies (see Schunk, 1991). Each of these motivational beliefs and values can be influenced by the classroom context (a point we return to later). Based on this, Pintrich et al. concluded that conceptual change is a “hot” rather than a cold process.

This work clearly indicates motivation’s role in conceptual change and engagement in cognitive processing. However, Pintrich (2003) discussed that there still is lit-

tle information on motivation’s relations to basic cognitive activity such as the activation, acquisition, and development of knowledge, and he called for research in this area. He also argued that motivational beliefs might be represented cognitively in similar ways to other kinds of content knowledge (see Winne & Marx, 1989, for a similar view that motivational thoughts and beliefs are governed by the basic principles of cognitive psychology). Cognitive psychologists have developed detailed depictions of knowledge representation, and some of these likely could be applied to motivational beliefs. We have focused so far on motivation’s relations to cognition; Pintrich also argued that cognition likely influences motivation and that researchers need to address these complex and likely cyclical relations.

### *Academic Help Seeking*

Some researchers have argued that another important aspect of self-regulation and volition is knowing when help is needed (Newman, 2002; A. M. Ryan, Pintrich, & Midgley, 2001). Children learn to do many tasks on their own; indeed, schools and parents often encourage children to become independent and self-reliant. However, there are times when children need help. Both Nelson-Le Gall and her colleagues (e.g., Nelson-Le Gall & Glor-Shieb, 1985; Nelson-Le Gall & Jones, 1990) and Newman and his colleagues (e.g., Newman, 1994, 2002; Newman & Goldin, 1990; Newman & Schwager, 1995) have articulated models of children’s help seeking that stress the difference between appropriate and inappropriate help seeking. Appropriate help seeking (labeled *instrumental* help seeking by Nelson-Le Gall and *adaptive* help seeking by Newman) involves deciding that one doesn’t understand how to complete a problem after having tried to solve it on one’s own, figuring out what and whom to ask, developing a good question to get the needed help, and processing the information received appropriately to complete the problem-solving task.

Adaptive help seeking can foster motivation by keeping children engaged in an activity when they experience difficulties. However, many children, and often the children that need the most help, are unwilling to ask for it in many classrooms, likely because they are concerned that asking for help will make them appear to others that they lack competence (A. M. Ryan, Gheen, & Midgley, 1998; A. M. Ryan et al., 2001). There are developmental differences here as well; younger children are more likely to ask for help than are older children. Newman (2002) described conditions under which children are more or less likely to ask for help; these

conditions include both characteristics of children and of the learning environments they experience. When children are self-regulated and perceive they are competent they are more likely to ask for help when it is needed. Teachers can facilitate help seeking by showing concern for children; focusing on mastery goals, improvement, and effort; and facilitating peer collaboration in the classroom.

### *Summary*

Work on links between motivation, self-regulation, and cognition has burgeoned over the last several years. This integrative work is crucial for a better understanding of the learning process and children's achievement, and likely will continue to grow. Developmental issues remain front and center in this work, as the complex regulation of achievement and other kinds of behaviors poses many challenges for young children in particular. We need more information about the development of these processes and models that take account of them.

## **THE DEVELOPMENT OF MOTIVATION: WITHIN-PERSON CHANGE AND GROUP DIFFERENCES**

Developmental and educational psychologists have focused on two major developmental questions:

1. How do the different beliefs, values, and goals defined in the different theories develop during childhood and adolescence?
2. What explains the emergence of individual differences in motivation?

Different sources of influence have been considered: Within-person changes resulting from growth and maturation in cognitive processing, emotional development, or other individual characteristics; socially mediated developmental changes resulting from systematic age-related changes in the social contexts children experience at home, in school and among peers as they grow up; and socially mediated influences that differ across individuals and contexts. These different sources often interact with one another, but the nature of this interaction is rarely studied. Consequently, we have organized our discussion of the development of motivation, and of individual differences in motivation, around these broad categories of influence. First, we present work on within-person changes, beginning with work on children's early self-evaluations, and then describe the

work on within-person changes in the constructs discussed thus far. We also include a consideration of the development of certain motivational problems. Also discussed in this section is the development of sex and ethnic differences in children's motivation. We include this work in this section because they emerge during children's development. The next major section considers how various socialization agents influence children's motivation.

### **Within-Person Change in Motivation**

Some researchers have looked at very young children's reactions to success and failure, reactions which likely provide the foundation for the development of the different motivational beliefs, values, and goals discussed in this chapter. Heckhausen (1987) found that children between 2.5 and 3.5 years start to show self-evaluative, non-verbal expressions following a successful or unsuccessful action. The earliest indicators of achievement motivation were facial expressions of joy after success and sadness after failure. The experience of success (around 30 months) preceded the experience of failure (around 36 months). Several months later, children showed postural expressions of pride and shame following success and failure. When competing with others, 3- and 4-year-old children initially showed joy after winning and sadness after losing. It was only when they looked at their competitor that they expressed pride and shame.

Stipek, Recchia, and McClintic (1992) identified three stages of development in young children's self-evaluations: The children younger than 22 months were neither concerned with others' evaluation of their performance nor self-reflective in their evaluations. However, they did show positive emotional reactions to accomplishing a task and negative emotions when they did not. Thus, unlike Heckhausen, Stipek, et al. found that reactions to success and failure occurred at the same time in development. Two-year-olds reacted more to others' evaluations by seeking approval when they did well and turning away when they did poorly. After age 3, the children were able to evaluate their own performance, without needing to see how adults reacted to that performance, and engaged in more autonomous self-evaluation. Children age 3 and older also reacted more strongly to winning and losing than did younger children.

Dweck and her colleagues (e.g., Burhans & Dweck, 1995; Heyman, Dweck, & Cain, 1992; Smiley & Dweck, 1994; see Dweck, 2002, for review) also have done interesting work on young children's reactions to failure; we

review this work more completely later when we discuss the development of learned helplessness. Generally, their findings show that some preschool children already react quite negatively to failure, reactions that may lead to later learned helplessness in response to failure.

Taken together, these studies show that reactions to success and failure begin early in the preschool years, likely laying the groundwork for the development of motivation in the middle childhood years and beyond. The results concerning children's reactions to failure are particularly important because they suggest that children are more sensitive to failure in the preschool years than was once believed (see Dweck, 2002).

### *The Development of Competence-Related Beliefs*

Much of the work on the development of children's achievement-related beliefs has looked at the development of children's ability and expectancy-related beliefs (e.g., see Dweck & Elliott, 1983; Stipek & Mac Iver, 1989, for reviews of the early work on this topic). We discuss three kinds of changes in these beliefs: (1) change in their factorial structure, (2) change in mean levels, and (3) change in children's understanding of them.

**The Factor Structure of Children's Competence-Related Beliefs.** Eccles et al. (1998) reviewed factor analytic research showing that children as young as age 5 or 6 appear to have distinctive competence perceptions among different academic and nonacademic domains of competence. Since that review researchers have looked at even younger children and found that these children also have differentiated competence-related beliefs (Mantzicopoulos, French, & Maller, 2004; Marsh, Ellis, & Craven, 2002). This does not mean that there is no change or refinement in children's beliefs from kindergarten through high school. The pattern of correlations of self-concept factors differs in meaningful ways for younger and older children (Marsh & Ayotte, 2003). Younger children use fewer of the scale points when responding to the items on the questionnaires, and their responses correlate less well with both their teachers' and their parents' estimates of their competencies (Eccles, Wigfield, et al., 1993; Wigfield et al., 1997).

Eccles and Wigfield (1995) and Eccles, Wigfield, et al. (1993) also have used factor analytic strategies to assess whether children's competence beliefs and expectancies for success are distinct constructs. Analyses of both children's and adolescents' responses indicate the ratings of their current competence, expectancies for

success, and perceived performance load on the same factor, suggesting that these components comprise a single concept for children age 6 to 18.

**Change in the Mean Level of Children's Competence-Related Beliefs.** Another well-established finding in the literature is that children's competence beliefs for different tasks decline across the elementary school years and through the high school years (see Dweck & Elliott, 1983; Eccles et al., 1998; Stipek & Mac Iver, 1989, for review). Many young children are quite optimistic about their competencies in different areas, and this optimism changes to greater realism and (sometimes) pessimism for many children. To illustrate, in Nicholls (1979) most first graders ranked themselves near the top of the class in reading ability, and there was no correlation between their ability ratings and their performance level. By contrast the 12-year-olds' ratings were more dispersed and correlated highly with school grades (.70 or higher). Recently, researchers in the United States have examined change over the entire elementary and secondary school years in children's competence beliefs for math, language arts, and sports (Jacobs et al., 2002; Fredericks & Eccles, 2002), and Watt (2004) looked at change across middle and senior high school years in Australia. Jacobs et al. examined change in children's competence for math, language arts, and sports across grades 1 through 12. Children's perceptions in each area were strongly positive early on. However, the overall pattern of change was a decline in each domain. There were some differences across domain with respect to when the strongest changes occurred, particularly in language arts and math. In language arts, the strongest declines occurred during elementary school and then little change was observed after that. In sports, the change accelerated during the high school years. The decline in math competence beliefs was steady over time. Fredericks and Eccles and Watt also found declines over time in competence beliefs and values, although the specific trends were somewhat different across these studies.

One caveat about this general "optimism early and realism later" pattern should be noted. As just discussed, researchers observing children's reactions to failure find that some preschool children already reacted negatively to failure (see Dweck, 2002; Stipek et al., 1992). Dweck notes that during the preschool years, children likely do not have a clearly defined notion of what ability is. So these earlier negative reactions to failure may

not mean that children doubt their ability, as their views of ability still are taking shape. But the connection between these reactions and level of ability beliefs likely begins to develop early in the school years, and children reacting negatively to failure early on may be more likely to be pessimistic about their abilities later.

In summary, children's competence beliefs and expectancies for success become more negative as they get older. The negative changes in children's competence-related beliefs have been explained in two ways: (1) Because children become much better at understanding, interpreting, and integrating the evaluative feedback they receive, and engage in more social comparison with their peers, children become more accurate or realistic in their self-assessments, leading some to become relatively more negative (see Dweck & Elliott, 1983; Nicholls, 1984; Ruble, 1983; Stipek & Mac Iver, 1989); (2) Because school environment changes in ways that makes evaluation more salient and competition between students more likely, some children's self-assessments will decline as they get older (e.g., see Eccles & Midgley, 1989; Wigfield, Byrnes, & Eccles, *in press*; Wigfield, Eccles, & Pintrich, 1996). We return to this issue of how school environments influence children's motivation later.

There are two important limitations to this work on mean-level change in the development of competence beliefs. First, most of it is normative, in the sense that researchers report overall mean differences in their studies. We thus know less about patterns of changes in different groups of children and adolescents, although there is some information about this (e.g., Harter, Whitesell, & Kowalski, 1992; Wigfield, Eccles, Mac Iver, Reuman, & Midgley, 1991). Wigfield et al. (1991) found that this pattern of change varied somewhat for children high or low in math ability. Second, the measures used in this work either are at the school level or (more frequently) at the domain-specific level. It is possible that children's beliefs about their competence for more particular activities may show different patterns of change, and we know little about this. We also know little about how children arrive at judgments of their competence in something as broad as reading or science; do they simply average their performance in a variety of different relevant tasks or use a more elaborate strategy (see Assor & Connell, 1992; Winne & Jamieson-Noel, 2002, for discussion of issues regarding measurement of individuals' beliefs and how individuals calibrate their beliefs)?

Finally, one other set of findings relevant to the issue of mean-level change should be mentioned. Longitudinal studies looking at relations of children's competence beliefs over time show that these beliefs become increasingly stable as children get older (e.g., Eccles et al., 1989; Wigfield et al., 1997). Even by the middle of the elementary school years, children's competence beliefs correlate quite highly across a 1-year period, with the correlations reaching as high as .74. Thus, by early adolescence there is much stability in these beliefs, even though the overall pattern of change is the decline just discussed. The implication of these findings is that individuals tend to maintain their relative position in their group, even as the group's mean declines.

**Changes in Children's Understanding of Competence-Related Beliefs.** The research on both the structure of and mean level differences in children's beliefs does not tell us about children's understanding of these constructs, because the questionnaire methodology used in these studies requires children to respond to researcher-defined constructs rather than generate their own definitions of a given construct. But it is important to understand how children conceptualize the different constructs to interpret comparisons of different-aged children's beliefs meaningfully.

Dweck (2002) described important developmental changes in children's understandings of ability. During the preschool years and into kindergarten, children do not have a clear sense of ability as a characteristic that determines outcomes, but as discussed earlier they do react to success and failure experiences. Part of this reaction is to think they are good when they do well and bad when they do poorly; indeed, Dweck argues that conceptions of goodness and badness are primary at this time. During the early school years concepts of ability begin to emerge, and children see ability as distinct from other qualities and also differentiate their ability across domains. They often think of ability as changeable, and use normative rather than comparative standards to judge ability, but some children begin to see ability as a stable characteristic. As children move through these ages, social comparison takes on increasing importance. Children's beliefs about ability also become more accurate, in the sense of correlating more strongly with performance measures. Between ages 10 and 12, children differentiate more clearly ability, effort, and performance, but they also see how they interrelate. These children more often use comparative

standards in judging ability. More children come to view ability as capacity (or take an *entity* view of intelligence, to use Dweck's term), which means they are less likely to believe that with increased effort their ability will improve.

Researchers have investigated children's understanding of ability, effort, task difficulty, and intelligence (see Eccles et al., 1998, for review). Nicholls and his colleagues found a developmental progression between ages 5 and 12 with respect to children's beliefs about ability, effort, and performance (Nicholls, 1978; Nicholls & Miller, 1984). They found four relatively distinct levels of reasoning: At level one (ages 5 to 6), effort, ability, and performance are not clearly by cause and effect. At level two (ages 7 to 9), effort is seen as the primary cause of performance outcomes. At level three (ages 9 to 12), children begin to differentiate ability and effort as causes of outcomes, but they do not always apply this distinction. Finally, at level four, adolescents clearly differentiate ability and effort, and they understand the notion of ability as capacity. They also believe that ability can limit the effects of additional effort on performance and that ability and effort are often related to each other in a compensatory manner and, consequently, success requiring a great deal of effort likely reflects limited ability.

As we discuss in more detail later in the section presenting work on Learned Helplessness, these different views of ability and intelligence have important implications for children's reactions to success and failure, particularly their reactions to failure. As Dweck and her colleagues have discussed, children with an entity view of ability are more likely to give up following failure, because they are less likely to believe that additional effort will improve their performance, because their ability is fixed. By contrast, children with an incremental view are more likely to continue to strive after failure because they think their ability can change.

Pomerantz and Saxon (2001; see also Pomerantz & Ruble, 1997) added another distinction to this discussion. They distinguished between (in their terms) "conceptions of ability as stable to external forces," and "conceptions of ability as stable to internal forces." Stability of ability with respect to external forces "is the view that ability is unlikely to be influenced by forces external to the individual possessing the ability (e.g., situational changes)" (Pomerantz & Saxon, 2001, p. 153). Pomerantz and Saxon argued that as children get older they increasingly hold this view about ability and a number of other characteristics, with the implication that

children see individuals' behaviors as relatively consistent across types of activities and over time. Pomerantz and Saxon see conceptions of ability as stable to internal forces as analogous to Dweck's (2002) entity theory of ability. One reason they see these as similar is that Dweck and her colleagues operationalize the entity view of ability as the belief that ability is not under one's own control (e.g., Cain & Dweck, 1995). For instance, one item from Cain and Dweck's measure of views of intelligence is "You're a certain amount smart, and you can't really do much to change it" (p. 153). The individual cannot do much to change his or her ability. Pomerantz and Saxon proposed that the latter, but not the former, conception about the nature of ability could have negative consequences for motivation and achievement.

They studied these two conceptions of ability in a sample of fourth through sixth grade children. Concepts of ability as stable to external forces were measured by the researchers describing to participants another child as either smart or not very smart at schoolwork, and then having children rate the other child's ability at four time points and in four situations. Similar procedures were used to measure social ability. Differences between children's ratings of the other's ability and the initial description were used to determine how much children believed that the other children's ability was stable with respect to external forces. Ability as stable with respect to internal forces was measured using Cain and Dweck's (1995) scale. Results showed that the two kinds of conceptions were inversely (but weakly) related. Children's beliefs that ability was stable with respect to external forces increased over time, and their conceptions of ability as stable with respect to internal forces decreased over time. Believing that ability is stable with respect to external forces correlated positively with the importance children attached to being competent, a preference for challenge, positive perceptions of competence, and academic performance. The opposite pattern of relations occurred for perceptions that ability is stable with respect to internal forces. It should be noted that both sets of correlations were relatively weak.

Pomerantz and Saxon (2001) concluded that seeing ability as stable, at least with respect to external forces, actually is a positive belief for children to have because of the pattern of its relations with other motivational beliefs and performance. By contrast, believing that ability is stable with respect to internal forces has negative implications for motivation and performance. Thus, it is not stability per se but the type of stability that is crucial. Further, they noted that viewing ability as stable

with respect to external forces was a more stable belief over time than was viewing ability as stable with respect to internal forces. These intriguing findings provide a more subtle representation of the impact of having “stable” beliefs on motivational and performance outcomes. However, because many of the observed relations were rather weak (albeit significant), this potentially important distinction requires further research. Further, both Dweck’s work and Nicholls’ work suggests that children increasingly view ability as stable as they get older, whereas Pomerantz and Saxon found just the opposite with respect to beliefs about stability of ability with respect to internal causes. This apparent contradiction needs to be resolved.

In sum, work on children’s understanding of ability converges with the factor analytic work in the sense of showing that young children differentiate ability into different areas. However, this work shows that younger and older children have different ideas about the nature of ability and its relations to effort, other achievement beliefs, and performance, which means we must take some care in how we interpret the factor analytic findings. Using the same scales to measure perceived ability at different ages may be problematic given the apparent differences in how younger and older children understand ability.

### ***Development of Efficacy Beliefs***

There has not been extensive research on the development of efficacy beliefs per se, although the work on ability beliefs and expectancies is directly relevant. Instead, research on children’s self-efficacy has focused primarily on interventions to enhance the self-efficacy and school performance of low-achieving children (e.g., see Schunk, 1994; Schunk & Pajares, 2002). Extant work on the development of efficacy shows that children’s efficacy beliefs increase across age. Shell, Colvin, and Bruning (1995) found that fourth graders had lower self-efficacy beliefs for reading and writing than did 7th and 10th graders, and the 7th graders efficacy beliefs were lower than 10th graders beliefs (see Zimmerman & Martinez-Pons, 1990, for similar findings). The inconsistency of these findings with those on children’s competence beliefs just discussed likely reflects the self-efficacy measure used by Shell et al. Their instrument measured children’s estimates of their efficacy on specific reading and writing skills rather than more general beliefs about competence reading and writing; the more specific beliefs should be higher among older children. Also, as noted earlier efficacy beliefs usually are

not measured comparatively, whereas many measures of competence beliefs include comparisons of a child’s ability with that of others. The latter kind of measure may be more likely to show declines over age.

Bandura (1997) and Schunk and Pajares (2002) discussed factors influencing the development of self-efficacy. They proposed that children who have mastery experiences in which they exert some control over their environments develop the earliest sense of personal agency. Through these experiences, infants learn that they can influence and control their environments. Parents and other adults can facilitate the growth of this sense of agency by the kinds of experiences they provide children. If parents do not provide infants with these experiences, they are not likely to develop a strong a sense of personal agency. Second, because self-efficacy requires the understanding that the *self* produced an action and an outcome, Bandura argued that a more mature sense of self-efficacy should not emerge until children have at least a rudimentary self-concept and can recognize that they are distinct individuals, which happens sometime during the 2nd year of life (see Harter, 1998). Through the preschool period, children are exposed to extensive performance information that should be crucial to their emerging sense of self-efficacy. However, just how useful such information is likely depends on the child’s ability to integrate it across time, contexts, and domains; Schunk and Pajares discuss the challenges children face in doing so. More work is needed to understand how children become able to integrate diverse sources of information about their performances (e.g., information about their own performance, and social comparison information) to develop a stable of self-efficacy. Schunk and Pajares also discuss the crucial role peers can play in the development, or demise, of self-efficacy.

Finally, Schunk and Pajares (2002) and Bandura (1997) stressed the importance of school environments for developing and supporting a high sense of efficacy or possibly undermining it if support is not provided. We return later to a discussion of how this can occur.

### ***Development of Control Beliefs***

Work on perceived control done in the 1980s and 1990s showed that there are developmental patterns in these beliefs. Weisz (1984) found that younger children actually believe they have greater control over chance events than do older children. Similarly, Connell (1985) found a decrease in the endorsement of all three of his locus of control constructs (internal control, powerful others

control, and unknown control) from third through ninth grade. Like Weisz's findings, the unknown belief results suggest that older children have a clearer understanding of what controls achievement outcomes. However, the older children also rated the other two sources of control as less important, making interpretation of these findings difficult.

Skinner examined age differences in both the structure and the mean levels of means-ends beliefs (see Skinner, 1995), and found the factor structure becomes increasingly complex as children get older. She also found the largest mean-level differences on some of the means-ends beliefs. At all ages between 7 and 12, children believe effort is the most effective means. In contrast, older children are much less likely to believe that luck is an effective means than younger children. As in Connell (1985), belief in the relevance of unknown control and powerful others also decreased across age levels.

In a landmark 3-year longitudinal study, Skinner, Gembeck-Zimmer, and Connell (1998) assessed the development of perceived control in children and early adolescents and how it predicted student engagement in school. Their cohort-sequential design encompassed third through seventh grade children. Skinner et al. measured overall control beliefs, beliefs about the strategies needed to do well in school (including the strategies of effort, ability, powerful others, luck, and unknown), and beliefs about the capacity to access one's effort, ability, powerful others, and luck. They also measured children's engagement in school and their perceptions of the structure and involvement provided by teachers, examining predictive relations among these variables.

Skinner et al. (1998) found that perceived control showed a curvilinear pattern of change, being stable at first, increasing slightly through fourth grade, and then declining after fifth grade. Student engagement declined during middle school, as did students' perceptions that teachers provided structure and were involved with them. Changes in perceived control related to changes in engagement, and change in the teacher-context variables predicted change in perceived control. Specifically, children initially either high or low in perceived control decreased in their control perceptions if they perceived that teachers were providing less structure and were less involved with them. A number of interesting age differences in the predictors of engagement and control emerged. Younger children's beliefs about their capacity to exert effort were a stronger predictor, whereas for older children it was their beliefs about their ability.

Grades predicted perceived control more strongly for older than younger children. Skinner et al. also suggested that the context provided by teachers may provide a stronger role in the development of perceived control for younger than for older children. Skinner et al. also examined how the constructs they measured varied across different subgroups in their sample, and thus went beyond the normative approach often taken in this area.

This fascinating study provides a rich depiction of the development of perceived control, and how it relates to students' engagement in the classroom. While rich in many respects, the measures of both academic performance and perceived control were done at the general level (see Eccles, 1998, for discussion of this and other issues with respect to this study). Based on work we reviewed earlier, these beliefs (and performances) likely vary across different areas. The measure of teacher context also focused on just a few features of the classroom context. Nevertheless, the study provides a model for how to study the development of motivational processes.

In overall summary of competence-related beliefs, there are numerous changes in children's competence and control beliefs. These changes include structural change, mean level change, and change in children's understanding of the constructs. We need more complex longitudinal studies such as those of Jacobs et al. (2002) and Skinner et al. (1998) to examine these changes over time, for different groups, and in relation to other contextual and psychological factors.

### *Development of Subjective Task Values*

Eccles, Wigfield, and their colleagues examined age-related changes in both the structure and mean levels of children's valuing of different activities. In Eccles, Wigfield, et al. (1993) and Eccles and Wigfield (1995), children's competence-expectancy beliefs and subjective values *within* the domains of math, reading, and sports formed distinct factors at all grade levels from 1st through 12th. Thus, even during the very early elementary grades children appear to have distinct beliefs about what they are *good* at and what they *value*. The distinction between various subcomponents of subjective task value appear to differentiate more gradually (Eccles, Wigfield, et al., 1993; Eccles & Wigfield, 1995). Children in early elementary school differentiate task value into two components: (1) interest and (2) utility/importance. In contrast, children in grades 5 through 12 differentiate task value into the three major subcomponents (attainment value/personal importance, inter-

est, and utility value) outlined by Eccles-Parsons et al. (1983). These results suggest that the interest component differentiates out first, followed later by the distinction between utility and attainment value.

As with competence-related beliefs, studies generally show age-related decline in children's valuing of certain academic tasks (e.g., see Eccles et al., 1998; Wigfield & Eccles, 2002b, for review). Jacobs et al. (2002), in the study described earlier in the section on the development of competence beliefs, found that children's valuing of the domains of math, language arts, and sports declined. As was the case for competence beliefs, children's valuing of language arts declined most during elementary school and then leveled off. By contrast, children's valuing of math declined the most during high school (see also Fredericks & Eccles, 2002).

Researchers have not addressed changes in children's understandings of the components of task value identified by Eccles-Parsons et al. (1983), although there likely are age-related differences in these understandings. An 8-year-old is likely to have a different sense of what it means for a task to be "useful" than an 11-year-old does. Further, it also is likely that there are differences across age in which of the components of achievement values are most dominant. Wigfield and Eccles (1992) suggested that interest may be especially salient during the early elementary school grades with young children's activity choices being most directly related to their interests. Young children likely try many different activities for a short time before developing a more stable opinion regarding which activities they enjoy the most. As children get older, the perceived utility and personal importance of different tasks likely become more salient, particularly as they develop more stable self-schema and long-range goals and plans. These developmental predictions need to be tested.

A related developmental question is how children's developing competence beliefs relate to their developing subjective task values. According to both the Eccles-Parsons et al. (1983) model and Bandura's (1997) self-efficacy theory, ability self-concepts should influence the development of task values. In support of this prediction, Mac Iver, Stipek, and Daniels (1991) found that changes in junior high school students' competence beliefs over a semester predicted change in children's interest much more strongly than vice versa. Does the same causal ordering occur in younger children? Bandura (1997) argued that interests emerge out of a child's sense of self-efficacy and that children should be more

interested in challenging than in easy tasks. Taking a developmental perspective, Wigfield (1994) proposed that initially young children's competence and task-value beliefs are likely to be relatively independent of each other. This independence would mean that children might pursue some activities in which they are interested regardless of how good or bad they think they are at the activity. Over time, particularly in the achievement domains, children may begin to attach more value to activities on which they do well for several reasons: First, through processes associated with classical conditioning, the positive affect a child experiences when he or she does well should become attached to the activities yielding success (see Eccles, 1984). Second, lowering the value a child attaches to activities that he or she is having difficulty with is likely to be an effective way to maintain a positive global source of efficacy and self-esteem (Eccles, 1984; Harter, 1990). Thus, at some point, the two kinds of beliefs should become more positively related to one another.

In partial support of this view, Wigfield et al. (1997) found that relations between children's competence beliefs and subjective values in different domains indeed are stronger among older than younger elementary school-aged children. Jacobs et al. (2002) found that changes in competence beliefs predicted changes in children's valuing of the activities, accounting for as much as 40% of the variance in change in children's valuing of the activities. This suggests that the causal direction in this relation goes from competence beliefs to values, but more longitudinal work is needed to assess this possibility.

### *Development of Interest and Intrinsic Motivation*

Eccles et al. (1998) summarized work on the early development of children's interests, which shows that children have general or universal interests at first, which become more specific relatively quickly (see also Todt, 1990). Todt argued that this early differentiation eventually leads to individual differences in interests in the social versus the natural sciences. The next phase of interest development—between 3 and 8 years of age—is characterized by the formation of gender-specific interests. According to Kohlberg (1966), the acquisition of gender identity leads to gender-specific behaviors, attitudes, and interests. Children strive to behave consistently with their gender identity and, thus, evaluate activities or objects as consistent with their gender identity more positively than other activities or objects.

As a consequence, boys and girls develop gender role stereotyped interests (see Eccles, 1987; Ruble & Martin, 1998).

At the next stage (ages 9 to 13), the emerging self-concept is assumed to be linked more directly to social group affiliation and cognitive ability, leading to occupational interests consistent with a child's social class and ability self-concepts (see Cook et al., 1996). The final stage (occurring after age 13 or 14) is characterized by an orientation to the internal, unique self leading to more differentiated and individualized vocational interests, based on abstract concepts of self (e.g., of personality). Thus, the development of vocational interests is a process of continuous elimination of interests that do not fit the self-concepts of a child's gender, social group affiliation, ability, and then personal identity (Todt, 1990). This process is assumed to depend mainly on the general cognitive development of the child or adolescent.

Changing needs or motives across the life span can influence the development of interests. A good example is the increasing interest in biology and psychology during puberty. The need to know oneself and to cope with rapid bodily and psychological changes seems to foster interest in biological and psychological domains of knowledge at this age (Todt, 1990).

Consistent with studies of American children (e.g., Eccles, Wigfield, et al., 1993; Gottfried et al., 2001; Harter, 1981; Wigfield et al., 1991), several European researchers have found that that interest and intrinsic motivation in different subject areas decline across the school years. This is especially true for the natural sciences and mathematics (e.g., Hedelin & Sjoberg, 1989), particularly during the early adolescent years. Pekrun (1993) found that intrinsic motivation stabilized after eighth grade, and Gottfried et al. (2001) reported surprisingly high stability coefficients for intrinsic motivation measured across a 1-year period for children ages 13 and above.

Baumert (1995) argued that the decline in school-related interests during adolescence reflects a more general developmental process in which the adolescents discover new fields of experience that lead to new interests and reduce the dominant influence of school. In contrast, other researchers have suggested that changes in a number of instructional variables like clarity of presentation, monitoring of what happens in the classroom, supportive behavior, cognitively stimulating experi-

ences, self-concept of the teacher (educator versus scientist), and achievement pressure may contribute to declining interest in school mathematics and science (e.g., Eccles & Midgley, 1989).

### *Development of Children's Goal Orientations*

There still is not a large body of work on the development of children's goals and goal orientations (see E. M. Anderman et al., 2002, for review of extant work). Instead, most of the work has focused on relations of goals to ability beliefs and on how different instructional contexts influence achievement goals. For instance, Dweck and her colleagues looked at relations of children's beliefs about ability and their goal orientations and found that performance-goal oriented children only show mastery behavior when their perceived ability is high. By contrast, mastery-oriented children engage in mastery-oriented behavior irrespective of their perceived ability (Burhans & Dweck, 1995; Smiley & Dweck, 1994). Butler and her colleagues have done an elegant series of studies in which they have shown how different learning conditions (competitive or noncompetitive; performance or mastery focused) influence children's subsequent motivation and found quite interesting differences in motivation depending on these conditions (see Eccles et al., 1998, for review).

Maehr, Midgley, and their colleagues conducted a number of studies looking at how classroom instructional practices relate to children's goal orientations and how these relations may change over time. L. H. Anderman and E. M. Anderman (1999) reported that adolescents endorse performance goals more than mastery goals. A major reason for this likely is that schools increasingly emphasize performance goals as children get older. One clear example of this is how evaluations of different kinds proliferate and have stronger consequences for adolescents' futures. Midgley (2002) and colleagues' work has shown two major things with respect to this point: (1) Elementary school teachers focus on mastery-oriented goals to a greater extent than do middle school teachers, and (2) middle school students perceive school as more performance oriented than do elementary school students. Thus, any observed changes in children's goal orientations seem very bound up in changes in the school goal culture. We return to this issue later.

Goal orientations often are studied at a relatively general level, but some researchers have looked at goal

orientations toward particular school activities. Meece and Miller (2001) studied the development during elementary school of students' goal orientations in reading and writing, looking at performance goals, mastery goals, and work-avoidant goals. They found that children's goal orientation were reasonably stable over a 1-year period; the lagged correlations were .44 for task-mastery goals, .58 for performance goals, and .45 for work-avoidant goals. With respect to change over time, following prediction children's mastery goals decreased over time. Contrary to prediction, performance goals did as well. The pattern of change in work-avoidant goals was less consistent.

There is much less work on the development of the content of children's goals. Thus, we know very little about how the contents of children's goals vary across age and context.

### *Development of Self-Regulation and Volition*

Eccles et al. (1998) reviewed work establishing two general developmental points concerning self-regulation. First, children's ability to self-regulate increases dramatically across the toddler period (Bullock & Lutkenhaus, 1988) due to increases in ability to focus on both the outcomes of their behaviors and the behaviors themselves (see Mischel & Mischel, 1983), increases in understanding of the self as a causal agent (Bandura, 1997; Jennings, 1991; Skinner, 1995), and increases in both the ability and desire to evaluate the success or failure of their achievement efforts (Heckhausen, 1987; Stipek et al., 1992). Second, parents play a critical role in the extent to which children regulate their own behavior. For instance, both the ways parents define and organize tasks for the children, and the control strategies they use, have a big impact on very young children's ability to regulate their behavior (e.g., use of indirect commands, verbal controls, and reasoning facilitates the early development of self-regulation, see Kopp, 1991).

From the self-determination theory perspective, development involves the process of internalization, where children take increasing control over their own behavior and thus become more self-determined (see Deci & Ryan, 2002b). Grolnick and her colleagues (2002) discussed the important role of autonomy support in the development of self-determination and intrinsic motivation. They reviewed research showing that when parents and teachers support children's autonomy, children have more positive competence beliefs, greater intrinsic mo-

tivation, and higher self-esteem. Along with autonomy support Grolnick et al. stressed the roles of affective support, involvement in children's lives, and the provision of adequate structure in children's environments as fostering the development of self-determination.

Turning to self-regulated learning, Zimmerman (2000) proposed a four-step developmental sequence of self-regulation. Children first learn effective strategies by observing successful models and focusing on process goals. Second, children imitate the strategies, following what the model did relatively closely. Third, they learn to use the strategies apart from the model; Zimmerman called this self-controlled learning. Although children do the strategies on their own, they still are dependent on the model. Finally, in the self-regulated phase children begin both to use the strategies in different situations and to tailor them to their own purposes. They also focus more on outcome goals. Research is beginning to show that individuals' ability to learn different behaviors relates to the kind of regulatory training they experience. Kitsantas, Zimmerman, and Cleary (2000) found that novice students learned best when learning from models rather than simply receiving performance feedback on their own performance. Zimmerman and Kitsantas (1999) found that as students moved through the levels of regulatory skill they learned more efficiently when focused on outcome goals rather than process goals because the former matched more clearly their level of self-regulation.

Pintrich and Zusho (2002) also discussed the development of self-regulation, discussing both phases of self-regulation, like those we discussed earlier, and different areas that need to be regulated (i.e., cognition, motivation, behavior, and context). Like Eccles et al. (1998) they noted that children become more efficient at regulating their cognition and behavior, and possibly their motivation, as they get older. However, they also discussed that older children may know how to regulate these areas but often do not, reflecting the pervasive competence/performance distinction that occurs in many areas of psychology. Pintrich and Zusho reviewed specific aspects of cognition and motivation that relate to the ability to self-regulate learning and behavior. With respect to motivation, a child's level of efficacy, degree of interest in the activity, and goals for the activity all relate to their self-regulation. When children are efficacious, interested in the activity they are doing, and hold learning goals, they are more likely to regulate

their behavior to accomplish a certain activity (see also Wolters, 2003). Further, there are potentially interesting developmental issues with respect to how each of these motivational constructs may relate to the regulation of achievement behavior. For instance, younger children's competence and efficacy beliefs relate less closely to their actual behavior and (particularly with respect to competence beliefs) often are overly optimistic, which may mean that younger children do not see the need to carefully regulate their actions to produce an outcome. As competence beliefs and performance become more closely calibrated, this likely changes. With respect to goal orientations, if mastery goals become less prevalent and performance goals more prevalent then self-regulation may decline (but see Pintrich, 2000b, on multiple pathways to different outcomes).

With respect to the use of different self-regulatory strategies, Zimmerman and Martinez-Pons (1990) found a complex pattern of differences across age in use of these strategies by older children and adolescents. Researchers have not yet systematically tested how strategies, goals, and self-efficacy interact to influence the regulation of learning in different-aged children. Additionally, it would be useful to compare Zimmerman's model with Deci and Ryan's discussion of the development of internalized regulation.

There is some developmental work on volitional strategies. For example, Kuhl and Kraska (1989), in German and Mexican elementary school-aged children, found increases in children's ability to use all of the strategies except for emotion control. But more developmental work is needed here as well.

### **The Development and Remediation of Motivational Problems**

Many children begin to experience motivational problems during the school years. We focus on three motivational problems that have received the most attention in the literature: (1) test anxiety, (2) learned helplessness, and (3) apathy. The first two of these problems are tied to beliefs about not being able to do different activities, whereas the third emerges when children devalue achievement related activities.

#### ***Anxiety***

Anxiety and test anxiety are estimated to interfere with the learning and performance, particularly in evaluative

situations, of as many as 10 million children and adolescents in the United States (Hill & Wigfield, 1984; Tobias, 1985; Wigfield & Eccles, 1989). This problem likely will get worse as evaluation and accountability become more emphasized in schools (Deci & Ryan, 2002a; Zeidner, 1998). Anxiety often is conceptualized as having two components—worry and emotionality—with worry referring to cognitive ruminations and emotionality referring to physiological reactions (see Morris, Davis, & Hutchings, 1981). Researchers have focused on the cognitive/worry aspect of anxiety because worry is more strongly and negatively related to performance than emotionality (e.g., Morris et al., 1981; Sarason, 1980).

Researchers (e.g., Dusek, 1980; Hill & Wigfield, 1984; Wigfield & Eccles, 1989; Zeidner, 1998) postulate that high anxiety emerges when parents have overly high expectations and put too much pressure on their children, but few studies have tested this proposition. Anxiety continues to develop across the school years as children face more frequent evaluation, social comparison, and (for some) experiences of failure; to the extent that schools emphasize these characteristics, anxiety becomes a problem for more children (Hill & Wigfield, 1984). With a few important exceptions (e.g., Silverman, La Greca, & Wasserstein, 1995; Vasey & Daleiden, 1994; Zeidner, 1998), work on anxiety has diminished. One reason for this is the argument that anxiety is simply the flip side of negative judgments about one's ability and efficacy. For instance, Nicholls (1976) concluded that many items on one of the major scales used to measure anxiety, the Test Anxiety Scale for Children, refer to negative ability beliefs. When he separated the ability and anxiety items, the ability items related more strongly to indicators of achievement than the anxiety items (cf. Bandura, 1997; Meece et al., 1990). Second, is increasing interest in other kinds of emotions and their relations to motivation and achievement (see Pekrun, 2000).

#### ***Anxiety Intervention Programs***

Many programs have been developed to reduce anxiety (Denny, 1980; Wigfield & Eccles, 1989; Zeidner, 1998). Earlier intervention programs, emphasizing the emotionality aspect of anxiety, focused on relaxation and desensitization techniques. Although these programs did reduce anxiety, they did not always lead to improved performance, and the studies had serious methodologi-

cal flaws. Anxiety intervention programs linked to the worry aspect of anxiety focus on changing the negative, self-deprecating thoughts of anxious individuals and replacing them with more positive, task-focused thoughts (e.g., see Denny, 1980; Meichenbaum & Butler, 1980). These programs have been more successful both in lowering anxiety and improving performance.

### ***Learned Helplessness***

"Learned helplessness . . . exists when an individual perceives the termination of failure to be independent of his responses" (Dweck & Goetz, 1978, p. 157). Eccles et al. (1998) reviewed the early work (primarily by Dweck and her colleagues) on how helpless and mastery-oriented children differ in their responses to failure (see also Dweck & Elliott, 1983; Dweck & Leggett, 1988). When confronted by difficulty (or failure), mastery-oriented children persist, stay focused on the task, and sometimes even use more sophisticated strategies. In contrast, helpless children's performance deteriorates, they ruminate about their difficulties, and often begin to attribute their failures to lack of ability. Further, helpless children adopt the entity view that their intelligence is fixed, whereas mastery-oriented children adopt the incremental view of intelligence.

As noted earlier, the "optimism to realism" pattern of change in children's ability-related belief led some researchers to conclude that helplessness is less likely to occur in younger children. Dweck and her colleagues' more recent work (e.g., Burhans & Dweck, 1995) shows that in fact some young (5- and 6-year-old) children respond quite negatively to failure feedback, showing the helpless pattern and judging themselves to be bad people (cf. Stipek et al., 1992). Indeed, they proposed that young children's helplessness is based more on their judgments that their worth as persons is contingent on their performance than on having a mature entity view of intelligence. This work suggests an important developmental modification to Dweck and Leggett's (1988) model of learned helpless versus mastery-oriented motivational styles that is based in beliefs about intelligence and goals.

What else influences the emergence of individual differences in learned helplessness in children? Dweck and Goetz (1978) stressed that whether children receive feedback, their failures are due to lack of ability or lack of skills and effort from parents and teachers. In support, Hokoda and Fincham (1995) found that mothers of

helpless third grade children (in comparison to mothers of mastery-oriented children) gave fewer positive affective comments to their children, were more likely to respond to their children's lack of confidence in their ability by telling them to quit, were less responsive to their children's bids for help, and did not focus them on mastery goals. Dweck and Lennon (2001) found that students' perceptions that their parents had entity views of intelligence (measured by the kinds of feedback they would provide their children about different achievement outcomes) predicted their own views of intelligence. For instance, students perceiving their parents had an entity view were more likely themselves to have an entity view.

### ***Alleviating Learned Helplessness***

Various training techniques (including operant conditioning and providing specific attributional feedback) have been used successfully to change children's failure attributions from lack of ability to lack of effort, improving their task persistence and performance (e.g., Andrews & Debus, 1978; Dweck, 1975; Forsterling, 1985). Two problems with these approaches have been noted. First, what if the child is already trying very hard? Then, the attribution retraining may be counterproductive. Second, telling children to "try harder" without providing specific strategies designed to improve performance is likely to backfire if the children increase their efforts and still do not succeed. Therefore, some researchers advocate using strategy retraining in combination with attribution retraining to provide lower achieving and/or learned helpless children with specific ways to remedy their achievement problems. Borkowski and his colleagues, for example, have shown that a combined program of strategy instruction and attribution retraining is more effective than strategy instruction alone in increasing reading motivation and performance in underachieving students (e.g., Borkowski, Weyhing, & Carr, 1988; Paris & Byrnes, 1989).

### ***Student Apathy***

Apathy has more to do with students' sense of the value of participating in different activities rather than their beliefs about whether they are capable of accomplishing the activity. Children who are apathetic about learning or participating in other activities do not find much worthwhile to do in school or in other situations; they may even be so alienated from these activities that they

actively resist attempts to get them involved. Brophy (2004) contended that apathy is the most serious motivational problem that teachers most contend with in their students—more serious than learned helplessness or anxiety. The apathy construct has some overlap with the construct of amotivation in SDT (Vallerand et al., 1993).

There has not been a lot of research on the development of apathy, but different researchers have discussed possible reasons for it. These range from broad social and cultural explanations to more psychologically oriented ones. Ogbu's (1992) discussion of why some minority children do well in school and others do not is an example of a broad cultural approach to this issue. Children who believe their ethnic or racial group is excluded from meaningful participation in the economic structure of this country may find little reason to engage in the school activities said to be needed to obtain good occupations. Ogbu has argued that such children often become oppositional to participation in school activities, resisting attempts of teachers to engage them in learning activities. We return to this issue later. A more psychological perspective on apathy can be drawn from Markus and Nurius's (1986) work on possible selves. Markus and Nurius argued that possible selves provide an important motivational force for engagement in different activities such as school or sport activities. If children do not see much of a future for themselves in these or other domains, they may not see much reason to be involved in school or other activities designed to prepare them for the future, and so they may be very apathetic about becoming involved in such activities.

We noted that apathy stems from the devaluing of different kinds of activities rather than from children's perceptions of their competence to accomplish them, but the interplay of competence beliefs and values may play a crucial role in the development of apathy. Recall our earlier discussion of how children maintain their self-worth by valuing those activities at which they are competent and devaluing activities where they are doing less well. Children doing poorly in school may begin to devalue school achievement, as a way to protect their self-esteem (see Covington, 1992). This devaluing could lead to apathy, again as a self-protective mechanism. Engaging in learning has risks, particularly for students not doing well, and one way to protect against those risks is to be apathetic about learning.

Finally, there likely are different developmental trajectories for the development of apathy. We noted two

major possibilities to this point: (1) children who perceive few opportunities for themselves or for their group and so come to devalue school, or (2) children who begin to do poorly in school and so begin to devalue it as a way to protect their self-esteem. We use school activities to illustrate these points, but it should be noted that these patterns could occur for other kinds of activities as well. Another trajectory occurs for students doing well in school during the early school years and who come from backgrounds and cultural groups who generally have succeeded in our society, but who decide (for a variety of reasons) to no longer engage in school. These children may become alienated from school and therefore apathetic about participating in school activities (National Research Council [NRC], 2004). To date, there is little developmental work on any of these trajectories, but it should be undertaken.

### *Summary*

In summary, work on anxiety, learned helplessness, and apathy shows that some children suffer from motivational problems that may debilitate their performance in achievement situations and may lead them to disengage from school and other achievement activities. Although most of the work in developmental and educational psychology has focused on these problems, there likely are other important motivational problems as well. In particular, some children may set maladaptive achievement goals, and others may have difficulties regulating their achievement behaviors. More comprehensive work on these kinds of motivational problems and how they affect children's achievement is needed.

### **The Development of Gender Differences in Motivation**

Despite recent efforts to increase the participation of women in advanced educational training and high-status professional fields, women are still underrepresented in many fields, particularly those associated with technology, physics and applied mathematics, and at the highest levels of almost all fields (see Wigfield, Battle, Keller, & Eccles, 2002). Efforts to understand these persistent sex differences in achievement patterns have produced a proliferation of theories and research (see McGillicuddy-DeLisi & DeLisi, 2002, for review). Eccles and her colleagues originally proposed their expectancy-value model of achievement choices

(see Figure 15.1) as an effort to organize this disparate research into a comprehensive theoretical framework (see Eccles-Parsons et al., 1983; Wigfield & Eccles, 2002b). This model predicts that people will be most likely to enroll in courses and choose careers that they think they will do well in and that have high task value for them. Expectations for success depend on the confidence the individual has in his or her intellectual abilities and on the individual's estimations of the difficulty of the course or activity. These beliefs have been shaped by the individual's experiences with the subject matter, by the individual's subjective interpretation of those experiences (e.g., Does the person think that her/his successes are a consequence of high ability or lots of hard work?), and by cultural stereotypes regarding both the difficulty of the course and the distribution of relevant talents across various subgroups. The value of a particular course is also influenced by several factors, including the following: Does the person like doing the subject material? How well does the course fit with the individual's self-concepts, goals, and values? Is the course seen as instrumental in meeting one of the individual's long- or short-range goals? Have the individual's parents or counselors insisted that the course be taken or, conversely, have other people tried to discourage the individual from taking the course? Does taking the course interfere with other goals and values activities? Existing evidence, reviewed next, supports the conclusion that gender-role socialization and internalization are likely to lead to gender differences in each of these broad motivational categories, which in turn could contribute to the underrepresentation of women in many high achievement-oriented occupations and activities (see Eccles, 1994).

### ***Gender Differences in Competence-Related Beliefs, Causal Attributions, and Control Beliefs***

Gender differences (often favoring males) in competence beliefs are often reported, particularly in gender-role stereotyped domains and on novel tasks, and these differences are apparent as early as kindergarten or first grade, if not before. For example, gifted and high-achieving females are more likely to underestimate both their ability level and their class standing (Frome & Eccles, 1995). In other studies, the gender difference depends on the gender-role stereotyping of the activity. For example, boys hold higher competence beliefs than girls for math and sports, even after all relevant skill-

level differences are controlled; in contrast, girls have higher competence beliefs than boys for reading and English, music and arts, and social studies. Recent work (Jacobs et al., 2002) shows that the gender differences in competence beliefs in math narrow during adolescence, but those in English remain. Further, the extent to which children endorse the cultural stereotypes regarding which sex is likely to be most talented in each domain predicts the extent to which girls and boys distort their ability, self-concepts, and expectations in the gender stereotypic direction (Eccles & Harold, 1991). However, these sex differences are generally relatively small when they are found (Marsh, 1989).

Gender differences are also sometimes found for locus of control, with girls having higher internal locus of responsibility scores for both positive and negative achievement events and the older girls had higher internality for negative events than did the younger girls (Crandall et al., 1965). These two developmental patterns resulted in the older girls accepting more blame for negative events than the older boys (cf. Dweck & Goetz, 1978). Connell (1985) found that boys attributed their outcomes more than girls to either powerful others or unknown causes in both the cognitive and social domains.

This greater propensity for girls to take personal responsibility for their failures, coupled with their more frequent attribution of failure to lack of ability (a stable, uncontrollable cause) has been interpreted as evidence of greater learned helplessness in females (see Dweck & Licht, 1980). However, evidence for gender differences on behavioral indicators of learned helplessness is quite mixed. In most studies of underachievers, boys outnumber girls 2 to 1 (see McCall, Evahn, & Kratzer, 1992). Similarly, boys are more likely than girls to be referred by their teachers for motivational problems and are more likely to drop out of school before completing high school. More consistent evidence exists that females, compared to males, select easier laboratory tasks, avoid challenging and competitive situations, lower their expectations more following failure, shift more quickly to a different college major when their grades begin to drop, and perform more poorly than they are capable of on difficult, timed tests (see Dweck & Licht, 1980; S. J. Spencer, Steele, & Quinn, 1999).

Gender differences also emerge regularly in studies of anxiety (e.g., Hill & Sarason, 1966; Meece et al., 1990). However, Hill and Sarason suggested that boys may be more defensive than girls about admitting anxiety on

questionnaires. In support of this suggestion, Lord, Eccles, and McCarthy (1994) found that test anxiety was a more significant predictor of poor adjustment to junior high school for boys even though the girls reported higher mean levels of anxiety.

Closely related to the anxiety findings, S. J. Spencer et al. (1999) documented another motivational mechanism likely to undermine females' performance on difficult timed tests: stereotype vulnerability. They hypothesize that members of social groups (like females) stereotyped as being less competent in a particular subject area (like math) will become anxious when asked to do difficult problems because they are afraid the stereotype might be true of them. This vulnerability is also likely to make them respond more negatively to failure feedback, leading to lowering their expectations and their confidence in their ability to succeed. They gave college students a difficult math test under different conditions: (a) after being told that males typically do better on this test, (b) after being told that males and females typically do about the same, or (c) after gender differences were not mentioned. The women scored lower than the males only in the first condition.

In sum, when gender differences emerge on competence-related measures of motivation, they are both consistent with gender-role stereotypes and are likely mediators of gender differences in various types of achievement-related behaviors and choices.

### ***Gender Differences in Achievement Values***

Eccles, Wigfield and their colleagues have found gender-role stereotypic differences in both children's and adolescents' valuing of sports, social activities, and English that begin quite early during children's development (e.g., Eccles et al., 1989; Eccles, Wigfield, et al., 1993; Wigfield et al., 1991). In Eccles, Wigfield, et al. (1993), girls also valued instrumental music more than boys. Earlier work showed gender differences in math value favoring boys emerging during adolescence (Eccles, 1984), but more recent studies show that boys and girls value math equally during adolescence (Jacobs et al., 2002). Although boys and girls now appear to value math equally, girls are less interested in science (with the exception of biology) and engineering than are boys, and they enroll much less frequently in these majors in college (see Wigfield et al., 2002, for review). Eccles et al. (1998) reviewed the work on the psychological

processes that underlie some of these sex differences in children's achievement values.

**Disidentification.** Earlier, we discussed the relationship between values and competence-related beliefs. Drawing on the writings of William James (1892/1963), we suggested that children will lower the value they attach to particular activities or subject areas if they lack confidence in these areas to maintain their self-esteem (see also Harter, 1990). S. J. Spencer et al. (1999) suggested a similar phenomenon related to stereotype vulnerability. They hypothesized that women will disidentify with those subject areas in which females are stereotyped as less competent than males. By disidentifying with these areas, the women will not only lower the value they attach to these subject areas, they will also be less likely to experience pride and positive affect when they are doing well in these subjects. Consequently, these subjects should become irrelevant to their self-esteem. These hypotheses need further testing.

### **The Development of Group Differences in Motivation: The Roles of Culture, Ethnicity, and Immigration**

As is the case in many areas of psychology (see Graham, 1992), less is known about the motivation of children from racial and ethnic groups other than European Americans. However, work in this area is growing quickly, with much of it focusing on the academic problems and prospects of African American (see Hare, 1985; Meece & Kurtz-Costes, 2001; Slaughter-Defoe, Nakagawa, Takanishi, & Johnson, 1990), Mexican American (e.g., Padilla & Gonzalez, 2001; Portes & Rumbaut, 2001), and Asian American youth (Fuligni & Tseng, 1999; S. J. Lee, 1994), both those born in this country and those who have immigrated here. Motivation theorists increasingly are interested in the applicability of their theoretical models to diverse groups of children. For instance, in a recent volume edited by McInerney and Van Etten (2004), theorists representing many of the theoretical perspectives reviewed in this chapter discussed the role of culture in their theoretical views, and whether their theories are applicable in different cultures.

This is an important time for renewed interest in how culture, ethnicity, and immigration relate to children's academic motivation, achievement, and future educa-

tional plans and attainments, as emerging and ongoing demographic trends in the United States and in developed countries all over the world show that large-scale immigration is taking place. For instance, in the United States today, the school-aged population stands at about 54 million individuals and is as large and diverse as it has ever been in U.S. history (U.S. Department of Education, 2003a). As of 2002, approximately 40% of the entire school-aged population was a member of an ethnic group other than European American, a large jump from the early 1970s that is due mainly to large-scale immigration from Mexico and certain East Asian countries (U.S. Department of Education, 2002). Thus, a significant proportion of the school-aged population today, approximately 20%, are “New Americans” who are growing up in immigrant families (Portes & Rumbaut, 2001; Suarez-Orozco & Suarez-Orozco, 2001).

This chapter is about motivation and not achievement, but it is important to understand achievement differences across groups to understand motivational differences. There are many individual differences in given groups, but overall Asian American children (both recent immigrants and those born here) perform better than many European American children. These two groups continue to outperform African American children and Latino and Mexican American children. Mexican American children have a very high school drop out rate relative to these other groups (U.S. Department of Education, 2003b).

There are interesting generational and gender differences in these effects. For instance, despite traditional socialization practices in many cultures that can exert strong pressures on females toward traditional gender roles associated with the home and not achievement in the outside world (e.g., Olson, 1997), there is evidence that second-generation immigrant females, like U.S. born females in general, tend to outperform their male counterparts in school and aspire to go further educationally and occupationally as well (Portes & Rumbaut, 2001). Understanding motivational dynamics behind these achievement differences is an important task, so we now turn to a discussion of the development of differences in motivation across different racial and ethnic groups.

Researchers interested in issues of culture, motivation, and achievement have examined the ways in which: (a) culture informs the development of self, motives, and behavioral scripts associated with achievement

(e.g., Markus & Kitayama, 1991; Ogbu, 1981); (b) culture shapes group members’ construal of the meaning of success and failure before and after achievement experiences (e.g., Grant & Dweck, 2001; Heine et al., 2001); (c) culture influences how universal and individual psychological needs are expressed (e.g., Chirkov, Ryan, Kim, & Kaplan, 2003); and (d) culture influences engagement in the classroom (e.g., Greeno, Collins, & Resnick, 1996; Hickey & McCaslin, 2001; Roeser & Nasir, *in press*). We focus on the first three in this section, and the fourth in the School Level Characteristics and Student Motivation section.

Contemporary cultural psychology focuses on variation in the self linked to culture-specific socialization practices. A major distinction in this work is between socialization practices anchored in more individualistic (priority placed on goals and preferences of the self) and those anchored in more collectivist (priority placed on needs and norms of the group) cultural traditions (Triandis & Suh, 2002). Markus and Kitayama (1991) developed the notion of “cultural frame” as a way of describing how cultural socialization practices come to literally inform the self. Cultural frames are meaning systems comprised of language, tacit social understandings, and scripts for enacting these social understandings in daily life. Individual’s self-construals (i.e., the individual’s understandings about what it means to be a person in the world) are a critical component of these cultural frames. Markus and Kitayama (1991) outlined two different cultural frames, each associated with a specific self-construal: (1) independence and (2) interdependence. In the independent construal of self, individuals come to see themselves as autonomous, self-contained, unique from others, and assertive in pursuing personal goals and desires. In contrast, in the interdependent self-construal, individuals assign primary significance to others in defining the self, feel a fundamental sense of connectedness to others, and attend, first and foremost, to social roles, in-group norms, and obligations and responsibilities to others (see Oyserman, Coon, & Kemmelmeier, 2002, for a comprehensive review of different strands of research on these two construals). Self-construals are assumed to be the seedbed of goals and motives, including one’s achievement-related goals and motives.

Although just beginning, research relating culture to motivation in this area tends to examine how (culturally informed) self-construals influence (a) the kinds of

motivations that are prevalent for members of different cultural groups (the issue of approach and avoidance motivation), (b) the kinds of values and goals that are taken up into the self by members of different cultural groups (the issue of diversity in goal content), and (c) the kinds of meanings that individuals from different cultural groups make both before and after engaging with an achievement task (issues of meaning and appraisal). For example, Elliot, Chirkov, Kim, and Sheldon (2001) hypothesized that individualistic self-construals should promote approach motivation in which goals associated with self-assertion are focal; in contrast, interdependent self-construals should promote avoidance motivation in which goals associated with the reduction of group discord are focal. They found some support for these hypotheses in a cross-cultural study of college students. Among non-Asian college students, small correlations exist between self-as-independent and approach goals and between self-as-interdependent and avoidance goals. Both Asian American college students and students from more collectivist societies (Korea and Russia) report higher levels of avoidance motivation than European American college students.

These findings are consistent with studies suggesting that both the level and impact of avoidance motivation on achievement may be greater among individuals from cultural groups that emphasize interdependence and group membership. For instance, Eaton and Dembo (1997) found that the fear of failure (an avoidance motive) best predicted ninth grade Asian and Asian American students' performance on an intellectual task; in contrast, the non-Asian students' performance was best predicted by their beliefs about the incremental nature of intelligence, the importance of effort, and their self-efficacy. The authors interpreted these findings in relation to cultural dimensions of Asian cultures such as collectivism in which avoidance motives serve the function of maintaining group harmony.

Looking more directly at the association of culture to individual's view of such basic universal needs as autonomy, Chirkov et al. (2003) tested the proposition that individuals can "take up" cultural practices associated with collectivism and individualism in either a self-determined (autonomous) or an other-controlled (heteronomous) way in a study of undergraduates in Turkey, Russia, the United States, and South Korea. Defining autonomy by individuals' self-reported level of internalization of various collectivist or individualistic cultural

practices, they found considerable variation in the extent to which individuals in any culture took up and internalized supposedly focal cultural practices. Despite this variation, Americans saw their culture as relatively individualistic, South Koreans saw their culture as relatively collectivistic, and Russians saw their culture as a mixture of both. Further, the greater the degree of internalization of any type of cultural practice (whether collectivist or individualist), the greater the association of that belief with well-being. The extension of this work to examine how such cultural orientations, and their level of internalization, affect young people's goals and values in relation to education is just beginning.

Researchers also have looked at racial and ethnic group differences in the achievement beliefs, values, and goals we have been discussing and we turn to that work next.

### ***Racial and Ethnic Group Differences in Children's Competence, Control, and Attribution Beliefs***

Graham (1994) reviewed the literature on differences between African American and European American students on such motivational constructs as need for achievement, locus of control, achievement attributions, and ability beliefs and expectancies. She concluded that, in general, the differences are not very large. Further, she argued that many existing studies have not adequately distinguished between race and socioeconomic status, making it very difficult to interpret any differences that emerge. Cooper and Dorr (1995) did a meta-analysis of many of the same studies reviewed by Graham. There were important points of agreement across the two reviews, but Cooper and Dorr concluded that there is evidence suggesting race differences in need for achievement favoring Whites, especially in lower socioeconomic status (SES) and younger samples.

Research on competence beliefs and expectancies has revealed more optimism among African American children than among European American children, even when the European American children are achieving higher marks (e.g., H. W. Stevenson, Chen, & Uttal, 1990). But more important, in H. W. Stevenson et al. (1990), the European American children's ratings of their ability related significantly to their performance but the African American children's did not. Graham (1994) suggested the following explanations: (a) African American and European American children may use different social comparison groups to help judge their own abilities; and (b) African American children may say

they are doing well to protect their general self-esteem, and may also devalue or *disidentify* academic activities at which they do poorly to protect their self-esteem. However, neither of these explanations has been adequately tested. If African American children's competence-related beliefs indeed do not predict their school performance, questions must be raised about how relevant the theories considered in this chapter are for understanding these children's motivation.

### ***Racial and Ethnic Group Differences in Achievement Values and Goals***

There are few ethnic comparative studies specifically focused on the kinds of achievement values measured by Eccles, Wigfield, and their colleagues, or of the kinds of goals measured by Nicholls, Dweck, Ames, and Wentzel. Researchers studying minority children's achievement values have focused instead on the broader valuing of school by minority children and their parents. In general, these researchers find that minority children and parents highly value school (particularly during the elementary school years) and have high educational aspirations for their children (e.g., Galper, Wigfield, & Seefeldt, 1997; H. W. Stevenson et al., 1990). However, the many difficulties associated with poverty may make these educational aspirations difficult to attain (see Duncan, Brooks-Gunn, & Klebanov, 1994; Huston, McLoyd, & Coll, 1994; McLoyd, 1990).

In two studies that did examine between-group differences in the achievement values among Latino, African American, and White youth, Graham, Taylor, and Hudley (1998) and Graham and Taylor (2002) used a peer nomination technique to assess group differences in achievement values. Participants indicated which children in their class they admired, respected, and wanted to be like, and Graham and her colleagues argued that this is one way to gauge what children value. Results showed that White, Latino, and African American girls chose high-achieving girls as those whom they admired, respected, and wanted to be like. For boys, this was only true for White boys; the other two groups of boys admired low achievers more. In a third study, they looked at this issue developmentally, and found that in second and fourth grades all children were more likely to nominate higher achievers. In seventh grade, the sex-differentiated pattern for the different groups emerged. This intriguing work needs to be followed up to look more closely at why the nomination patterns shift be-

tween fourth and seventh grades; and what it is about entering adolescent and puberty that seems to cause many African and Mexican American youth to endorse values and role-models that exclude school achievement (e.g., Tatum, 1997).

In a study of high school students in Australia, McInerney, Hinkley, Dowson, and Van Etten (1998) tested whether significant cultural differences between Anglo, immigrant, and Aboriginal Australians would eventuate in different achievement goal profiles. They found that Aboriginals were lower on mastery and performance goals compared to the Anglo and immigrant Australians. Nonetheless, mastery goals were positively associated with achievement for all groups. That mastery goals may be interpreted differently by members of different cultural groups—mastery as a means of self-improvement and role fulfillment (interdependent self) or mastery as a means of self-improvement and personal success (independent self)—may explain why this goal seems to operate effectively across a wide diversity of cultural settings (Urdu, 1997).

### ***Race, Ethnicity, and Motivation at the Interface between Expectancies and Values***

Researchers interested in ethnic and racial differences in achievement have proposed models linking social roles, competence-related beliefs, and values. For example, Steele (1992, 1997) proposed stereotype vulnerability and disidentification to help explain the underachievement of African American students (see also Aronson, 2002; Aronson & Steele, 2005): Confronted throughout their school career with mixed messages about their competence and their potential and with the widespread negative cultural stereotypes about their academic potential and motivation, African American students should find it difficult to concentrate fully on their school work due to the anxiety induced by their stereotype vulnerability (for support see Steele & Aronson, 1995). In turn, to protect their self-esteem, they should disidentify with academic achievement leading to both a lowering of the value they attach to academic achievement and a detachment of their self-esteem from both positive and the negative academic experiences. In support, several researchers have found that academic self-concept of ability is less predictive of general self-esteem for some African American children (Winston, Eccles, Senior, & Vida, 1997). A key mediator of this process is African Americans' beliefs about the nature of

their intelligence (Dweck & Leggett, 1988). In a recent experimental intervention with college students, Aronson, Fried, and Good (2001) found that by encouraging African American college students to adopt a mind-set in which they viewed their own intelligence as malleable, there were able to increase their enjoyment and engagement in academics as well as their grades compared to controls. This exciting research suggests interventions at the level of the meaning of intelligence and the purpose of learning may bear fruit for ameliorating the effect of stereotype threat on the achievement of African Americans.

Fordham and Ogbu (1986) have made a similar argument linking African American students' perception of limited future job opportunities to lowered academic motivation: Because society and schools give African American youth the dual message that academic achievement is unlikely to lead to positive adult outcomes for them and that they are not valued by the system, some African American youth may create an oppositional culture that rejects the value of academic achievement. Ogbu (1992) discussed how this dynamic will be stronger for involuntary minorities who continue to be discriminated against by mainstream American culture (e.g., African Americans) than for voluntary minority immigrant groups (e.g., recent immigrants from Southeast Asia). Although voluntary minorities have initial barriers to overcome due to language and cultural differences, these barriers can be overcome somewhat more easily than the racism faced by involuntary minorities, giving voluntary minorities greater access to mainstream culture and its benefits. This analysis is intriguing, but it may oversimplify the nature of different kinds of immigrants and does not attend enough to individual differences in these groups.

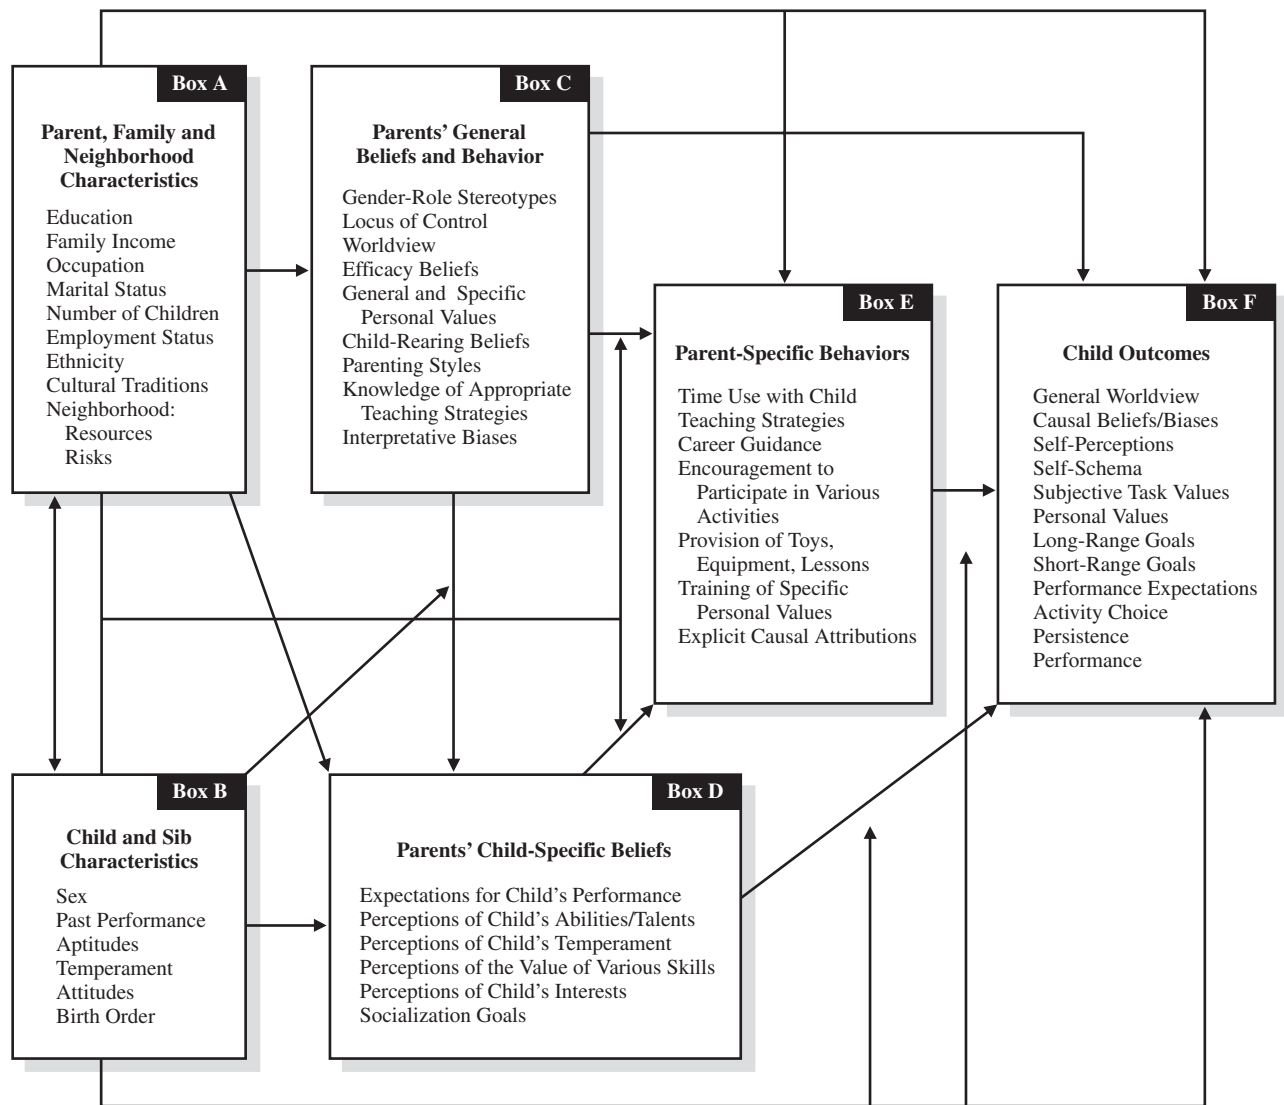

Contrary to this view, several investigators found no evidence of greater disidentification with school among African American students (e.g., M. B. Spencer, Noll, Stoltzfus, & Harpalani, 2001; Steinberg, Dornbusch, & Brown, 1992; Taylor, Casten, Flickinger, Roberts, & Fulmore, 1994). But several studies show that disidentification, particularly as a result of inequitable treatment and failure experiences at school, undermines achievement and academic motivation (e.g., see Finn, 1989; Taylor et al., 1994). Some students, particularly members of involuntary minority groups, may have these experiences as they pass through the secondary school system. Longitudinal studies of the process of

disidentification and how to ameliorate it when it occurs are needed.

In summary, as researchers continue to highlight the importance of understanding racial, ethnic, and immigrant variations in educational achievement given the demographic trends in our society (Kao & Thompson, 2003; Portes & Rumbaut, 2001), a deeper understanding of the role of academic motivational processes in explaining such variation in achievement behavior among different cultural, ethnic, and racial groups will continue to be critical topics of study in the developmental literature, as will further work that will help us to understand better the factors influencing the development of motivation in diverse groups of children (Graham, 1994; Pintrich, 2003).

## THE SOCIALIZATION OF MOTIVATION: PARENTAL INFLUENCES

In the previous edition of this chapter, Eccles et al. (1998) reviewed the early literature on how parents influence child motivation through socialization process. In the past decade, the socialization research has become more focused and has begun to examine the various processes and pathways where socialization strategies might be exerting their influence (see Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). The research has also become more general as the research has moved from the laboratory settings in which researchers link specific parenting practices to specific motivational constructs but generalizability is limited to large-scale nationally representative studies of child development and parenting (e.g., Panel Study of Income Dynamics-Child Development Supplement, National Longitudinal Study of Youth, and Early Childhood Longitudinal Study) that use global indicators of parenting practices and beliefs and examine how they link to motivational and performance outcomes. This transition to more complicated examination of socialization processes has been motivated by both advances in theory as well as advances in statistical and analytic techniques that have allowed for more complicated analyses of parent influence to be examined and for moderators and mediators of this influence to be taken into account. In both small- and large-scale studies, there have been attempts to link parenting practices both to their an-

**Figure 15.2** Model of parental influences on children's motivation and achievement.

tecedents and to their socialization consequences. Figure 15.2 provides a general overview of the types of associations tested. Although this specific model was proposed and elaborated by Eccles and her colleagues (Barber & Eccles, 1992; Eccles, 1989, 1993; Eccles & Harold, 1993), similar social cognitive mediational models of parental behavior and influence have been proposed by several other researchers (e.g., K. L. Alexander & Entwisle, 1988; Bronfenbrenner & Morris, 1998; Clark, 1983; J. J. Goodnow & Collins, 1990; Grolnick & Slowiaczek, 1994; H. W. Stevenson et al., 1990).

Although there is extensive work on some components of this model, very few studies include the several components underlying parenting behaviors outlined in Box E. Much of this literature focuses on the association of the exogenous characteristics (Boxes A and B) with parents' beliefs (Box C) or child outcomes (Box F)—for example, linking family socioeconomic status and/or ethnicity with parents' child-specific beliefs (Box D), specific parenting practices (Box E), and children's academic outcomes (Box F; Entwisle & Alexander, 1990; B. Schneider & Coleman, 1993; Steinberg et al., 1992; H. W.

Stevenson et al., 1990). Recently, however, research is beginning to appear that directly examines the mediating and moderating hypotheses implied in Figure 15.2 on achievement outcomes (Corwyn & Bradley, 2003; Davis-Kean, 2005; Davis-Kean & Magnuson, 2004). In general, this research has focused on the role that parent beliefs and behaviors may play in the socialization of achievement motivation in the individual child. This research indicates that parent's beliefs and behaviors are critical in setting a climate for children's motivation development by providing various activities or resources in the home environment that may provide stimulation to pursue various activities across time. For example, recent work on activity involvement suggests that parents play a role in promoting certain types of involvement in academic and sports domain in the early elementary years and that this emphasis translates into greater interest and motivation to continue with these activities over time and to choose course work and extracurricular activities consistent with these activities in adolescence (Simpkins, Fredricks, Davis-Kean, & Eccles, *in press*). Only in the past few years, this specific research has started to develop, and the research remains quite general; for example, linking family SES and general family socialization styles to general school achievement, achievement motivation, and other general motivational constructs such as mastery orientation, learned helplessness, and school engagement.

### Family Demographic Characteristics

Researchers in sociology, economics, and psychology have documented the importance of factors such as family structure, family size, parents' financial resources, parents' education, parents' occupation, community characteristics, and dramatic changes in the family's economic resources in shaping children's academic motivation and achievement (e.g., K. L. Alexander & Entwisle, 1988; Corwyn & Bradley, 2003; Marjoribanks, 2002; Teachman, Paasch, & Carver, 1997; Thompson, Alexander, & Entwisle, 1988; Yeung, Linver, & Brooks-Gunn, 2002). Several mechanisms could account for these associations. First, family demographics could affect children's motivation indirectly through their association with both parent beliefs and practices and the opportunity structures in the child's environment. For example, parents with more

education are more likely to (a) believe that involvement in their children's education and intellectual development is important, (b) be actively involved with the children's education, and (c) have intellectually stimulating materials in their home (e.g., Davis-Kean & Magnuson, 2004; DeBaryshe, Patterson, & Capaldi, 1993; B. Schneider & Coleman, 1993).

Second, some demographic characteristics could influence motivation indirectly through the competing demands they place on parents' time and energy. For example, the negative association of single-parent status, time spent at work, and large family size on children's school achievement might reflect the fact that these factors reduce the time and energy parents have for engaging their children in activities that foster high motivation (e.g., Marjoribanks, 2002; B. Schneider & Coleman, 1993). Similarly, the psychological stress associated with some demographic factors could influence parents' ability to engage in the kinds of behaviors associated with high motivation. Ample evidence documents how much harder the job of parenting becomes when the family lives in a high-risk neighborhood or is financially stressed (e.g., Conger et al., 2002; Elder, Eccles, Ardel, & Lord, 1995; Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999; McLoyd, 1990; Mistry, Vandewater, Huston, & McLoyd, 2002). Such parents not only have limited resources to implement whatever strategies they think might be effective but also have to cope with more external stressors than middle-class families living in stable, resource-rich neighborhoods. Not surprisingly, their children also evidence less positive motivation toward conventional school success.

Third, demographic characteristics can also affect parents' perceptions of, and expectations for, their children. Both parent educational level and family income are related positively to parents' expectations regarding both their children's immediate school success and long-term educational prospects (e.g., K. L. Alexander & Entwisle, 1988; Davis-Kean, Malanchuk, Peck, & Eccles, 2003; Teachman et al., 1997). Similarly, divorced parents have lower expectations for their children's academic achievement (Barber & Eccles, 1992). Ogbu has highlighted this mechanism as one way poverty and anticipated discrimination can undermine academic motivation in some minority populations: If parents believe that there are limited opportunities for their children to obtain conventional forms of success, they are likely to

shift their socialization efforts toward other goals and interests (Fordham & Ogbu, 1986; Ogbu, 1985).

Fourth, demographic characteristics can influence parents' beliefs and behaviors, and children's outcomes, in even less direct ways like those associated with role modeling. Family demographic characteristics are often associated with things like parents' jobs and leisure-time activities and with the kinds of role models children see outside the home. These behaviors and models can influence children's achievement goals, values, and self-perceptions through observational learning (Furstenberg et al., 1999; Kohn, 1997). Very little work has addressed this hypothesis directly. Instead, the mechanisms are typically inferred from correlational findings.

Fifth, demographic characteristics such as culture and ethnicity can influence parents' behaviors and children's motivation through mechanisms linked directly to values, goals, and general belief systems (e.g., Garcia Coll & Pachter, 2002; Gutman & Midgley, 2000; Luster, Rhoades, & Haas, 1989). For example, Ogbu (1985) has argued that parents value those characteristics that they assume will help their children succeed in their world. Other scholars describe cultural differences in valued activities, motivational orientation, and behavioral styles (e.g., H. W. Stevenson et al., 1990; Super & Harkness, 2002). Such differences can affect the socialization of motivated behavior through variations in: (a) valued activities (e.g., athletic versus musical competence), (b) valued goals (e.g., communal goals versus individualistic goals, mastery versus performance goals, doing versus being goals), and (c) approved means of achieving one's goals (e.g., competitive versus cooperative means). Further, there are cultural differences in the extent to which perceived family obligations influence children's motivation and achievement. Urdu and Giancarlo (2001) found that children from collectivist cultures had a stronger sense of obligation to their families that extended to the importance of doing well in school. Roeser, Lowe, Sattler, Gehlbach, and Strobel (2003) examined two kinds of family obligation goals that might motivate eighth grade Latino's academic achievement—those associated with making their parents proud through academic accomplishment (approach goals); and those associated with avoiding dishonoring the family through academic failure (avoidance goals). Compared to European American early adolescents, the Latino adolescents were more likely to endorse the pur-

suit of both types of goals (Roeser & Rodriguez, 2004), and family goals predicted Latino students' language achievement in school even after controlling for a host of sociodemographic, cognitive aptitude, and other motivational variables.

Researchers studying cultural differences in school achievement found cultural differences in parents' expectations and achievement-related beliefs and linked them to cultural differences in achievement. For example the work by H. W. Stevenson and his colleagues has demonstrated that European American parents, compared to Japanese parents, overestimate their children's academic abilities, are less aware of their children's academic difficulties, and are more satisfied with school performance that falls below their expectations (e.g., Crystal & Stevenson, 1991). Similarly, H. W. Stevenson et al. (1990) found differences in parents' achievement beliefs across African American, Hispanic, and European American parents in the United States.

In summary, there are many ways for family demographic characteristics to directly or indirectly affect motivation. However, even though family demographic characteristics have been linked repeatedly to children's school achievement; their effects are almost always indirect and mediated by their association with parents' beliefs, practices, and psychological resources. In addition, parents' beliefs and psychological and social resources can override the effects of even the most stressful demographic characteristics on children's school achievement and motivation (e.g., Clark, 1983; McLoyd, 1990). Finally, there are often complex interactions among various demographic characteristics in predicting either parenting beliefs and practices or child outcomes.

### *General Child-Rearing Climate*

Historically, researchers studying parental influence have focused on the impact of the general patterns and philosophy of child rearing on children's overall orientation toward achievement. Researchers have related a set of general behaviors and beliefs to the development of self-esteem, achievement motivation, locus of control, sense of personal efficacy, and so on. The variables investigated have included the general emotional warmth and supportiveness in the home (e.g., Connell, Halpren-Felsher, Clifford, Crichlow, & Usinger, 1995; Gutman, Sameroff, & Eccles, 2002; Wagner & Phillips, 1992); valuing of achievement (e.g., Clark, 1983; DeBaryshe, 1995); general parental child-rearing beliefs, theories,

values, and goals, as well as sex-typed goals and cultural beliefs, goals, and values (e.g., Goodnow & Collins, 1990; Miller & Davis, 1992); general child-rearing style, as well as authority structure, discipline tactics, and general interaction patterns (e.g., DeBaryshe et al., 1993; Lord et al., 1994; Steinberg et al., 1992; Yee & Flanagan, 1985); parental locus of control and personal efficacy (Bandura, 1997; Gutman et al., 2002); and communicative style and teaching style (McGillicuddy-DeLisi & Sigel, 1991). Similarly, researchers have documented the benefits of active involvement with, and monitoring of, children's and adolescents' school work (e.g., Clark, 1993; Connell et al., 1994; Eccles, 1993; B. Schneider & Coleman, 1993; Steinberg et al., 1992; H. W. Stevenson et al., 1990).

Several investigators have stressed an integrated view of how these various parenting characteristics work together to produce optimal motivational outcomes. For example, Grolnick and Ryan (1989) stressed the interplay of three components of general parenting in promoting self-determination in children and adolescents: (1) involvement and interest in the child's activities, (2) support for autonomous behaviors, and (3) adequate structure (e.g., Connell & Wellborn, 1991; Skinner, 1990). Grolnick and colleagues (2002) suggest that these parenting behaviors are important in helping children form a sense of autonomy and interest in activities that leads to greater achievement performance and a reduction in learning problems. Similarly, Csikszentmihalyi, Rathunde, and Whalen (1993) suggest the positive motivational development is optimized when there is appropriate synergy in the family's provision of support, harmony, involvement, and freedom. Finally, Eccles (1993) stressed the importance of emotional support, role models, and the right balance between structure, control, challenge, and developmentally appropriate levels of support for autonomy. This balance depends on cultural systems, on the specific context in which the family is living, the age of the child, and other individual characteristics.

Although the magnitude of effects varies by race/ethnicity, sex, social-economic class, and nationality, there is consensus that these general parental practices do impact on a variety of indicators of children's motivation and motivated behavior (e.g., Eccles, 1993; D. L. Stevenson & Baker, 1987). The results are consistent with three general principles: (1) appropriate levels of structure (as evident in Vygotsky's notion of appropriate scaffolding and Hunt and Paraskevopoulos's, 1980, no-

tion of good match), (2) consistent and supportive parenting, and (3) observational learning. Families who know enough about their child to provide the right amount of challenge with the right amount of support seem more likely to produce highly competent and motivated children. These parents are also likely to be able to adjust their behavior to meet the changing developmental needs and competencies of their children. Families that provide a positive emotional environment are more likely to produce children who want to internalize the parents' values and goals and therefore want to imitate the behaviors being modeled by their parents. Consequently, children growing up in these homes are likely to develop a positive achievement orientation if their parents provide such a model and value those specific tasks, goals, and means of achieving one's goals valued by their parents.

### **General Beliefs**

Researchers have shown that parents' general beliefs such as valuing of achievement and school competence, general parental child-rearing beliefs and theories, values and goals, sex-typed ideologies and goals, and culturally based beliefs, goals, and values are linked to parenting behaviors in the school achievement arena in the predicted direction (e.g., Eccles, 1993; Eccles, Freedman-Doan, Fromme, Jacobs, & Yoon, 2000; Goodnow & Collins, 1990; Jacobs & Eccles, 2000; Miller, 1988; Sigel et al., 1992). We are beginning to know more about how these general beliefs relate to specific behaviors and motivational beliefs across various achievement-related activity domains. Figure 15.2 depicts a general overview of how one might think about these interrelationships. Several important questions are suggested by this depiction: First, what is the relation of parents' general beliefs and practices to domain and child-specific parental beliefs, values, and practices? For example, do parents' gender-role stereotypes affect their perceptions of their own child's abilities in various activity domains? Relevant research is reviewed later.

Similarly, do parents' beliefs regarding the nature of ability affect their motivational parenting? Dweck has hypothesized that different ways of viewing the nature of ability and incompetence account for individual differences in academic achievement orientation (Dweck, 2002). As discussed earlier, children who think that incompetence is a temporary and modifiable state should respond to failure with increased mastery efforts more than children who think that current incompetence is a

sign of insufficient aptitude that cannot be modified. Parents also likely differ in their beliefs regarding the origins of individual differences in competence, the meaning of failure, and the most adaptive responses to failure. These beliefs should influence both their response to their children's failures and their efforts to help their children acquire new competencies and interests. Hokoda and Fincham (1995) provide support for these ideas.

Second, do cultural beliefs about things like the nature of ability affect the attributions parents' provide to their children for the child's successes and failures? Hess and his colleagues (e.g., Hess, Chih-Mei, & McDevitt, 1987; Holloway, 1988) and Stevenson and his colleagues (Lee, Ichikama, & Stevenson, 1987; H. W. Stevenson et al., 1990) have found that Japanese and Chinese parents make different causal attributions than European American parents for their children's school performances, with Japanese and Chinese parents emphasizing effort and hard work and European American parents emphasizing natural talent. Similarly, cultural differences in beliefs regarding the nature of ability and competence should relate to the kinds of statements parents make to their children about the origins of individual differences in performance—statements such as “You have to be born with math talent” versus “Anyone can be good at math if they just work hard enough” (Holloway, 1988; H. W. Stevenson et al., 1990). An interesting cross-cultural difference in the relation between the age of the child and parents' beliefs regarding ability is also emerging. Knight (1981) found that European Australian parents become more nativist in their view of their children's cognitive abilities as their children get older. In contrast, Japanese mothers become less nativist as their children get older.

***Child-Specific Beliefs, Values, and Perceptions:  
Parents as Interpreters of Competence-Relevant  
Information***

Parents hold many specific beliefs about their children's abilities, which affect motivationally linked outcomes, such as the well-established positive link between parents' educational expectations and academic motivation and performance (e.g., K. L. Alexander, Entwisle, & Bedinger, 1994; Brooks-Gunn, Guo, & Furstenberg, 1993; Davis-Kean, Eccles, & Schnabel, 2002; Grolnick & Slowiaczek, 1994; V. E. Lee & Croninger, 1994; B. Schneider & Coleman, 1993). Along with others, Eccles (1993) suggested the follow-

ing specific parental beliefs as particularly likely influences on children's motivation:

- Causal attributions for their children's performance in each domain
- Perceptions of the difficulty of various tasks for their children
- Expectations for their children's probable success and confidence in their children's abilities
- Beliefs regarding the value of various tasks and activities coupled with the extent to which parents believe they should encourage their children to master various tasks
- Differential achievement standards across various activity domains
- Beliefs about the external barriers to success coupled with beliefs regarding both effective strategies to overcome these barriers and their own sense of efficacy to implement these strategies for each child

Such beliefs and messages, particularly those associated with parents' perceptions of their children's competencies and likely success, influence children's self-beliefs and task beliefs (e.g., Fredricks & Eccles, 2002; Frome & Eccles, 1998; Miller, Manhal, & Mee, 1991; Pallas, Entwisle, Alexander, & Stluka, 1994; H. W. Stevenson et al., 1990). For example, parents' perceptions of their adolescents' abilities are significant predictors of adolescents' estimates of their own ability and interest in math, English, and sports even after the significant positive relation of the child's actual performance to both the parents' and adolescents' perceptions of the adolescents' domain-specific abilities is controlled (Eccles, 1993; Fredricks & Eccles, 2002; Jacobs, 1992; Jacobs & Eccles, 1992). Furthermore, Eccles and her colleagues found support for the hypothesized causal direction of this relationship using longitudinal panel analyses (Eccles, 1993; Eccles et al., 2000; Fredricks & Eccles, 2002; Yoon, Wigfield, & Eccles, 1993). In addition, in this same longitudinal study (The Michigan Study of Adolescent Life Transitions—MSALT), there was a negative relation between mothers' perceptions of their adolescents' English ability and the adolescents' perceptions of their own math ability. Individuals use a variety of information in deciding how good they are in various domains including their relative performances across various domains (i.e., they may decide they are very good at math because they find it easier to do

better in math than in other school subjects; see Eccles, 1987; Marsh, 1990a). These results suggest that a similar phenomenon may characterize the impact of parents' perceptions of their children's abilities on the development of the children's self-perceptions. The adolescents in this study had lower estimates of their math ability than one would have predicted based on their teachers' and their mothers' rating of their math ability if their mothers also thought that they were better in English than in math (Eccles et al., 1993).

**Influences on Parents' Perceptions of Their Children's Competencies.** How do parents form their impressions of their children's abilities? Parents appear to rely quite heavily on objective feedback, such as school grades (K. L. Alexander, Entwisle, & Bedinger, 1994; Arbreton & Eccles, 1994). The causal attributions parents make for their children's performances should also influence parents' perceptions. Support for this hypothesis is provided by Arbreton, Eccles, & Harold's (1994) longitudinal study. They found that parents' attributions of success to talent lead to increments in the parents' perceptions of their children's abilities in math, English, and sports and decrements in parents' estimates of how hard their children will have to work to be successful in math, English, and sports even after appropriate controls for prior performance and prior ability ratings are included.

Researchers have also assessed sex of child effects on parents' attributional patterns to help explain the gender role stereotypic distortions in parents' impression of their children's academic and nonacademic abilities that exist from a very early age on, even after one controls for actual performance differences (e.g., Eccles, 1993, 1994; Jacobs, 1992; Jacobs & Eccles, 1992). For example, in Jacobs (1992), mothers gave gender-role stereotypic causal attributions for their adolescent children's successes and failures in mathematics, English and sports: Sons' successes in math and sports were more likely to be attributed to natural talent than daughters'; daughters' success in English was more likely to be attributed to natural talent than sons'. Furthermore, as predicted, the sex differences in these mothers' ratings of their adolescents' abilities in each domain were substantially reduced once these sex differences in the mothers' causal attributions was controlled, supporting the hypothesis that parents' gender-role stereotyped causal attributions mediate parents' gender-role stereotyped perceptions of their children's math competence.

Using path-analytic techniques, Jacobs and Eccles (1992) tested whether parents' gender-role stereotypes generalized to their perceptions of their own children's ability. They found that parents who endorsed a gender-role stereotype regarding which sex is most interested in, and has the most natural talent for, math, English, and sports also distorted their ratings of their own children's abilities in each of these domains in the gender-role stereotypic direction.

#### ***Child-Specific Beliefs, Values, and Perceptions: Parents as Interpreters of Task Value***

Parents may convey differential task values through explicit rewards and encouragement for participating in some activities rather than others. Similarly, parents may influence children's interests and aspirations, particularly with regard to future educational and vocational options, through explicit and implicit messages they provide as they counsel children or work with them on different academic activities (e.g., Eccles & Harold, 1993; Jacobs & Eccles, 2000; Tenenbaum & Leaper, 2003). For instance, Tenenbaum and Leaper found that fathers used higher order conceptual language when discussing physics activities with sons than with daughters, which gave boys and girls different messages about their ability in science. Whether this encouragement directly affects either the value the children attach to math or their participation in math activities has not been established.

#### ***Provisions of Specific Experiences at Home***

There is ample evidence that parents influence their children's motivation through the specific types of learning experiences they provide for their children. For example, researchers have shown that reading to preschool children and providing reading materials in the home predicts the children's later reading achievement and motivation (e.g., Davis-Kean & Eccles, 2003; Linver, Brooks-Gunn, & Kohen, 2002; Wigfield & Asher, 1984). Such experience likely influences the child's skill levels and interest in doing these activities, both of which have a positive impact on the child's transition into elementary school and subsequent educational success (Entwisle & Alexander, 1993). Similarly, by providing the specific toys, home environment, and cultural and recreational activities for their children, parents structure their children's experiences (Jacobs, Davis-Kean, Bleeker, Eccles, & Malanchuk, 2004). However, the extent to which these experiences actually influence

children's motivation should depend on the affective and motivational climate that is created by parents when the children are engaged with any particular experience. Finally, the differential provision of such experiences to girls and boys and to children from various ethnic groups might explain group differences in subsequent motivation to engage various types of achievement activities (see Jacobs et al., 2004, for discussion relating to gender).

Another avenue through which parents indirectly influence the provisions in the home is the way they manage the family. Parents manage the resources and time of their children and thus choose or help in choosing activities for their child that may increase interest and competence in these areas (Davis-Kean & Eccles, 1999; Simpkins et al., in press). Many parents try to organize and arrange their children's social environments to promote opportunities, to expose their children to particular experiences and value systems, and to restrict dangers and exposure to undesirable influences. Consider, for example, the amount of attention some parents give to the choice of child care during early childhood, to picking a place to live, and to selecting appropriate after-school and summer activities for their children to ensure desirable schools and appropriate playmates for their children and to help their children acquire particular skills and interests. In the arena of school achievement, parents' engagement in managing their children's experiences in relation to intellectual skills (e.g., reading, acquisition of general information, and mastering school assignments) is directly and powerfully related to children's subsequent academic success even in stressful contexts such as poverty (Furstenberg et al., 1999). Given the consistency of the evidence in this one domain, understanding the specific ways parents organize and manage their children's experiences across a wide range of activities is a promising approach to understanding how parents shape individual differences in specific skills, self-perceptions, interests, and activity preferences. For example, children are most likely to acquire those skills that their parents make sure they have the opportunity to learn and practice.

### Summary

The studies reviewed suggest a multivariate model of the relation between antecedent child-rearing variables and the development of achievement orientation: The development of achievement motivation likely depends on the presence of several variables interacting with each

other and mediating and moderating children's motivation. Specifically, proper timing of demands creates a situation in which the child can develop his or her sense of competence in dealing with his environment. An optimally warm and supportive environment creates a situation in which the child will choose his parents as role models. The presence of high yet realistic expectations creates a demand situation in which the child will perform in accord with the expectancies of the parents. Finally, the ability level of the child must be such that attainment of the expected level of performance is within his or her capacity. All these factors, as well as the availability of appropriate role models, are essential for the child to develop a positive, achievement orientation. The exact way this orientation will be manifest is likely dependent on the values the child has learned, which are directly influenced by the culture in which the family lives and the social roles that the child is being socialized to assume.

### THE SOCIALIZATION OF MOTIVATION: INFLUENCES OF SCHOOL/ INSTRUCTIONAL CONTEXTS AND SCHOOL TRANSITIONS

In this section, we review work on two broad topics: (1) how teachers, classroom contexts, and school contexts influence motivation; and (2) how school transitions influence children's motivation. Given space limitations, we provide only an overview of the types of work being done in these areas. There is a continuing trend for motivational researchers to study contextual influences on motivation and the work on motivation in context has burgeoned since the last edition of this *Handbook* was published (see Hickey & McCaslin, 2001; Urdan, 1999, for further discussion of this topic).

Much of the recent work is directly related to notions inherent in person-environment fit perspectives. The researchers, either implicitly or explicitly, assume that motivation will be optimized in learning settings that meet individual's basic and developmental needs. The exact nature of the basic or universal needs has been articulated in various ways. As discussed earlier, Deci, Ryan, Connell, and their colleagues focus attention on three basic needs: (1) competence, (2) relatedness, and (3) autonomy (e.g., R. M. Ryan & Deci, 2002). Eccles suggested that the need to matter (e.g., to make a real and meaningful difference in one's social world) is an additional universal value likely to influence

achievement-related motivation particularly as individuals' mature into and through adolescence (Eccles, 2004). Eccles, Midgley, and their colleagues (e.g., Eccles, Midgley, et al., 1993) articulated a set of changing developmental needs that are often not met in school settings as children move from elementary school into secondary school. We believe that many of the constructs discussed in the next sections relate directly to these basic and developmental needs and thus influence individuals' motivation through their impact on the individuals' believing and feeling that their cognitive, emotional, and social needs are being met.

### **Teacher Beliefs and General Instructional Practices in the Classroom**

There are several beliefs teachers have about their students and instructional practices they undertake that influence children's motivation. We discuss each in turn.

#### ***Teachers' General Expectations and Sense of Their Own Efficacy***

Both teachers' general expectations for their students' performance and teachers' confidence in their own teaching efficacy (e.g., confidence in their ability to influence their students through their teaching) predict students' school achievement likely through their impact on students' sense of competence. When teachers hold high generalized expectations for student achievement and students perceive these expectations, students achieve more, experience a greater sense of esteem and competence as learners, and resist involvement in problem behaviors during both childhood and adolescence (Eccles, Midgley, et al., 1993; V. E. Lee & Smith, 2001; NRC, 2004; Weinstein, 1989). Similarly, teachers who feel they are able to reach even the most difficult students, who believe in their ability to affect students' lives, and who believe that teachers are an important factor in determining developmental outcomes communicate such positive expectations and beliefs to their students (V. E. Lee & Smith, 2001; Midgley, Feldlaufer, & Eccles, 1989; Roeser, Marachi, & Gehlbach, 2002; Tschannen-Moran, Woolfolk-Hoy, & Hoy, 1998). Such expectations, when communicated to students, become internalized in positive self-appraisals that enhance both feelings of competence and worth, which enhance engagement in the learning tasks offered in school (V. E. Lee & Smith, 2001; NRC, 2002; Roeser, Eccles, & Sameroff, 1998).

#### ***Differential Teacher Expectations***

Equally important are the differential expectations teachers hold for various individuals in the same classroom and the differential treatment practices that sometimes accompany these expectations. These person-specific expectations may be one of the most direct social influences on students' feelings of competence in classrooms. The research indicates that teacher-expectancy effects are mediated by the ways in which teachers interact with the students for whom they have high versus low expectations (Brophy, 1985; Eccles-Parsons et al., 1983; Rosenthal, 1974; Weinstein, 1989). Whether the effects are positive or negative depends on the exact nature of these interactions. For example, a teacher can respond to low expectation by providing the kinds of help and structure that increase the student's sense of competence and ability to master the material being presented. Alternatively, the teacher can respond in ways that communicate low expectations and little hope that the student will be able to master the material. In the latter case, the students' own sense of competence should decrease and the student should disengage from the classroom's learning agenda as much as is possible. Teachers' expectations for individual students are directly related to how well the student has done in the past (Jussim, Eccles, & Madon, 1996). What is critical is how these perceptions translate into the teachers' actual behavioral interactions with each of the students in the class.

A great deal of this work has focused on differential treatment related to gender, racial/ethnic group, and/or social class. There are small but fairly consistent negative effects of low teacher expectations on girls (for math and science), on minority children (for all subject areas), and on children from lower social class family backgrounds (again, for all subject areas; see Baron, Tom, & Cooper, 1985; Eccles & Wigfield, 1985; Ferguson, 1998; Jussim et al., 1996).

#### ***Teacher-Student Relationships***

Many researchers have stressed the importance of human relationships for human development; the clearest exemplars of this view in the motivation field are self-determination theorists, who posit relatedness as a basic human need (Baumeister & Leary, 1995; R. M. Ryan & Deci, 2002). Consistent with these suggestions, there is strong evidence for the importance of positive teacher-student relationships and a sense of belonging for children's development in school (L. H. Anderman, 1999; Furrer & Skinner, 2003; Lynch & Cicchetti, 1997;

Wentzel, 2002a). Teachers who are trusting, caring, and respectful of students provide the kind of social-emotional support adolescents need to approach, engage, and persist on academic learning tasks and to develop positive achievement-related self-perceptions and values, high self-esteem, and a sense of belonging and emotional comfort at school (Eccles et al., 1998; C. Goodnow, 1993; Midgley et al., 1989; Roeser & Eccles, 2000; Roeser, Midgley, & Urdan, 1996). In addition, teachers represent one stable source of adult models and mentors for children in a highly complex society. Teachers can provide guidance and assistance when social-emotional or academic problems arise, and they may be particularly important in promoting developmental competence when conditions in the family and neighborhood do not (Eccles et al., 1998; Lord et al., 1994; Simmons & Blyth, 1987).

### ***Classroom Management***

Work related to classroom management focuses on two general issues: (1) orderliness/predictability and (2) control/autonomy. We focus on the latter because issues of autonomy are so important to student motivation in this culture. Many researchers believe that classroom practices that support student autonomy are critical for fostering intrinsic motivation to learn and for supporting socioemotional development during childhood and adolescence (Deci & Ryan, 1985; Grolnick et al., 2002). Support for this hypothesis has been found in both laboratory and field-based studies (Deci & Ryan, 1985; Grolnick & Ryan, 1987). However, it is also critical that the teacher supports student autonomy in a context of adequate structure and orderliness (Skinner & Belmont, 1993). This issue is complicated by the fact that the right balance between adult-guided structure and opportunities for student autonomy changes as the students mature: Older students desire more opportunities for autonomy and less adult-controlled structure. To the extent that the students do not experience these changes in the balance between structure and opportunities for autonomy as they pass through kindergarten to 12th grade, their school motivation should decline as they get older.

### ***The Nature of Academic Work***

Many researchers believe that the meaningfulness of the academic work influences sustained attention, high investment of cognitive and affective resources in learning, and strong identification with educational goals and aims (NRC, 2004). In general, research supports this hypothesis: For example, students' reports of high levels of

boredom in school, low interest, and perceived irrelevance of the curriculum are associated with poor attention, diminished achievement, disengagement, and finally, alienation from school (e.g., Jackson & Davis, 2000; NRC, 2004; Roeser, Eccles, & Strobel, 1998; Roeser, Strobel, & Quihuis, 2002). Unfortunately, evidence from several different perspectives suggests that the curriculum to which most students are exposed is often not particularly meaningful from either a cultural or a developmental perspective. Several researchers suggest that the disconnect of traditional curricula from the experiences of several cultural groups can explain the alienation of some group members from the educational process, sometimes leading to school drop out (Dehyle & LeCompte, 1999; Fordham & Ogbu, 1986; Sheets & Hollins, 1999; Valencia, 1991). There is also a disconnect between increases in students' cognitive sophistication, life experiences, and identity needs and the nature of the curriculum as students move from the elementary into the secondary school years (Jackson & Davis, 2000; V. E. Lee & Smith, 2001; NRC, 2004). As one indication of this, middle school students report higher rates of boredom than elementary school students when doing schoolwork, especially passive work (e.g., listening to lectures), especially in social studies, math, and science (Larson & Richards, 1991). This could lead to some of the apathy problems discussed earlier.

### ***Integrated Approaches to Within-Classroom Experiences***

We have seen an increase over the past 20 years in studies that look at multiple aspects of the classroom simultaneously. During the past 8 years, this approach, in contrast to looking at single classroom or teacher characteristics one at a time, has predominated in keeping with our increasingly integrated view of motivation. In this section, we provide examples of this more integrated approach.

Rosenholtz and Simpson (1984) hypothesized that individualized versus whole group instruction, ability grouping practices, and the relatively public versus private nature of feedback work together to create a classroom environment that fundamentally shapes children's school motivation. Specifically, they argued that these practices make ability differences salient and thereby undermine motivation, particularly of low-achieving students, by increasing the salience of extrinsic motivators and ego-focused learning goals. Such motivational orientations are hypothesized to lead to greater incidence of social comparison behaviors and to increased

perception of one's abilities as fixed entities rather than malleable ones. Mac Iver (1987) provided support for some of these predictions. More recently, the work of Midgley, Maehr, and their colleagues has shown that school reform efforts designed to reduce these types of classroom practices, particularly those associated with socially comparative feedback and reward systems, and teachers' use of competitive motivational strategies have positive consequences for adolescents' academic motivation, persistence on difficult learning tasks, and socioemotional development (Maehr & Midgley, 1996; Midgley, 2002).

Drawing on similar insights from different theoretical traditions, Guthrie, Wigfield, and their colleagues developed an instructional program in reading (Concept Oriented Reading Instruction—CORI) focused on enhancing students' reading motivation along with their reading comprehension. The program integrates instruction in reading and science and is based in part on principles derived from self-determination theory, self-efficacy theory, and expectancy-value theory (Wigfield & Tonks, 2004). Teachers work to enhance students' motivation by providing content goals for their learning and by having students engage in hands-on activities in science that tie to the content goals. Students have a variety of interesting texts in their classrooms that tie directly to the hands-on activities and content goals. They are given autonomy with respect to which books to read, which questions to address, and the nature of the projects that they do. Students also collaborate extensively with each other (Guthrie, Wigfield, & Perencevich, 2004). Guthrie, Wigfield, Barbosa, et al. (2004) found that CORI students surpassed students experiencing a cognitively based strategy instruction reading program in both reading motivation and reading comprehension. The more general implication of these results is that when teachers utilize teaching practices known to enhance student motivation, their motivation does indeed grow.

### *Gender Differences in Classroom Experiences*

Research on gender differences in achievement is another example of an attempt to identify a broad set of classroom characteristics that influence students' motivation; due to space limitations we discuss the example of gender differences in interest in math, physical science, and engineering (see Wigfield, Byrnes, & Eccles, in press, for a more detailed review). Courses in these subject areas are often taught in a manner that females

find either boring, irrelevant to their interests, or threatening (Eccles, 1989; Hoffmann & Haeussler, 1995). Females respond more positively to math and science instruction when it is taught in a cooperative or individualized manner rather than a competitive manner, when it is taught from an applied/person centered perspective rather than a theoretical/abstract perspective, when it is taught using a hands-on approach rather than a book-learning approach, when the teacher avoids sexism in its many subtle forms, and when the examples used to teach general concepts reflect both stereotypically female and male interests (e.g., using the heart as an illustration of the principles associated with pumps). The reason often given for these effects is the fit of the teaching style and format with females' values, goals, motivational orientation, and learning styles (see Eccles, 1989; Krapp, Hidi, & Renninger, 1992). Interestingly, more males are also motivated by these same approaches suggesting that these characteristics fit well with a broad range of human needs.

### *Experiences of Racial/Ethnic Discrimination in Classrooms*

Researchers interested in the relatively poor academic performance of children from some ethnic/racial groups have suggested another classroom level experience as critical for academic motivation and achievement: experiences of racial/ethnic discrimination (Fordham & Ogbu, 1986; Garcia Coll et al., 1996; Roeser et al., 1998; Ruggiero & Taylor, 1995; Taylor et al., 1994; Wong, Eccles, & Sameroff, 2003). Whereas elementary school-aged children may lack the requisite social understandings and cognitive skills to judge discrimination experiences (though not always—see Quintana & Vera, 1999), and may also have too little life exposure to such incidents to make them impactful; beginning in early adolescence, young people are more likely to say they have experienced discrimination, and these experiences are negatively associated with young people's mental health and, sometimes, their motivation in school (Quintana & Vera, 1999; Roeser et al., 1998; Szalacha et al., 2003).

Two types of discrimination have been discussed: (1) anticipation of future discrimination in the labor market, which might be seen as undermining the long-term benefits of education (Fordham & Ogbu, 1986); and (2) the impact of daily experiences of discrimination on one's mental health and academic motivation (Wong et al., 2003). Wong et al. found that anticipated future

discrimination leads to increases in African American youth's motivation to do well in school, which in turn leads to increases in academic performance. In this sample, anticipated future discrimination appeared to motivate the youth to do their very best so that they would be maximally equipped to deal with future discrimination (Eccles, 2004). In contrast, daily experiences of racial discrimination from their peers and teachers led to declines in school engagement and confidence in one's academic competence and grades, along with increases in depression and anger. In a study of Asian, Mexican, Central and South American immigrant high school students growing up in major metropolitan areas of the United States, Portes and Rumbaut (2001) found that a majority of youth in their sample reported feeling discriminated at school and in other settings. The major sources of this perceived discrimination were White classmates, teachers, and neighbors. Such experiences were associated with greater feelings of depression among the youth. In a sample of Mexican American high school students in California, perceived discrimination in school was found to have a strong, negative multivariate relation to school belonging (Roeser, 2004b).

Wong et al. (2003) also found that a strong, positive African American social identity helped to buffer these negative effects. These results suggest a possible buffering effect of ethnic identity on the potential debilitating effects of perceived discrimination, perhaps because a strong connection to one's ethnic group provides a context of shared meaning around issues of discrimination that assist group members in defusing its potential negative impact on the self and therefore, on motivation to succeed (Szalacha et al., 2003).

It is also critical in this discussion to consider the quality of the educational institutions that serve many of these youth. Thirty-seven percent of African American youth and 32% of Hispanic youth, compared to 5% of European American and 22% of Asian youth, are enrolled in the 47 largest city school districts in this country; in addition, African American and Latino youth attend some of the poorest school districts in this country. Twenty-eight percent of the youth enrolled in city schools live in poverty and 55% are eligible for free or reduced cost lunch, suggesting that class may be as important (or more important) as race in the differences that emerge. Teachers in these schools report feeling less safe than teachers in other school districts, dropout rates are the highest, and achievement levels at all grades are the lowest (Council of the Great City Schools,

1992). Finally, schools that serve these populations are less likely than schools serving more advantaged populations to offer either high quality remedial services or advanced courses and courses that facilitate the acquisition of higher order thinking skills and active learning strategies. Even children who are extremely motivated may find it difficult to perform well under these educational circumstances. These facts highlight the importance of focusing on the conjoint influences that poverty, discrimination, and debilitating work conditions for (often under qualified) teachers can have on the educational motivation, achievement, and attainments of African and Latin American youth.

### **School Level Characteristics and Student Motivation**

Researchers suggest that variations at the school level in the climate and general expectations regarding student potential affect the development of both teachers and students in very fundamental ways (e.g., Bandura, 1997; Bryk, Lee, & Holland, 1993; Darling-Hammond, 1997; V. E. Lee & Smith, 2001; Mac Iver, Reuman, & Main, 1995; NRC, 2004). For example, Bryk et al. (1993) pointed out how the culture in Catholic schools is fundamentally different from the culture in most public schools in ways that positively affect academic motivation and achievement. This culture (school climate) values academics, has high expectations that all children can learn, and affirms the belief that the business of school is learning. Similarly, V. E. Lee and Smith (2001) showed that between-school differences in teachers' sense of their own personal efficacy as well as their confidence in the general ability of the teachers at their school to teach all students accounted, in part, for between-school differences in adolescents' high school performance and motivation. Finally, Maehr, Midgley, and their colleagues have argued that a school-level emphasis on different achievement goals creates a school psychological environment that affects students' academic beliefs, affect, and behavior (e.g., Maehr & Midgley, 1996; Midgley, 2002). For example, because schools' use of public honor rolls and assemblies for the highest achieving students, class rankings on report cards, and differential curricular offerings for students of various ability levels make relative ability, competition, and social comparison salient; these practices can create a school-level ability rather than mastery/task focus. In contrast, schools can promote a school-level

focus on discovery, effort and improvement, and academic mastery by focusing school-wide recognition efforts on academic effort and improvement as well as on a wide range of competencies that include as many students as possible and by implementing practices that emphasize learning and task mastery such as block scheduling, interdisciplinary curricular teams, and cooperative learning (see also Finn, 1989; Figueira-McDonough, 1986; Roeser et al., 1998).

### *Academic Tracks/Curricular Differentiation*

Curricular tracking (e.g., college track course sequences versus general or vocational education sequences) is another important school-level contextual feature that is quite common in secondary schools (Oakes, Gamoran, & Page, 1992). Differentiated curricular tracking influences adolescents' school experiences in two important ways: First, tracking determines the quality and kinds of opportunities to learn each student receives (Oakes et al., 1992); second, it determines exposure to different peers and thus, to a certain degree, the nature of social relationships that youth form in school (Fuligni, Eccles, & Barber, 1995).

Despite years of research on the impact of tracking practices, few strong and definitive answers have emerged. The results vary depending on the outcome assessed, the group studied, the length of the study, the control groups used for comparison, and the specific nature of the context in which these practices are manifest. The situation is complicated by the fact that conflicting hypotheses about the likely direction and the magnitude of the effect emerge depending on the theoretical lens one uses to evaluate the practice. The best justification for these practices derives from a person-environment fit perspective. Students are more motivated to learn if the material can be adapted to their current competence level. There is some evidence consistent with this perspective for children placed in high ability classrooms, high within-class ability groups, and college tracks (Fuligni et al., 1995; Kulik & Kulik, 1987; Pallas et al., 1994). The results for adolescents placed in low ability and noncollege tracks do not confirm this hypothesis. By and large, when long-term effects are found for this group of students, they are negative primarily because these adolescents are typically provided with inferior educational experience and support (Dreeban & Barr, 1988; Oakes et al., 1992; Pallas et al., 1994). Low track placement is related to poor attitudes toward school, feelings of incompetence, and problem behaviors both in

school (e.g., nonattendance, crime, misconduct) and in the broader community (e.g., drug use, arrests) as well as to educational attainments (Oakes et al., 1992).

Yet another way to think about the impact of ability grouping on development is by its impact on peer groups: Between-classroom ability grouping and curricular differentiation promotes continuity of contact among adolescents with similar levels of achievement and engagement with school. For those doing poorly in school, such practices can structure and promote friendships among students who are similarly alienated from school and are more likely to engage in risky or delinquent behaviors (Dryfoos, 1990). The "collecting" of adolescents with poor achievement or adjustment histories also places additional burdens on teachers who teach these classes (Oakes et al., 1992).

Another important and controversial aspect of curriculum tracking involves how students get placed in different classes and how difficult it is for students to move between class levels as their academic needs and competencies change once initial placements have been made. These issues are important both early in a child's school career (e.g., Pallas et al., 1994) and later in adolescence when course placement is linked directly to the kinds of educational options that are available to the student after high school. Minority youth, particularly African American and Hispanic boys, are more likely to be assigned to low ability classes and noncollege bound curricular tracks than other groups; furthermore, many of these youth were sufficiently competent to be placed in higher ability level classes (Dornbusch, 1994; Oakes et al., 1992).

### *Extracurricular Activities*

Schools differ in the extent to which they provide a variety of extracurricular activities for their students. Research on extracurricular activities has documented a positive link between adolescents' extracurricular activities and high school GPA, strong school engagement, and high educational aspirations (see Eccles & Barber, 1999; Holland & Andre, 1987). This work has also documented the protective value of extracurricular activity participation in reducing dropout rates as well as involvement in delinquent and other risky behaviors (e.g., Mahoney & Cairns, 1997; McNeal, 1995). Participation in sports, in particular, has been linked to lower likelihood of school dropout and higher rates of college attendance (Deeter, 1990; Eccles & Barber, 1999; McNeal, 1995), especially among low achieving and blue-collar

male athletes (Holland & Andre, 1987). These effects likely reflect the impact of extracurricular activities on students' sense of belonging in the school, as well as on the increased likelihood of participation leading to good relationships with particular teachers.

### **School Transitions and Motivational Development**

We reviewed earlier normative developmental work showing that many aspects of children's motivation decline as they go through school. These declines are most marked as children make major school transitions (e.g., from elementary school into middle or junior high school and then again into high school). In this section, we briefly review the research focused on explaining these developmental declines.

#### ***Transition into and through Elementary School***

Entrance into kindergarten and then the transition from kindergarten to first grade introduces several systematic changes in children's social worlds (see Pianta, Rimm-Kaufman, & Cox, 1999). First, classes are age stratified, making within-age ability social comparison much easier. Second, formal evaluations of competence by "experts" begin. Third, formal ability grouping begins usually with reading group assignment. Fourth, peers have the opportunity to play a much more constant and salient role in children's lives. Each of these changes should impact children's motivational development (Pianta et al., 1999). Unfortunately, very little longitudinal research has focused on this transition. We do know that many of the gains made in high quality preschool programs for children living in poverty can be lost as the children move into elementary school, although there are notable exceptions (Ramey & Ramey, 1999). In addition, we know that early school transitions are changing and will continue to change during this decade, with a stronger focus on academic aspects of schooling beginning earlier and earlier (Pianta & Cox, 1999). These transitions are happening earlier as more and more students begin school at earlier ages. In addition, the population of children is getting increasingly diverse and many public schools (particularly in urban and rural settings) now serve large groups of children living in poverty. The impact of these kinds of changes, and changes stemming from the No Child Left Behind Act, on students' motivation needs to be studied.

Instead, most of the research on the early elementary school years has focused on individual differences in the link between children's early school experiences and their subsequent development. This research suggests significant long-term consequences of children's experiences in the early school years, particularly experiences associated with ability grouping and within-class differential teacher treatment. For example, teachers use a variety of information to assign first graders to reading groups including temperamental characteristics like interest and persistence, race, gender, and social class (e.g., K. L. Alexander, Dauber, & Entwisle, 1993; Brophy & Good, 1974). K. L. Alexander et al. (1993) demonstrated that differences in first grade reading group placement and teacher-student interactions predict subsequent motivation and achievement even after controlling for initial differences in reading competence. Furthermore, these effects are mediated by both differential instruction and the amplifying impact of ability group placement on parents' and teachers' views of the children's abilities, talents, and motivation (Pallas et al., 1994).

These findings are important because they point to early school years as critical for subsequent school achievement. They are also important because they bring attention to the potential role of elementary schools in reproducing the economic stratification that exists in our society. Elementary schools are located in the communities they serve; thus, there can be great variations in the populations different schools serve, as well as in the curriculum offered, and the resources available, at different schools. Interestingly, in analyses of data from their Baltimore School Study, Entwisle and Alexander (1999) found that low SES and high SES children progressed equally during the school year when school was in session. Differences in performance emerged over the summer when school is not in session, with the low SES children losing more ground in what they are able to do over the summer than the high SES children.

We reviewed earlier the research showing that many children's motivation declines during the elementary school years. Researchers doing this work suggest that these changes reflect a combination of cognitive changes in the children and contextual changes in the classrooms (although more longitudinal studies are needed to assess these explanations fully). More specifically, children's ability to use social comparison information increases over the elementary school years making it easier for them to compare

their relative ability with that other children (Ruble, 1983). This change should lead some children to lower their confidence in their own ability to master the school material (Eccles, 1984). Similarly, it is possible that teachers increase their use of social comparative information and their emphasis on ability as entity based rather than incremental. The increasing emphases as children go through school on evaluation and performance outcomes also likely play a strong role (Maehr & Midgley, 1996). More work is needed to test these hypotheses.

### *Transitions from Elementary School into Secondary School*

As was true in 1998, most of the research on secondary school transition effects has focused on the transition to middle or junior high school. But more work is coming out on the transition into high school. Because the principles underlying the declines in students' motivation are quite similar across these two transitions, we focus on these principles rather than the specific grade levels at which the transitions are made.

As noted earlier, there are substantial declines in academic motivation and achievement across the upper elementary and secondary school years, including changes in grades, interest in school, perceptions of competence in different areas, and increases in performance goals at the expense of mastery goals (see Eccles et al., 1998; B. Schneider & Coleman, 1993, for reviews). These changes are particularly large for students who are doing poorly (either emotionally or academically) in school (Lord et al., 1984). These changes are also likely to be especially problematic for children from low SES communities and families, children who find the school curriculum particularly meaningless and children who find the school climate particularly unsupportive and uncomfortable.

In explaining such changes, Eccles et al. (1998) discussed how the multiple changes that occur during this time period (puberty, school transitions, changing relations with parents, increasing cognitive maturity, increasing concern with identity, increasing sexuality and heterosociality, and increasing focus on peer relationships) likely have an impact on students' motivation and achievement. They also discussed how differences in school environments between elementary and secondary schools could contribute to these changes (see also Eccles & Roeser, 2003; NRC, 2004; Wigfield & Eccles, 2002b; Wigfield & Tonks, 2002). Traditional secondary schools differ structurally in important ways from ele-

mentary schools. Most secondary schools are substantially larger than elementary schools. As a result, students' friendship networks often are disrupted as they attend classes with students from several different schools. In addition, students are likely to feel more anonymous and alienated because of the large size of many secondary schools. Finally, the opportunity to participate in and play leadership roles in school activities often decline over these school transitions due to the limited number of slots in such niches and the increasing size of the student body. These kinds of changes should affect the students' sense of belonging as well as their sense of social competence.

The nature of instruction also changes: Secondary school instruction is organized and taught departmentally—making it likely that secondary school teachers teach several different groups of students each day and are unlikely to teach any particular students for more than 1 year. This departmental structure can create a number of difficulties for students. First, the curriculum often is not integrated across different subjects. Second, students typically have several teachers each day with little opportunity to interact with any one teacher on any dimension except the academic content of what is being taught and disciplinary issues. As a result, the likelihood of students and teachers forming close, supportive bonds is much less in secondary than in elementary schools. This result can be problematic for a number of reasons. First, it could reduce the likelihood that a teacher will be able to identify whether a particular student is having problems and make an appropriate referral recommendation. Second, it could reduce the likelihood that a teacher will have time to provide adequate instructional supports for students who need extra academic help. Both of these changes are likely to undermine low-performing students' sense of competence and sense of belonging.

Finally, grading systems are more likely to be based on social comparative performance, ability-level tracking via curricular tracking is common, and teachers are more likely to hold entity, rather than incremental, views of ability differences (Eccles & Midgley, 1989; Wigfield, Eccles, & Pintrich, 1996). These characteristics, in turn, are likely to lead to an increase in performance rather than mastery goal focus in the classroom and the school building. As noted earlier, these changes are likely to undermine low performing students' sense of competence. Because the nature of these changes is so dramatic at the shift from elementary school to mid-

dle or junior high school, it is not surprising that there is a major decline in motivation for many students as they make this transition.

Recent work on the transition to high school suggests that similar changes occur at this transition (V. E. Lee & Smith, 2001; Mac Iver et al., 1995; NRC, 2004; Wehlage, Rutter, Smith, Lesko, & Fernandez, 1989). For example, high schools are typically even larger and more bureaucratic than middle and junior high schools. V. E. Lee and Smith (2001) provide numerous examples that the sense of community among teachers and students is undermined by the size and bureaucratic structure of most high schools. There is little opportunity for students and teachers to get to know each other and, likely as a consequence, there is distrust between them and little attachment to a common set of goals and values. There is also little opportunity for the students to form mentorlike relationships with the teachers and there is little effort to make instruction meaningful to the students. Such environments are likely to undermine the motivation and involvement of many students, especially those not doing particularly well academically or who are alienated from the values of the adults in the high school.

Furthermore, research based on both teacher and student reports shows that schools become more socially comparative and competitive in orientation as students progress from elementary to middle to high school (Roeser et al., 2002). The coincidence of declining social support and increased social comparison and competition at both the middle and high school levels likely contribute to some adolescents' decisions, those who are already on the margins of the school community, to withdraw from school prior to graduation. For example, Fine (1991) documented how these kinds of secondary school practices cumulate to drive out students who are not doing very well academically. In a large study of students in the Chicago public schools, Roderick and Camburn (1999) showed how failure rates increase dramatically after students made the transition to high school (this was particularly true for minority students), and how early failures in high school strongly predict later poor performance. Other studies of ethnic minority youth document the negative impact of alienating and noninclusive high school practices on school engagement and achievement of students of color (e.g., Darling-Hammond, 1997; Deyhle & LeCompte, 1999; Ferguson, 1998; Jackson & Davis, 2000; Taylor et al., 1994; Valencia, 1991). More work is needed on this transition point.

### *School Experiences as Related to Ethnic and Cultural Identity Formation*

As noted earlier, typical secondary school practices may be particularly problematic for adolescents from cultural minority groups. Adolescence is the prime developmental period for identity development. A great deal of work in the past 10 to 15 years has focused on the potential disconnect between what goes on in typical American secondary schools and the goals, values, and experiences of cultural minority groups in the United States (see Meece & Kurtes-Costes, 2001; Okagaki, 2001).

Much of this work has focused on how individuals from different ethnic and cultural groups navigate the sometimes disparate social worlds of home and school by "managing" the relation of their in-school identity with broader aspects of their social identities (e.g., Roeser et al., 2003). Perhaps the most well-known view of how members of different ethnic minorities manage, or rather fail to manage, aspects of their ethnic/racial and student identities is that of John Ogbu and Signthia Fordham, some of whose work was reviewed earlier. These authors highlighted the identity conflicts that members of particular ethnic minority groups may experience between ethnic loyalty and school identification. Another view of how members of traditionally disenfranchised groups address these kinds of potential identity conflicts comes from scholars such as Oetting and Beauvais (1991) and Lafromboise, Coleman, and Gerton (1993). These authors have pointed to the strategies that members of nonmajority groups use to develop bicultural identities—those that integrate a sense of ethnic pride and engagement with activities of the majority culture in a complementary rather than conflictual way (Phinney & Devich-Navarro, 1997). This work underscores how some members of stigmatized ethnic minority groups integrate their sense of ethnic pride and their pursuit of success in school, with the presumption that success in school is defined as a "majority" activity. In this instance, neither ethnic loyalty nor commitment to education "gives way" to the other. Evidence for the existence of such subgroups among Mexican American youth, for example, has been found at the middle school (Roeser et al., 2003) and high school level (Matute-Bianchi, 1986).

The emerging literature on social identities and academic identity among ethnic minorities (see Wigfield & Wagner, 2005) raises several possibilities concerning what Roeser and his colleagues (2003) have called "school identity configurations." Young people from

**TABLE 15.1 Recommendations for Restructuring Middle Grades Schools**

Recommendations from the Carnegie Council on Adolescent Development
1. Turn large schools into smaller learning communities.
2. All students should receive a common core of high-level knowledge.
3. All students should be given the opportunity to succeed.
4. Teachers and school administrators should have decision-making authority.
5. Middle grades teachers should receive special preparation for working with early adolescents.
6. Early adolescents' fitness and health should be a strong focus of middle school education.
7. Families should be involved in middle schools.
8. School-community connections need to be established.
Recommendations from the National Middle School Association
1. Middle school educators should be knowledgeable about young adolescents.
2. The middle school curriculum should be responsive to the needs of young adolescents.
3. There should be a range of organizational arrangements in middle schools.
4. Instructional strategies should be varied.
5. There should be full exploratory programs in different schools.
6. Comprehensive advising and counseling should be provided for all students.
7. All students should make continual progress.
8. Evaluation procedures should be compatible with the nature of young adolescents.
9. Teachers should have time for cooperative planning.
10. Each middle school should have a positive school climate.

various nonmajority ethnic groups may integrate their sense of ethnic pride and school commitment in the ways described by those who study biculturalism. Others may manage different facets of identities inside and outside of school by code switching in the ways that scholars such as Fordham (1988) have proposed, whereas some individuals who have difficulty managing different dimensions of identity may show oppositional patterns of disengagement as described by Fordham and Ogbu (1986). However, such conflicts are not confined to ethnic minority youth but rather are a broader phenomena characteristic of many adolescents (Arroyo & Zigler, 1995; Roeser et al., 2003).

#### ***Middle School Reform Efforts and Student Motivation***

Based in part on the research just reviewed, proposals by middle schools experts, and the *Turning Points* report written by the Carnegie Council on Adolescent Development, middle school reform has become very popular (see Carnegie Foundation, 1989; Jackson & Davis, 2000;

Midgley & Edelin, 1998). There is growing consensus about what kinds of changes should be made in middle grades schools (Lipsitz, Mizell, Jackson, & Austin, 1997). One structural change adopted in many school districts has been to move the transition to middle school from after to before sixth grade. However, this change on its own accomplishes little and often simply moves the transitional problems 1 year earlier in the students' development. What is more important is changing school organization and instructional practices in systematic ways (Mac Iver & Epstein, 1993). Both the Carnegie Council on Adolescent Development and the National Middle Schools Association have made recommendations for how middle schools should be changed; a summary of their recommendations is presented in Table 15.1. As can be seen in the table, there is much overlap between these recommendations. The broadest goal of these recommendations is to provide developmentally appropriate education for early adolescents.

There are a number of important ways in which these recommendations have been implemented in different middle schools. One is replacing departmentalized curriculum structures with teams of teachers working with the same group of students. This practice allows groups of teachers to spend more time with the same group of adolescents, thus getting to know them better. It also allows for greater integration across the curriculum. Teachers who serve as advisors and counselors have become more prevalent, so that adolescents can develop closer relationships with their teachers. To create smaller learning communities in often-large middle schools, "schools within schools" have been created, in part through the teaming approach just discussed. This is particularly likely to occur for the youngest group in a middle school, whether they are fifth graders, sixth graders, or seventh graders. Cooperative learning practices are used more frequently, in part to reduce the use of ability grouping or tracking.

Lipsitz and her colleagues (1997) discussed middle school reform efforts across the country. They focused in particular on three sets of middle schools in Illinois, Michigan, and Indiana in which reform efforts in line with the recommendations included in Table 15.1 have been undertaken in meaningful ways. Felner et al. (1997) reported systematic evaluations of the schools in the Illinois network. They conducted longitudinal studies in schools implementing fully the recommendations from the Carnegie Council, comparing them with schools implementing the recommendations to a degree

and not at all. The comparison schools are matched carefully on demographic and other characteristics. Felner et al. obtained measures of students' achievement, school attitudes, and behavior problems. Preliminary analyses indicate that schools in which the implementation has been fullest have higher achieving students. Students in these schools report higher self-esteem and fewer worries about bad things happening to them in schools; the teachers report fewer behavior problems. These results provide encouraging support for the efficacy of the reform efforts. One crucial point made by Felner et al. is that comprehensive reform is needed. Schools in which one or two of the recommendations have been implemented, or schools in which the implementation of several recommendations has proceeded slowly, have not been as successful. Unfortunately, as noted earlier, many schools are just beginning to implement change, or are doing so selectively.

There is not yet a great deal of information about how reform efforts have affected students' motivation. Felner and his colleagues measured self-esteem but not the different aspects of motivation we have discussed in this chapter. Mac Iver and his colleagues began a middle school reform effort (Mac Iver & Plank, 1997; Mac Iver, Young, & Washburn, 2002) focused on schools serving early adolescents who live in high poverty areas. The program involves the implementation of many of the recommendations discussed in this section: detracking the schools, using cooperative learning extensively, team teaching, offering a challenging core curriculum (including algebra) to all students, and providing advising services. Preliminary results for both achievement and motivation outcomes are encouraging.

As mentioned earlier, Maehr and Midgley (1996) used goal theory to work with teachers and administrators to change the culture organization and climate of a middle school and an elementary school in a city in Michigan. The school-university team worked extensively to restructure the school toward a focus on mastery goal; they spent 3 years in each school. At the middle school, they focused on creating teams of teachers, "schools within the school," lessening the use of ability grouping practices, and changing the student recognition patterns so that not just the "honor roll" students were recognized. They also worked to loosen the rigid bell schedule so that longer class periods were sometimes possible. Changing the school culture in the middle school was very difficult due to some teachers' (especially the math teachers) resistance to change, par-

ticularly with respect to doing away with grouping, difficulties in adjusting the rigid middle school bell schedule to accommodate teaming and flexible class scheduling, and parents' objections that their high-achieving students did not receive enough recognition. However, despite these difficulties, the changes had positive effects on students' motivation (E. M. Anderman, Maehr, & Midgley, 1999).

In contrast, much less work has been done on high school reform effort and the results of this work are less consistent (NRC, 2004). Reform efforts have followed similar principles aimed at creating schools that better meet the competence, belonging, autonomy, and mattering needs of the adolescent students. As is true for the middle school reform efforts, when these principles are well implemented, improvements in students' motivation, school engagement, and academic performance are obtained (NRC, 2004). But successfully implementing these kinds of changes has proven to be very difficult at the high school level.

## THE SOCIALIZATION OF MOTIVATION: ROLES OF PEERS

How might peers affect motivation and achievement? We focus on four possible links: (1) the role of social comparison in self-evaluation, (2) the relation between social competence and school motivation/achievement, (3) peers as co-learners, and (4) the reinforcing and socializing mechanism in peer groups.

### Social Comparison and Self-Evaluation

Given the importance of ability self-concepts in all motivational theories, understanding the role that peers play in self-evaluation is critical to our understanding of motivation. Researchers interested in social comparison have addressed this issue, focusing specifically on age-related increases in children's use of social comparison information in forming perceptions of their own abilities. In general, older children and adolescents use social comparison more often and more accurately in forming their own self-evaluations than younger children (e.g., Ruble, 1994). Ruble (1994) also suggested that the use of social comparison may increase during transitional phases in a child's life like the school transitions discussed earlier. Together these transitional processes and the age-related increases in the use of social comparison make adolescents exceptionally

vulnerable to the motivational consequences of such comparisons (Eccles, Midgley, et al., 1993; Fuligni et al., 1995). Cultural background (either in terms of gender or ethnic group) also likely influences the extent and the type of social comparison. Finally, as noted earlier, social comparison processes are very sensitive to social context, particularly those linked to the types of classroom experiences linked to performance versus mastery orientation.

### **Social Competence and Motivation**

Many studies document the positive association of good social skills with both better performance and higher motivation in school (e.g., Asher & Coie, 1990; Juvonen & Wentzel, 1996; Wentzel, 1998). Further, social competence and social support can help ease school transitions (Birch & Ladd, 1996; Lord et al., 1994; Rubin, Bukowski, & Parker, 1998; Rubin, Coplan, Chen, Buskirk, & Wojslawowicz, 2005). The exact mechanisms underlying these associations are just beginning to be understood. Some suggest that the association represents the influence of some underlying form of inherited intelligence or temperament/motivational orientation that facilitates the acquisition of both social and academic competence (e.g., Martin, Drew, Gaddis, & Moseley, 1988; Wentzel, 1991b). Others focus on the link between social support and mental health: Children should be able to focus more of their attention on learning if they feel socially supported and well-liked by both their peers and the adults in their learning context and if they feel that they belong (Furrer & Skinner, 2003; C. Goodnow, 1993; Lynch & Cicchetti, 1997; Roeser et al., 1996; Sage & Kindermann, 1999). Well-liked children may also place more value on learning in such a context.

### **Peers as Co-Learners**

The extensive work on the advantages of cooperative learning provides another link between peers and motivation. This work suggests that doing learning activities in a social context is usually more fun and, thus, more intrinsically interesting (Slavin, 1995; Stevens & Slavin, 1995). Peers also help each other understand and learn the material through group discussion, sharing of resources, modeling academic skills, and interpreting and clarifying the tasks for each other (Schunk, 1987). Each of these characteristics should influence achievement through its impact on children's expectations for suc-

cess, their valuing of the activity, and their focus on learning rather than performance goals.

### **Peer Group Influences**

Much of the classic work on peer influences on school achievement focused on the negative effects of peer groups on children's commitment to doing well in school (see Brown, 1990, 2004, for review). More recently, researchers have investigated the specific mechanisms by which peer groups can have either a positive or negative affect on motivation across various activity settings. These researchers document that children cluster together in peer groups sharing similar motivational orientations and activity preferences and that such clustering reinforces and strengthens their existing motivational orientation and activity preferences over time (e.g., Guay, Boivin, & Hodges, 1999; Kindermann, McCollam, & Gibson, 1996; A. M. Ryan, 2001). Altermatt and Pomerantz (2003) found in a study of early adolescents that best friends' report-card grades were similar, as were their beliefs about their competence in different subject areas. In addition, friends had significant (but modest) influences on each others' grades and motivational beliefs across the 2 school years studied. Whether such effects are positive or negative depends on the nature of the peer groups' motivational orientation. High-achieving children who seek out other high achievers as friends develop even more positive academic motivation over time. In contrast, low achievers who join a low-achieving peer group should become even less motivated to do school work and more motivated to engage in other activities more consistent with their peer group's values (see Brown, 2004; Kindermann, 1993; Kindermann et al., 1996).

The role of peer group influence varies across ages, with peers in an especially important role in relation to motivation and achievement during adolescence for two reasons: First, adolescents are more aware of, and concerned about, peer-group acceptance and spend much more unsupervised time with peers groups than younger children (Brown, 2004). Consequently, adolescents should be especially vulnerable to peer group influences on their goals, interests, and values. In addition, however, the potential negative impact of peers may be especially problematic for some adolescents' academic achievement motivation. For example, early adolescents rate social activities as very important and more enjoyable than most other activities, particularly academic

activities (Eccles et al., 1989; Wigfield et al., 1991). Consequently, to the extent that one's peer group devalues academic achievement relative to other goals and activities, the adolescents should shift their focus away from academic pursuits to maintain peer acceptance. Finally, given other changes associated with adolescent development, it is quite likely that a substantial number of adolescents will be recruited into such a peer group. Some of these adolescents will be recruited into gangs—a particularly problematic peer group in terms of antisocial behavior and low school achievement (Battin-Pearson, Thornberry, Hawkins, & Krohn, 1998; NRC, 2004).

Another growing concern about the impact of peers on children's school motivation focuses on bullying and peer violence at school. Fighting increases during the middle school years, and more students are bullied in middle school than in either elementary or high school (Juvonen, Le, Kaganoff, Augustine, & Constant, 2004). Being bullied is associated with many negative developmental outcomes, including loneliness, depression, and social anxiety, as well as lower school performance (Juvonen & Graham, 2001; Juvonen, Nishina, & Graham, 2001). Increasing percentages of both middle and high school students report concerns about their safety in school, which distracts them from their school learning and can lead to motivational disengagement from school (Brand, Felner, Shim, Seitsinger, & Dumas, 2003). Creating safer school environments where bullying and other forms of violence are less likely is an important priority to maximize all students' school engagement and motivation.

## CONCLUSIONS

Research on the development of children's motivation remains vibrant. Many of the same theories that were reviewed in the previous chapter in this *Handbook* continue to be influential, although the influence of some theories has waned, and others grown. Research in these different theoretical traditions is giving us a more complete understanding of the development of motivation across the childhood and adolescent years.

We believe the research since the last edition of this *Handbook* was published has made especially important advances in the following areas. First, we have learned much about contextual influences on motivation and how children's motivation varies across different con-

texts, such as in different kinds of families, and different school contexts. We have long known that motivation is not solely a characteristic of the individual, but the new emphasis on "motivation in context" has brought that point out much more clearly (Hickey & McCaslin, 2001; Urdan, 1999). Further, as we understand better contextual influences in schools and other settings that influence motivation, we are making progress in developing ways to foster the development of children's motivation in these settings (e.g., Guthrie, Wigfield, & Perencevich, 2004; Maehr & Midgley, 1996). Through this intervention work the often-noted declines in children's motivation can be reversed or avoided.

Second, we have learned much about the development of motivation in diverse groups of children in this country and others. Although much remains to be done in this area, motivation researchers increasingly include diverse samples in their work, revising their theories to incorporate culture more clearly in their models, and testing their theories in diverse groups (see the McInerney & Van Etten, 2004 volume for good examples of this work). Following Graham's (1994) call, much of this work is looking at variation *within* different cultural groups, rather than comparisons across groups. This is an important trend because we need to know much more about variation in motivation within different groups rather than how one group's mean level of motivation compares to the mean level of another group.

Third, progress has been made in understanding the relations between motivation, cognition, and self-regulation, which provides us with a more complete picture of children's functioning in different kinds of achievement settings (e.g., Boekaerts et al., 2000; Pintrich, 2003; Wolters, 2003; Zimmerman, 2000). Yet, as Pintrich notes, much work remains to be done on this topic, as there is (potentially) great complexity in these relations. Along with the relations of motivation, cognition, and self-regulation, there has been increasing interest in research on relations between motivation and affect (e.g., Pekrun, 2000; Pintrich, 2003), and we think this work will grow over the next few years. Understanding relations among the different motivational beliefs, values, and goals; cognitive processes; and the regulation of behavior and affect is a major priority for the next several years.

Another important advance over the past 8 years is the growing concern for how motivation constructs are defined, and there are attempts to specify the similarities and differences in related constructs (e.g.,

self-efficacy and expectations for success). A particular example of this is Murphy and Alexander's (2000) article in their special issue of *Contemporary Educational Psychology* devoted to motivational terminology, but others have contributed to these efforts as well (e.g., Bandura, 1997; Pintrich, 2003; Schunk & Pajares, 2002; Wigfield & Eccles, 2000). As motivation terminology becomes increasingly clearly defined, theoretical clarity, and the similarities and differences across different theories, also should be better understood. Indeed, we believe it may be time for greater integration across some of the major theories of motivation rather than a continued proliferation of theories focused primarily on one or two constructs.

Finally, in a chapter for the *Handbook of Child Psychology* we think it important to note that there needs to be more truly developmental work on the nature and development of motivation. Many researchers have focused on individual differences and group differences in motivation, but not always on motivational development. One important developmental issue that needs more attention is how children at different ages understand their own motivational beliefs, values, and goals. The only such belief that has been investigated systematically in this way is children's conceptions of the nature of ability. This work has shown clearly that children have rather different conceptions of ability at different ages, which has many implications for our understanding of how motivation operates at different ages, as well as for how we measure children's sense of ability. Such work has not been done with the other major belief, value, and goal constructs discussed in this chapter, and this work should be undertaken.

There have been important methodological advances that allow us to study the development of motivation in increasingly sophisticated ways. Studies we reviewed earlier by Jacobs et al. (2002), Skinner et al. (1998), and Watt (2004) are good examples, and there are other examples in the literature. These researchers (and others) are using newly developed statistical methods to analyze short- and long-term change in the belief, value, and goal constructs that impact motivation. These researchers also are examining what explains different patterns of change in children's beliefs, values, and goals. Continuing such work will lead to an even better understanding of the *development* of motivation. Coupling such work with investigations into the *processes* involved in motivation's relations to outcomes also will advance the field.

### REFERENCES 1049

The study of adolescence began with Hall's (1904) two-volume work, *Adolescence: Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion, and Education*. Hall's vision blended attention to individual and contextual factors, as well as basic and applied concerns, and this breadth of perspective continues to characterize research on adolescence today. The most prominent line of study, however, has focused on individual attributes as the hallmarks of psychosocial development and on parents as the most significant source of influence. The contemporary vitality of that tradition is evident in the publication of no fewer than

three recent handbook chapters (Collins & Laursen, 2004b; Granic, Dishion, & Hollenstein, 2003; Grotevant, 1998) and other widely cited reviews (e.g., Steinberg, 2001; Steinberg & Silk, 2002) on family influences and parent-child relationships as contexts of adolescent development.

As the twentieth century came to an end, the individualistic orientation and dominance of family influences gradually broadened to include *relational* processes in development (Collins & Laursen, 2004a). Rather than focusing exclusively on outcomes such as achievement, competence, self-esteem, psychopathology and other problems of individual functioning, researchers began to attend to adolescents' abilities for high-quality affiliations, to seek support effectively from others, and to cooperate and collaborate on formal and informal tasks (Collins, Gleason, & Sesma, 1997; Epstein, 1989; Savin-Williams & Berndt, 1990). Researchers also recognized

---

The authors thank the editor of this volume, as well as Willard W. Hartup and Brett Laursen, for helpful comments on earlier versions of this chapter. In addition, we are grateful to Amy Luckner and Jessica Siebenbruner for their assistance in preparation of the manuscript.

that extrafamilial interpersonal relationships contributed significantly to both individual and relational competence in childhood and adolescence (for reviews, see B. Brown, 2004; Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Darling, Hamilton, & Shaver, 2003; Hartup, 1996). Socialization and acculturation increasingly were viewed as occurring in networks of relationships in both proximal (e.g., neighborhood or ethnic communities) and distal (e.g., societal or cultural) contexts (Brewer & Caporael, 1990; Cooper, 1994; Masten et al., 1995).

This more relational orientation has transformed traditional approaches to research on adolescence in two ways. First, it has led to findings that yield a vastly different picture of the social world of adolescents than the prevailing view in the middle decades of the past century (e.g., Allen & Land, 1999; Collins & Laursen, 2004b; Grotevant, 1998). Researchers now recognize that adolescents of different ages differ in their capacities as relationship partners and that social contacts during adolescence differ from those of childhood. Although family relationships remain salient, the proportion of time that adolescents spend with persons outside of the family increases, and these extrafamilial relationships serve many of the same functions that previously were considered the exclusive province of family relationships during childhood (Collins & Laursen, 2004b). Today, research on adolescents' social relationships has been refocused to include interest in interpersonal *transformations* in which the properties and conditions of relationships within and outside of the family change without subverting the bond between parent and child (Collins, 1995).

Second, an increased emphasis on relationships has altered perspectives on the nature and course of psychosocial achievements that long have been regarded as touchstones of adolescent development. One is the development of a sense of *independence*, including both behavioral and emotional autonomy from parents. The other is the development of *interdependence* by forming connections with others in which mutual influence and support can occur. Of these complementary tasks, the former has received the lion's share of empirical and theoretical attention (Collins, 2003; Zimmer-Gembeck & Collins, 2003), probably because of the emphasis in Western culture on attaining abilities for functioning outside of the family of origin. At the same time, experiences in adolescence long have been considered primary

to the process of establishing emotionally intimate relationships with peers and sexual relationships with romantic partners. Increasingly, research is encompassing the facilitating role of both familial and extrafamilial relationships in achieving age-appropriate independence, as well as the formation and maintenance of effective relations with others (for reviews, see Collins, Gleason, et al., 1997; Collins & Laursen, 2004b).

The topic of this chapter is the nature and significance of familial and extrafamilial relationships during adolescence and their role in the development of the competencies associated with independence and interdependence. The chapter begins with a brief overview of research and theory pertaining to three key processes of individual development: (1) biological maturation, (2) cognitive development, and (3) changes in social definitions and expectations. Three sections then examine links between individual development and salient interpersonal contexts. The first of these is an overview of three dominant conceptual perspectives in current research on adolescent interpersonal experiences: (1) ecological models; (2) models of interpersonal interaction and influence; and (3) biosocial models, including evolutionary and behavioral genetics approaches. The second subsection addresses family relationships and extrafamilial relationships as salient interpersonal contexts of adolescent development. Our discussion of extrafamilial contexts emphasizes interpersonal features of peer groups and of close relationships with friends and of romantic interests. The third section on links between relationships and individual development addresses the impact of settings such as schools, workplaces, volunteer activities, leisure pursuits, and neighborhoods on developmentally significant interpersonal experiences. The subsequent section then outlines the role of interpersonal contexts in the development of independence and interdependence. The importance given to these two complementary processes in psychosocial development varies across cultures, and even among subcultural and social-status groups in cultures, and these realities of adolescent development recur throughout the chapter.

The chapter concludes with reflections on current knowledge of the extensive interrelations among the interpersonal and other contexts of contemporary adolescence. A key theme of this part of the chapter is the futility of searching for singular answers to questions about *which* experiences are developmentally optimal

and the potential benefits of attending to more nuanced questions of *how* and *under what conditions* developmentally positive outcomes are likely.

## DEFINING FEATURES OF ADOLESCENCE AND PSYCHOSOCIAL DEVELOPMENT

Two decades ago Hill (1983) proposed three principles that remain fundamental to contemporary views of the period. First, biological, cognitive, and social definitional changes are defining features of adolescent social and personality development. Second, social and personality development in adolescence involves transformations in existing psychological capacities rather than new issues that arise for the first time at adolescence. Third, the impact of biological, cognitive, and social-definitional changes on personality and social development is moderated by the proximal and distal contexts in which these changes occur.

The transitions that form the tacit boundaries of the period—one from childhood into adolescence and one from adolescence into adulthood—have received unequal attention, with far more attention having been devoted to the study of the entrance into adolescence than to the transition out of it. Since the mid-1970s the early (ages 10 to 13) and middle (ages 14 to 17) portions of adolescence have dominated psychologists' interests, while the psychosocial transition between adolescence and adulthood—though of considerable interest to sociologists and anthropologists concerned with educational attainment, labor force participation, and family formation—has been largely ignored. Although several writers (Arnett, 2000; Keniston, 1970) have noted that the transition between adolescence and adulthood has been lengthened in contemporary society, this observation has not yet generated a great deal of empirical research on the psychological implications of this social change.

A full discussion of the specific nature of biological, cognitive, and social definitional changes in adolescence is beyond the scope of this chapter. Comprehensive reviews may be found in Susman and Rogol (2004), with regard to puberty; Keating (2004), with regard to cognitive development; and Modell and Goodman (1990) and Schlegel and Barry (1991), with regard to changes in social status and social definition. In the following subsections, we briefly emphasize some key im-

plications of these changes for psychosocial development and interpersonal relationships.

### Biological Change

Researchers have focused considerable attention on the co-occurrence of changes in psychological functioning and interpersonal relationships and hormonal and somatic changes of puberty. Indeed, the study of puberty and its impact on social and emotional development is one of the oldest and most enduring topics in the field, beginning with the classic studies of early- and late-maturing youth conducted by Jones and associates (M. Jones, 1957, 1965; M. Jones & Bayley, 1950; M. Jones & Mussen, 1958; Mussen & M. Jones, 1957, 1958) and continuing today (e.g., Ge, Brody, Conger, Simons, & Murry, 2002; Ge, Conger, & Elder, 2001; Ge et al., 2003).

Puberty is best understood as a lengthy process that is set in motion long before any external manifestations of biological change are evident (Susman & Rogol, 2004). Recent studies, enabled by advances in measuring and monitoring endocrine and neuroendocrine activity, have illuminated the exceedingly complex hormonal changes associated with the chief physical manifestations of puberty. These include rapid acceleration in height and weight, which is typically referred to as the "adolescent growth spurt," and emergence of secondary sex characteristics (changes in the genitals and breasts; the growth of pubic, facial, and body hair; and the further development of the external sex organs). The endocrinological changes that stimulate these somatic transformations occur across multiple hypothalamic-pituitary-end organ axes—most notably, the hypothalamic-pituitary-gonadal (HPG) and the hypothalamic-pituitary-adrenal (HPA) axes. There is considerable variability in the timing and pace of pubertal maturation, owing to both genetic and environmental factors, with some early-maturing girls showing signs of puberty as early as 7 and some late-maturing boys not displaying any signs of puberty as late as 14. Generally, girls mature approximately 2 years earlier than boys (Eveleth & Tanner, 1990).

There is no simple answer to the question: "How does puberty affect the psychological development and social relationships of the adolescent?" The answer depends on the gender of the adolescent, the particular aspect of puberty in question, the adolescent's pubertal stages, the timing and pace of pubertal change, and the broader

context in which puberty takes place. Studying the relation between pubertal and psychological development is further complicated by the fact that the timing of puberty is itself influenced by social factors. The exact mechanisms remain unknown, but several studies indicate that girls reared in hostile or distant family environments mature somewhat earlier than their peers. This finding implies that the often reported link between pubertal maturation and parent-adolescent conflict may be reciprocal rather than unidirectional (Ellis & Garber, 2000; Ellis, McFadyen-Ketchum, Dodge, Pettit, & Bates, 1999; Graber, Brooks-Gunn, & Warren, 1995; Moffitt, Caspi, Belsky, & Silva, 1992; Steinberg, 1988).

Despite this complexity, a few broad generalizations can be drawn about puberty and adolescent psychological development. First, the direct effects of hormonal changes at puberty are surprisingly small in magnitude, especially given popular stereotypes of adolescent moodiness or unpredictability as the products of "raging hormones" (Buchanan, Eccles, & Becker, 1992; Flannery, Torquati, & Lindemeier, 1994; Susman & Rogol, 2004). There is some evidence that negative affect may be higher during periods of relatively more rapid hormonal change than during periods in which hormonal levels are changing more gradually. In addition, some evidence suggests that adolescents' affect may be more closely linked to levels of adrenal hormones than to levels of gonadal hormones. Generally, however, studies of direct hormone-behavior relations in adolescence have yielded inconsistent and largely unimpressive findings (Buchanan et al., 1992). Second, links between psychological functioning and puberty are stronger when somatic indicators of puberty are measured rather than endocrinological ones (Susman & Rogol, 2004). This pattern suggests that puberty may affect psychological functioning chiefly through its impact on appearance, which likely transforms both self-conceptions and social interactions. Third, studies examining the impact of pubertal timing (i.e., the adolescent's level of pubertal maturation relative to his or her peers or to norms established for a specific chronological age) yield stronger findings than studies examining the impact of pubertal status *per se* (i.e., which stage of puberty the adolescent is in; Susman & Rogol, 2004).

A fourth and final psychosocial implication of biological maturation comes from well-documented associations between early pubertal maturation and higher rates of negative affect (including clinical depression)

among girls (Aro & Taipale, 1987; Ge et al., 2003; Graber, Brooks-Gunn, & Warren, in press; Hayward et al., 1997; Stice, Presnell, & Bearman, 2001) and higher rates of problem behavior (including antisocial behavior and substance use) among both girls (Dick, Rose, Pulkkinen, & Kaprio, 2001; Flannery, Rowe, & Gulley, 1993; Ge, Conger, & Elder, 1996; Graber, Brooks-Gunn, & Galen, 1999; Magnusson, Ståttin, & Allen, 1986; Stice et al., 2001; Wiesner & Ittel, 2002; Wichstrom, 2001) and boys (Andersson & Magnusson, 1990; Dick et al., 2001; Silbereisen, Kracke, & Crockett, 1990; Wichstrom, 2001; Williams & Dunlop, 1999). Prevailing theories point to two potential mechanisms for this connection: (1) the negative impact of puberty on body image among girls (Petersen, 1988; Wichstrom, 2001) and (2) the increased likelihood of early maturers having older friends, which may lead early maturers to experiment with various risky behaviors when they are younger and relatively immature (Magnusson et al., 1986). Notably, the link between early maturation and negative affect among girls is particularly strong in Western countries where cultural beliefs about attractiveness emphasize thinness. This observation is consistent with other research showing that correlates of early and late maturation vary across cultures, societies, neighborhoods, and even schools (Caspi, Lynam, Moffitt, & Silva, 1993; Dick, Rose, Viken, & Kaprio, 2000; Dyer & Tiggemann, 1996; Richards, Boxer, Petersen, & Albrecht, 1990; Silbereisen, Petersen, Albrecht, & Kracke, 1989).

Studies of pubertal maturation and changes in social relationships fall into two broad categories. One group of studies has tracked changes in parent-adolescent relationships, especially parent-adolescent conflict, as a function of pubertal maturation. Overall, the effects of pubertal timing on parent-adolescent conflict are larger and more robust than those of pubertal status (for reviews, see Collins & Laursen, 2004b; Laursen & Collins, 1994). Meta-analyses (e.g., Laursen, Coy, & Collins, 1998) have revealed a small positive linear association between pubertal status and negative affect in parent-adolescent interchanges but not between pubertal status and the *rate* of parent-adolescent conflict. In other words, as adolescents mature, they do not fight with their parents more often, but when they do, the fighting tends to be more intense (Laursen et al., 1998). Generally, early-maturing sons and daughters experience more frequent and more intense parent-child con-

flict than adolescents who mature on-time or late. Several explanations have been offered, most suggesting that parents do not agree with adolescents that physical precocity is a sufficient basis for granting greater autonomy. The effects of pubertal maturation on parent-adolescent harmony are less well-studied. A few investigations of this have suggested that pubertal maturation may be associated with diminished closeness, manifested mainly in increased privacy-seeking on the part of the adolescent and diminished physical affection between teenagers and parents, but the effects are small and inconsistent across studies (Collins & Laursen, 2004b; Montemayor, 1983, 1986).

The other broad class of studies of the impact of puberty on relationships examines the role of puberty in adolescents' sexual behavior. This literature shows that a complete understanding of the role of puberty in adolescent sexual behavior necessitates examining biological and social influences in interaction with each other rather than focusing on either set of influences alone (Billy & Udry, 1985; E. Smith, Udry, & Morris, 1985; Udry, Talbert, & Morris, 1986). Adolescents become sexually active in part because of increases in sex hormones at puberty and in part because sexual activity becomes accepted in their peer group. Consistent with this, adolescents who mature earlier than their peers are also likely to have sexual intercourse earlier, as a consequence of both biological and social factors (Lam, Shi, Ho, Stewart, & Fan, 2002; B. Miller, Norton, Fan, & Christopherson, 1998).

Although motivation to have sex appears to be hormonally driven in both sexes, influences on actual sexual activity are both hormonal and social and differ somewhat between males and females (Savin-Williams & Diamond, 2004). Among both males and females, initial *interest* in sex, as well as arousal in response to sexual stimuli, is influenced primarily by the pubertal surge in sex hormones (E. Smith et al., 1985; Udry, 1990; Udry et al., 1986). Links between hormonal change and sexual *activity*, however, are stronger among males than females. Some evidence indicates that boys whose friends are sexually active are themselves more likely to be involved in sex, apparently because boys tend to have friends who are at a similar level of pubertal development and who therefore are likely to have similar androgen levels and rates of sexual activity.

Because male adolescents are traditionally more likely to initiate sex than female adolescents, girls' sex-

ual activity is influenced both by their sex drive and their receptivity to males' sexual advances. Perhaps because of this, numerous studies show that social factors are far more important in influencing girls' involvement in sexual intercourse than boys' (Crockett, Bingham, Chopak, & Vicary, 1996; Savin-Williams & Diamond, 2004; Udry & Billy, 1987). Among girls with high levels of androgens, for example, those who have sexually permissive attitudes and sexually active friends are more likely to engage in intercourse than those with more conservative attitudes and inactive or less active friends. Conversely, among girls whose social environment is less encouraging of sex, even those girls with high levels of androgens are unlikely to be sexually active. One explanation for this sex difference is that boys develop in an environment that is more uniformly tolerant and encouraging of sexual behavior than girls do, thus permitting the direct effects of hormonal changes on sexual activity to be more easily realized among males.

There is strong evidence that the impact of pubertal maturation on adolescent psychosocial development is more likely to be interpersonally mediated than to result from the direction action of hormonal change on mood or emotional functioning. This conclusion is supported by evidence of three kinds: (1) findings that the effects of puberty are stronger when observable manifestations of changes in physical appearance, rather than hormonal indices, are used to measure maturation; (2) results showing that pubertal timing, which necessarily involves some sort of social comparison, is a better predictor of psychosocial functioning than pubertal status; and (3) indications that the impact of puberty on psychological functioning is moderated by the social context in which adolescents mature.

### Cognitive Change

During early adolescence, individuals show marked improvements in reasoning (especially deductive reasoning), information processing (in both efficiency and capacity), and expertise. Abstract, multidimensional, planful, and hypothetical thinking also increases from late childhood into middle adolescence. According to a recent review (Keating, 2004), it is probably more sensible to view improvements in thinking as involving an interrelated "suite" of changes than to search for a single driving force that accounts for the multiple advances in thinking that occur during adolescence.

After a period of relative inactivity during the late 1980s and early 1990s, the study of intellectual development during adolescence has been revitalized in two ways. First, research in developmental neuroscience has redirected attention to the study of structural and functional aspects of brain development (e.g., Casey, Giedd, & Thomas, 2000; Giedd et al., 1999; Sowell, Trauner, Gamst, & Jernigan, 2002; Spear, 2000). These studies have pointed to significant growth and change in multiple regions of the prefrontal cortex throughout the course of adolescence, especially with respect to processes of myelination and synaptic pruning (both of which increase the efficiency of information processing; Huttenlocher, 1994; Paus et al., 1999; Sowell et al., 2002). These changes are believed to undergird improvements in executive functioning (i.e., long-term planning, metacognition, self-evaluation, self-regulation, and the coordination of affect and cognition; Keating, 2004). Improved connectivity between regions of the prefrontal cortex and several areas of the limbic system also occur during adolescence, and this restructuring likely affects evaluations and responses to both risk and reward (Martin et al., 2002; Spear, 2000). Substantial changes also apparently occur in brain systems that regulate the ways in which individuals process and respond to social stimuli, such as facial displays of affective states (E. Nelson, Leibenluft, McClure, & Pine, 2005). Whether and to what extent these changes in brain structure and function are linked to processes of pubertal maturation is not known. Some aspects of brain development are coincident with, and likely linked to, neuroendocrinological changes occurring at the time of puberty, but others appear to take place along a different, and later, timetable. Disentangling the first set from the second is an important challenge for the field (see Dahl, 2001).

A second relatively new direction examines cognitive development as it plays out in social contexts and, in particular, as cognitive functioning affects the development of judgment, decision making, and risk taking (Cauffman & Steinberg, 2000; Fried & Reppucci, 2001; Maggs, Almeida, & Galambos, 1995; D. Miller & Byrnes, 1997; Scott, Reppucci, & Woolard, 1995; Steinberg & Cauffman, 1996). New perspectives emphasize that adolescent thinking in the real world is a function of social and emotional, as well as cognitive, processes; thus, a full account of the ways in which the intellectual changes of adolescence affect social and emotional development must address the ways in which affect and cognition interact (Keating, 2004). Studies of adoles-

cents' reasoning and problem solving using laboratory-based measures of intellectual functioning may provide better information about adolescents' potential competence than about their actual performance in everyday settings, where judgment and decision making are likely affected by emotional states and social influences (Steinberg, 2003). Thus, although studies of responses to hypothetical dilemmas involving the perception and appraisal of risk show few reliable age differences after middle adolescence (e.g., Beyth-Marom, Austin, Fischhoff, Palmgren, & Jacobs-Quadrel, 1993), studies of actual risk taking (e.g., risky driving and unprotected sexual activity) indicate that adolescents are significantly more likely than adults to make risky decisions. One reasonable hypothesis is that adults and adolescents age 16 and older share the same logical competencies but that age differences in social and emotional factors, such as susceptibility to peer influence or impulse control, contribute to age differences in actual decision making (Steinberg & Scott, 2003).

Similarly, although it is reasonable to assume that the intellectual advances of adolescence transform, and are transformed by, individuals' relationships with parents, peers, and other individuals, direct examinations of this proposition are surprisingly infrequent. Research on links between the cognitive changes of adolescence and social or emotional development during the period more typically has examined age-related differences in social cognition rather than the relation between cognitive advances and changes in social relationships.

An extensive literature, however, has shown that the ways in which individuals think about others becomes more abstract, more differentiated, and more multidimensional during adolescence (for a review, see Eisenberg & Morris, 2004). Recent studies have attempted to clarify the conditions under which relatively more advanced displays of social cognition are likely. These efforts have included attention to gender and cultural differences in certain aspects of social cognition, such as prosocial reasoning (e.g., Boehnke, Silbereisen, Eisenberg, Reykowski, & Palmonari, 1989; Jaffee & Hyde, 2000) and impression formation (e.g., Crystal, Watanabe, Weinfurt, & Wu, 1998), as well as efforts to examine links between social cognition and social behavior. The findings imply that patterns of social cognitive development vary both as a function of the content under consideration and the emotional and social context in which the reasoning occurs. As an example, reasoning about moral dilemmas becomes more principled

over the course of adolescence, but thinking about real-life problems often is less advanced than that seen when adolescents are asked to reason about hypothetical situations. When individuals perceive that they will be hurt severely by morally advanced actions (e.g., defending someone in the face of being punished oneself), they are less likely to reason at a higher moral level (Sobesky, 1983).

The correlation between adolescents' moral reasoning and their moral behavior is especially likely to break down when individuals define issues as personal choices rather than ethical dilemmas (e.g., when using drugs is seen as a personal matter rather than a moral issue; Kuther & Higgins-D'Alessandro, 2000). Similarly, when faced with a logical argument, adolescents are more likely to accept faulty reasoning or shaky evidence when they agree with the substance of the argument than when they do not (Klaczynski, 1997; Klaczynski & Gordon, 1996). In other words, social reasoning is influenced not only by adolescents' basic intellectual abilities but also by their desires, motives, and interests.

Although advances in hypothetical thinking and social perspective taking are presumed to stimulate the development of more egalitarian relationships with parents and more intimate relationships with peers, most work in this area has focused on links between cognitive development and parent-adolescent conflict, to the neglect of research on the ways in which more mature reasoning may permit the adolescent to establish a closer, more sympathetic relationship with his or her parents. For example, studies of family interaction and moral reasoning generally indicate that adolescents who display relatively more advanced reasoning and social perspective taking are more likely to have parents who are warm and supportive and who engage the adolescent in discussions in which the young person is encouraged to express independent opinions (Boyes & Allen, 1993; Grotevant & Cooper, 1985; Hauser, Powers, & Noam, 1991; M. Pratt, Arnold, A. Pratt, & Diessner, 1999; Walker & Taylor, 1991), whereas adolescents with parents who are challenging but critical, hostile, and intolerant of the adolescent's assertiveness demonstrate less sophisticated reasoning. Furthermore, whereas high-conflict, challenging interactions between parents and adolescents are associated with adolescents who are likely to engage in less mature reasoning (Walker & Hennig, 1999; Walker, Hennig, & Krettenauer, 2000), comparably challenging and conflictual interactions between adolescents and their peers is associated with

more mature reasoning (Walker et al., 2000). These associations have been reported in multiple studies. Though consistent with reciprocal influences between social interactions and cognitive change, the cross-sectional nature of most research on the topic makes it impossible to answer questions of causality. Research that examines developmental changes in cognitive abilities assessed over time and under varying social and emotional conditions is needed to elucidate this complex interplay among contexts and intrapersonal and interpersonal processes.

### Changes in Social Definition

Changes in social definition refer to changes in the legal or social standing of the adolescent that ordinarily carry with them changes in rights, privileges, or responsibilities. In nonindustrialized societies, such changes are typically marked by ceremonial rites of passage and transformations in the adolescent's appearance or form of address designed to signify to members of the community that the young person either has transitioned out of childhood or has entered into adulthood. Often, adolescents undergo two different rites of passage—one marking the beginning of adolescence, and one marking its conclusion (Schlegel & Barry, 1991). In industrialized societies, where ceremonial rites of passage are not universal and are idiosyncratic to particular religious or cultural groups, the social recognition of the adolescent is rarely a public event. Nevertheless, changes in social definition do occur in contemporary society through the legal regulation of the transition to adulthood—in the form of laws concerning the age at which individuals are eligible for employment in the formal labor force, driving, voting, autonomous medical or financial decision making, and the purchase of regulated substances such as alcohol and tobacco (Scott & Woolard, 2004).

Compared to biological or cognitive maturation, the social and emotional implications of the changes in social definition during adolescence have received much less attention. Adolescents' psychosocial development may be influenced in important ways by changes in social definition. As examples, receipt of a driver's license may diminish parental monitoring, facilitate the maintenance of romantic relationships, and change the dynamics of peer interactions; entrance into the formal labor force may provide additional financial autonomy not ordinarily associated with the receipt of an allowance and thereby transform power relationships in the family; and

the ability to obtain contraception without parental consent may alter patterns of sexual activity. A reasonable hypothesis is that attaining various adult privileges may affect adolescents' perceptions of their own independence and competence. Some research has examined how adolescents' self-conceptions are affected by paid employment (e.g., Mortimer, 2003), but associations between other changes in social definition and adolescent psychological functioning have not been studied.

Biological and cognitive changes, as well as altered expectations regarding adolescent behavior, thus both stimulate and reflect the central role of interpersonal processes in adolescent development. The remaining sections of the chapter examine these processes and their significance for individual development in the adolescent years.

### CONCEPTUAL PERSPECTIVES ON ADOLESCENT DEVELOPMENT IN INTERPERSONAL CONTEXTS

Theories of adolescent development provide overlapping accounts of differences and changes in interpersonal contexts, but contrasting explanations of their significance for individual psychosocial development. *Ecological perspectives* view individuals and relationships as features of larger contexts in which the elements are multilayered and interconnected. *Interpersonal perspectives* focus on patterns of interaction and affect in social interactions and the principles by which close relationships exert pressures toward continuity and coherence. *Biosocial perspectives* emphasize intrapersonal biological and motivational pressures toward engaging in relationships and adapting them to changing contexts. This section elaborates these three views.

#### Ecological Perspectives

The ecological perspective on adolescence construes context as a series of nested environments, each level of which is embedded in a larger level (Bronfenbrenner, 1979). Although most studies of the role of context in shaping adolescent behavior and development are studies of single contexts examined in isolation from one another, the ecological perspective provides a conceptual framework for investigating more complex interactions between persons and environments. Three premises are especially important in this regard.

The first premise is that proximal settings are connected to each other, in that events that occur in one setting often have ramifications for individual behavior and development in another. Socialization in the family context influences how adolescents behave in the peer group (e.g., B. Brown, Mounts, Lamborn, & Steinberg, 1993; Fuligni & Eccles, 1993), peer influence processes affect how adolescents behave in the classroom (e.g., Mounts & Steinberg, 1995; Steinberg, Dornbusch, & B. Brown, 1992), experiences in the workplace affect family relationships and behavior in school (e.g., Mortimer, 2003; Steinberg, Fegley, & Dornbusch, 1993), and so on.

Second, these proximal settings are contained in broader institutional and community contexts that shape the structure of settings and influence what takes place in them (Duncan & Raudenbush, 2001; Jencks & Mayer, 1990). This realization has stimulated considerable research in recent years on neighborhood influences on adolescent development (Leventhal & Brooks-Gunn, 2004). Qualities of neighborhoods are now known to influence the functioning of adolescents' families and friendship networks (Furstenberg, T. Cook, Eccles, Elder, & Sameroff, 1999). Parents interact with their children differently in poor neighborhoods than they do in more affluent ones; as a consequence, adolescent development may vary across neighborhood contexts (McLoyd, 1990). Similarly, schools exist in communities, and characteristics of communities—urban versus rural or tightly knit versus impersonal—influence the ways in which schools are organized and operate (Eccles, 2004).

A third premise is that proximal settings and the broader environments that contain them (macrosystems) are located in particular historical, social, economic, political, geographical, and cultural contexts. These contexts in turn are linked to the nature, structure, function, organization, and influence of all levels of the environment (Larson & Wilson, 2004). In addition, important social and economic events—wars, economic depressions, or natural disasters—shape proximal and distal settings in important ways that have ramifications for individuals' behavior and development (Elder, 1998).

The preeminence of contextual perspectives on adolescent development during the past several decades stands in stark contrast to the emphasis placed on studies of intraindividual development during the 1950s, 1960s, and 1970s. During that period, grand theories of adolescent development, such as Freud's theory of detachment (1958), Erikson's theory of identity development (1968), or Piaget's theory of formal operations

(Inhelder & Piaget, 1958), defined the empirical agenda. Even a cursory examination of articles in today's scientific journals reveals just how much the influence of these intraindividual perspectives has waned and has been supplanted by less theoretically driven studies of the contexts in which adolescents develop.

Two important ramifications of the ascendance of contextual perspectives deserve comment. First, research on social and personality development in adolescence has shifted away from the description of processes of normative social and emotional development toward an emphasis on diversity in adolescent experiences attributable to variations in the family, peer group, school, workplace, and neighborhood. As a result, recent research on adolescence has tended to emphasize individual differences in behavior, psychosocial functioning, and mental health far more than universal (or, at least, putatively universal) aspects of social or emotional maturation. Second, as Steinberg and Morris (2001) noted, "No comprehensive theories of normative adolescent development have emerged to fill the voids created by the declining influence of Freud, Erikson, and Piaget. Instead, the study of adolescence has come to be organized around a collection of 'mini-theories'—frameworks designed to explain only small pieces of the larger puzzle. As a consequence, although the field of adolescence research is certainly much bigger now than before, it is less coherent and, in a sense, less developmental than it had been in the past" (pp. 101–102).

One attempt to bridge developmental and contextual approaches has involved the study of "stage-environment fit." This approach identifies whether a given context or set of contexts provides opportunities for processes of normative development to unfold along an appropriate timetable. Studies of stage-environment fit, which examine the match between a context and the developmental needs associated with a particular period, should not be confused with studies of "person-environment fit," which examine the match between individual characteristics such as temperament and the contexts in which the individuals live (e.g., Stice & Gonzales, 1998). The former emphasize development, whereas the latter focus on individual differences. An example of stage-environment fit research is the study of the mismatch between the typical social climate of middle or junior high schools and the capabilities and psychosocial needs of young adolescents (e.g., Eccles et al., 1993). Underlying this work is the hypothesis that the normative press toward behavioral independence clashes with the overly rigid and inflexible nature of most educational environ-

ments for early adolescents, hindering healthy development. Similar themes appear in research on family relationships that distinguishes between patterns of interaction that seem consonant with the young person's interests in being granted greater emotional and behavioral autonomy versus those that stifle the adolescent's independence striving (e.g., Allen, Hauser, Bell, & O'Connor, 1994; Fuligni & Eccles, 1993). The ecological perspective thus integrates consideration of individual changes and the contexts (including relational ones) that facilitate or interfere with those changes.

### Interpersonal Perspectives

Interpersonal perspectives emphasize how adolescents' experiences in social relationships change and how these changes, in turn, contribute to individual development. At least three formulations exemplify interpersonal perspectives on development during adolescence. The three differ primarily in the degree to which changes in dyadic relationships are attributed to individual maturation or to constraints and demands from larger contexts (e.g., schools). All three, however, assign a significant developmental role to the interactions that occur within dyads and social groups.

#### *Interdependence Models*

In interdependence models, joint patterns of actions, cognitions, and emotions between two individuals are the primary locus of contextual influences on individuals (Hinde, 1997; Kelley et al., 1983; Laursen & Bukowski, 1997). A *close relationship* is one in which two persons are highly interdependent; they interact with each other frequently, across a variety of settings and tasks, and exert considerable influence on each others' thoughts and actions (Berscheid, Snyder, & Omoto, 1989; Kelley et al., 1983; Repinski, 1992). Defining closeness by the degree of interdependence between two persons avoids potential confounds between the degree to which adolescents are interdependent with their relationship partners and the emotional qualities of those relationships, which can be either positive or negative (Berscheid et al., 1989).

During adolescence interdependencies in family relationships continue, though often in different forms than in earlier life, and interdependencies with friends and romantic partners become more apparent (Collins & Laursen, 2004a). In parent-child relationships, expectancies must be adjusted on both sides to preserve

sufficient interdependence to assure parents a continuing role in facilitating development (Collins, 1995; Darling & Steinberg, 1993). In peer relationships, skills must be developed for maintaining interdependence on the basis of shared interests, commitments, and intimacy, even when contact is relatively infrequent (Parker & Gottman, 1989). In both types of relationships, discrepancies in the expectancies of the relationship partners may stimulate conflicts, but these conflicts often stimulate adjustments of expectancies that gradually restore harmony (Collins, 1995).

The process by which discrepant perceptions mediate changes in interactions has yet to be examined directly, although Collins (1995) offered one possible model. Seeking to explain how both stability and change are inextricably involved in the natural history of relationships, including those involving adolescents, the model begins with the assumption that interactions between parents and children are mediated by cognitive and emotional processes associated with *expectancies* about the behavior of the other person. In periods of rapid developmental change, such as the transition to adolescence, parents' expectancies often are violated, generating emotional turmoil and conflict and stimulating parents and children to realign their expectancies appropriately. In younger and older age groups, change may occur more gradually, so that discrepancies are both less frequent and less salient than in periods of rapid multiple changes. Baumrind (1991) and Holmbeck (1996) also have proposed models implying links between individual development and adaptations in parent-adolescent relationships. Interdependence models thus provide for both continuity and change during development, two requirements for the development of independence and interdependence.

### *Attachment Perspectives*

In contrast to the behavioral emphasis of interdependence views, attachment formulations emphasize the strong emotional ties between parents and adolescents. As a mutually regulated system, parents and children collaborate in maintaining the qualities of parent-child relationships. Relationship qualities are based in emotions associated with feelings of security and insecurity (Bowlby, 1982). Although the qualities and functions of these relationships are presumed to be inherently stable over time (Allen & Land, 1999), specific forms and modes of interaction between parent and child differ from one age period to another, reflecting the developing capabilities and needs of the child and parent and

the varying challenges associated with age-graded tasks and settings.

Attachment in adolescence is distinctive, both behaviorally and cognitively, from attachment in earlier relationships. Compared to children, adolescents manifest emotional ties to their parents subtly and often privately, often through such behaviors as friendly teasing and small acts of concern, as well as shared activities and self-disclosure. Cognitive advances in adolescence make possible more complex and integrated views regarding experiences that involve caregiving, caretaking, and confidence in the availability of significant others. Consequently, adolescents are increasingly attuned to both the similarities and the differences between relationships with parents, other significant adults, friends, and eventually romantic partners and offspring (Allen & Land, 1999; Furman & Wehner, 1994).

Despite these differing attachment behaviors, the functions of secure relationships for adolescents are similar to the functions for infants. Whereas security in infancy facilitates exploration of the immediate environment, security in adolescence provides a sense of confidence in family support for explorations outside of the family, thus facilitating relationships with peers and other adults (Collins & Sroufe, 1999). Longitudinal findings have shown that measures of the quality of caregiver-child relationships in infancy and early childhood forecast measures of quality in relationships with romantic partners in adolescence and even in adulthood (Collins, Hennighausen, Schmit, & Sroufe, 1997; Collins & Van Dulmen, 2006b).

Attachment formulations may appear to emphasize the development of interdependence to the potential detriment of appropriate independence. A key implication of attachment views, however, is that a history of sensitive, responsive interactions and strong emotional bonds facilitates adaptation during the transitions of adolescence—transitions that permit functioning outside the immediate sphere of close relationships, while simultaneously transforming existing bonds into more age-appropriate ones (Collins, 1995; Collins & Sroufe, 1999).

### *Social-Psychological Perspectives*

The distinctive developmental issues of adolescence reflect the multiple adaptations required during the transition from childhood to adulthood (Combrinck-Graham, 1985; Lewin, 1931; Simmons & Blyth, 1987). Adolescent transitions are due partly to the physical changes of puberty and the emergence of behavior commonly expected of physically adult, reproductively mature indi-

viduals, but also to age-graded changes in expectations, tasks, and settings (Bandura, 1964). In the social-psychological perspective, this confluence of maturational changes and age-graded shifts in tasks and settings can affect the psychosocial adaptation of individuals more extensively than either can alone (Simmons & Blyth, 1987). A well documented instance is the deleterious impact on seventh grade girls' self-esteem when pubertal maturation, the onset of dating, and a shift from elementary to junior high school coincide (Simmons & Blyth, 1987; Simmons, Burgeson, & Reef, 1988).

The impact of adolescent transitions on interpersonal relationships has three major sources. One is the increase in ambient anxiety and tension from adapting to the multiple changes of early adolescence. Another is that some difficulties in adjusting to the world beyond the family are imported into family relationships, perhaps because families provide relatively safe settings for expressing the bewilderment, anger, and frustration that cannot be expressed freely with nonfamily members (Hartup, 1979; Youniss, 1980). A third is the pressure to diminish dependency on the family to adapt successfully to extrafamilial contexts (Brooks-Gunn, Petersen, & Eichorn, 1985; R. Lerner, 1985). These latter pressures frequently affect psychosocial variables that may play a role in diverse relationships (e.g., self-esteem, perceived independence, value placed on independence, perceived acceptance, methods of control, and implicit timetables for "acting older"; Collins, 1995; Simmons & Blyth, 1987). Parental role confusion and satisfaction also have an impact on the transitions of this period (Silverberg & Steinberg, 1990; Wynne, 1984), a convergence of life-course issues in the two generations that has been frequently cited as a likely source of difficulties in parent-adolescent relationships (e.g., Hill, 1987; Rossi, 1987; Silverberg & Steinberg, 1990). Family development perspectives regard the life-cycle changes experienced by offspring as having ramifications for family systems, which in turn affect the individual development of both parents and children (Combrinck-Graham, 1985; Wynne, 1984).

The social-psychological viewpoint, like other interpersonal perspectives, implies an increase and then a decrease in relationship difficulties from early to late adolescence (Collins & Laursen, 2004b). The course of development may be more episodic than other theories imply, however. For example, social age-grading implies that adolescents will encounter periodic recurrence of shifts in age-related social expectancies; similarly, changes could recur in connection with

changes in family status (e.g., Combrinck-Graham, 1985; Wynne, 1984). An alternate, but conceptually consistent, prediction is that early adolescence might be the primary period of change, with gradual restabilization as appropriate accommodations are made to further age- or status-related transitions. Relationship changes may vary, moreover, as a function of timing of puberty. Hill (1988) has suggested that very early pubertal timing for girls may result in long-lasting perturbations in relationships, but the reasons for a different pattern of resolution for this group than for other timing-of-puberty groups are not readily apparent. One possibility, suggested several decades ago by Peskin (1967), is that very early puberty (which characterizes early-maturing girls) occurs well before mature "ego skills" have developed, leaving the adolescent vulnerable to developmental difficulties.

### *Summary Comment*

Interpersonal perspectives elaborate ecological views of the role of social systems in adolescent development by describing the dynamics of adaptation in the proximal arena of close relationships. A particular strength of interpersonal formulations is the implied balance between continuity and change. This balance fosters the simultaneous growth of abilities for autonomous functioning and the capacities required for forming healthy, well-functioning relationships outside of the family and maintaining positive connections in the family.

### **Biosocial Perspectives**

Biosocial perspectives on development in interpersonal contexts come largely from evolutionary psychology and research on behavior genetics, especially more recent work based on molecular genetics and multivariate models of genetic-environment influence. Although the evolutionary view deals primarily with tendencies and processes characteristic of human adolescents in general and that of behavior genetics with individual differences among adolescents, together they provide a picture of the ways in which intraindividual biological processes are relevant to understanding variations in interpersonal experiences during the adolescent years.

### *Evolutionary Perspectives*

In view of the importance of the development of reproductive capability as a defining feature of adolescence, it is not surprising that theorists have drawn on evolutionary perspectives (more specifically, the

perspectives of sociobiology and behavioral ecology) in attempting to account for transformations in social relations during the period. The basic argument is that the attainment of reproductive capability should be accompanied by changes in social relationships that increase reproductive fitness (Weisfeld, 1999). This general notion has been used to explain a wide range of social phenomena in adolescence, including the establishment of dominance hierarchies among adolescent males (Savin-Williams, 1979), distancing in the parent-adolescent relationship during puberty (Steinberg, 1989), the emergence of romantic relationships in adolescence (Gray & Steinberg, 1999; Laursen & Jensen-Campbell, 1999), processes of mate selection (Steinberg & Belsky, 1996), the differential patterns of social relationships evinced by early versus late maturers (Belsky, Steinberg, & Draper, 1991; Ellis et al., 1999), and the development of both internalizing (Cyranowski, Frank, Young, & Shear, 2000) and externalizing (Steinberg & Belsky, 1996) problems. In each case, theorists have suggested ways in which the social phenomenon in question might be viewed as a strategic behavior that originally evolved to facilitate the dispersal of an individual's genes in subsequent generations.

Evolutionary perspectives on adolescent social development are grounded in the observation that many social behaviors seen among human adolescents share a great deal in common with those seen among adolescents in other mammalian species and, in particular, with adolescents among other primates—for example, transformations in parent-child relationships at puberty. As is the case among humans, among most nonhuman primates living in the wild, pubertal maturation is generally accompanied by increased distance in the parent-child relationship, either by increased physical distance or heightened aggression; in many primate species, juveniles leave the natal group at puberty, either voluntarily or forcibly (Caine, 1986; Steinberg, 1989). The human and animal studies combined suggest that reproductive maturation may be inhibited by physical closeness to parents and accelerated by distance from them (see also Belsky et al., 1991). Sociobiological explanations of this phenomenon are plausible in that postpubertal distance in the parent-child relationship would minimize inbreeding and thereby increase reproductive fitness (Steinberg, 1989). The fact that parallel changes in parent-child relations occur during puberty across different primate species adds an important new twist to the standard psychoanalytic interpretation of in-

creased parent-adolescent bickering at puberty because monkeys and apes probably do not harbor unresolved Oedipal tension. Although the cross-species similarities do not argue against psychological accounts of transformations in family relations (e.g., such transformations are the result of independence seeking on the part of the adolescent). The fact that parent-adolescent distance occurs routinely at puberty across primate species suggests that it probably has played some role in primate evolution. Similar arguments have been made about the adaptive significance of other “problematic” aspects of adolescent social behavior such as risk taking (Steinberg & Belsky, 1996).

### *Behavioral Genetics*

Growing interest in understanding the joint influence of biology and environment has led to an increase in behavioral genetics research in recent years focused specifically on adolescent social development. Most of this work has employed an additive statistical model, where the variance of a psychological or interpersonal characteristic is partitioned among three components: genetic influences, shared environmental influences (i.e., facets of the environment that family members, such as siblings, share in common), and nonshared environmental influences (i.e., facets of the environment that family members do not share in common; Plomin & Daniels, 1987). Both genetic and nonshared environmental influences, such as parental differential treatment, peer relations, and school experiences, are particularly strong in adolescence. In contrast, shared environmental factors, such as socioeconomic status, neighborhood quality, and parental psychopathology, are less influential (e.g., McGue, Sharma, & Benson, 1996; Pike, McGuire, Hetherington, Reiss, & Plomin, 1996).

Genetic factors contribute to individual variations in social behavior during adolescence, including aggression, antisocial behavior, and delinquency. These individual differences in aggression appear to have a more substantial genetic basis than other behaviors, although both shared and nonshared influences on aggression and other externalizing behaviors have been identified (Deater-Deckard & Plomin, 1999; Eley, Lichenstein, & Stevenson, 1999; Spotts, Neiderhiser, Hetherington, & Reiss, 2001). Genetic factors also have been linked to adolescent internalizing problems, such as risk for suicide and depressed mood (Blumenthal & Kupfer, 1988; Jacobson & Rowe, 1999).

Nonproblem behaviors such as self-perceptions of scholastic competence, athletic competence, physical appearance, social competence, and general self-worth also are highly heritable, with little evidence for shared environmental influences and only modest evidence for nonshared environmental influences (McGuire et al., 1999). Intelligence in adolescence (as indexed by IQ) is strongly influenced by heredity as well; and these genetic influences compound over time, becoming stronger determinants of IQ-test performance than family environmental influences (Loehlin, Willerman, & Horn, 1988). Parental education moderates the heritability of IQ, however. Genetic influences are stronger in families with highly educated parents, consistent with the general notion that heritability estimates are generally higher in more favorable environments (Rowe, Jacobson, & van den Oord, 1999).

One of the most important findings to emerge in recent years is that assessments of the adolescent's family environment via adolescent or parent reports—measures previously presumed to assess the environment—also may reflect features of the parents' genetic make-up, which in turn affect individuals' perceptions and descriptions of their family situations (Plomin, Reiss, Hetherington, & Howe, 1994). Genetic factors contribute significantly to actual and reported levels of conflict, support, and involvement in the family (Neiderhiser, Reiss, Hetherington, & Plomin, 1999), in part, because adolescents who display hostile and antisocial behaviors are more likely to elicit negative behaviors from their parents than adolescents less prone to these problems (Ge et al., 2002). Genetic influences on family relations become even more pronounced as adolescents mature, perhaps because older adolescents have more influence in family relationships (Elkins, McGue, & Iacono, 1997).

An important note is that most psychological traits and behaviors are influenced by *both* nature and nurture and that, among environmental influences, the nonshared component generally contributes more heavily to individual characteristics than shared environment does (Plomin & Daniels, 1987). On average, shared family environment explains only 5% to 10% of the variance in psychological behaviors and attitudes (Collins et al., 2000). Research findings also indicate that variation in the family climate, as opposed to the adolescent behavior or personality trait in question, across sibling and parent-adolescent relationships is explained more by shared influences than nonshared ones (Bussell et al., 1999).

### **Summary Comment**

Ecological, interpersonal, and biosocial perspectives are neither mutually exclusive nor incompatible. Rather, they address different levels of analysis and together promise a richer understanding of the significance of adolescents' interpersonal contexts than any single perspective alone. Developmental systems models (e.g., Magnusson & Stattin, 1998; Sameroff, 1983) incorporate these multiple perspectives. Such models are daunting, both conceptually and methodologically, and few examples exist of thoroughgoing application to research on adolescents. Nevertheless, awareness of the contrasting and the overlapping implications of multiple perspectives provides a useful touchstone for appraising findings from research on adolescent development in interpersonal contexts.

## **SIGNIFICANT INTERPERSONAL RELATIONSHIPS DURING ADOLESCENCE**

The psychosocial challenges of adolescence arise in rapidly diversifying personal and social contexts. This section addresses both relationships established in earlier life periods (e.g., with family members, long-time peers) and those that emerge during adolescence (e.g., with secondary school classmates, romantic interests, extrafamilial adult mentors). In each case, we consider distinctive features of particular types of relationships, the developmental course of these relationships during adolescence, the contributions of the maturation and changes in social expectations that define adolescence, and the significance of relationship changes for adolescent development. We give particular attention to the importance of differing relationships for accomplishing the psychosocial tasks of independence and interdependence.

### **Familial Relationships and Influences**

The role of the family in social development is arguably the most studied topic in the field of adolescence (Steinberg, 2001). Because the literature on parent-adolescent relations has been reviewed so frequently, so extensively, and so recently (Collins & Laursen, 2004b; Grotevant, 1998; Steinberg & Silk, 2002), our brief discussion is oriented toward articulating the major themes and conclusions on the topic.

Research on adolescent development in the family context has focused almost exclusively on adolescents' relationships with their parents or stepparents. Far less is known about relations with brothers or sisters, and almost nothing is known about relationships with family members other than siblings or parents. Given the changing demography of adolescence and the relative increase in the proportion of adolescents from ethnic minority groups in which extended family members are especially important, research on the variations and impact of relationships with grandparents, aunts, uncles, and cousins would be a valuable addition to the literature. Extant research on African American adolescents indicates that, for example, social support from extended family members is an important resource for inner-city adolescents growing up in single-parent homes (Mason, Cauce, Gonzales, & Hiraga, 1994; Salem, Zimmerman, & Notaro, 1998; Taylor, 1996; Taylor, Casten, & Flickinger, 1993; Taylor & Roberts, 1995). Support from kin, in particular, appears to increase single parents' effectiveness in child rearing, and this, in turn, tends to limit adolescents' misbehavior.

Scholars interested in parent-adolescent relationships generally have asked two related questions. First, how do family relationships change over the course of adolescence (i.e., What is the impact of adolescence on the family)? Second, how does adolescent adjustment vary as a function of variations in the parent-adolescent relationship (i.e., What is the impact of the family on the adolescent)?

### *Transformations in Family Relationships*

Researchers have tracked changes in parent-child relations across three different dimensions: (1) autonomy (the extent to which the adolescent is under the control of the parents); (2) conflict (the extent to which the parent-adolescent relationship is contentious or hostile); and (3) harmony (the extent to which the parent-adolescent relationship is warm, involved, and emotionally close; Collins & Laursen, 2004b; Collins & Repinski, 1994). Generally, the most important transformations in family relationships occur during the early portion of the period. Many theorists have argued that the biological, cognitive, and social changes of early adolescence disturb an equilibrium that had been established during middle childhood and that it is not until middle or even late adolescence that a new equilibrium is in place (Collins, 1995).

Autonomy-related changes are probably the most salient of the relational transformations in the family context during adolescence. Adolescents' early attempts at establishing behavioral autonomy in the family frequently precipitate conflict between parents and teenagers, especially during early adolescence (Collins, 1995). As a result, young adolescents may interrupt their parents more often during family discussions but have little impact—a state of affairs that may lead to escalating conflict (Steinberg, 1981). By middle adolescence, however, teenagers behave much more like adults, and thus may no longer need to assert their opinions through interruptions or immature behavior (Grotevant, 1998). Greater freedom to spend time outside of direct parental supervision also may diminish the frequency of autonomy-related struggles. During adolescence, a shift occurs from patterns of influence and interaction that are asymmetrical and unequal to ones in which parents and their adolescent children are on a more equal footing (Collins, 1995).

Despite firmly held popular notions and pervasive media portrayals of conflict as the hallmark of family relations during this period, research has established that frequent, high-intensity, angry fighting is not normative during adolescence (Collins & Laursen, 2004b; Steinberg, 1990). Although fighting is not a central feature of normative family relationships in adolescence, however, nattering or bickering is. Smetana (1995) and colleagues (Smetana & Asquith, 1994; Smetana, Crean, & Daddis, 2002; Smetana & Daddis, 2002; Yau & Smetana, 1996) have argued that much parent-adolescent conflict results from changes in the adolescent's reasoning about the legitimacy of parental authority. Parents and adolescents often squabble over matters that are defined by parents as moral or prudential issues but by adolescents as questions of personal choice and, accordingly, as less appropriate for parental regulation. With increasingly more sophisticated reasoning abilities, adolescents gradually better appreciate distinctions among the personal, the prudential, and the moral, and they begin to challenge parental authority when they believe it is not legitimate. Adolescents appear less likely to challenge parental authority when they identify a source of disagreement as a moral or prudential (rather than personal) issue (Smetana & Daddis, 2002).

Many of the frustrations associated with parent-adolescent conflict may be related less to the content of the conflict and more to the manner in which conflict

is typically resolved. Conflicts between teenagers and parents tend to be resolved not through compromise but through submission (i.e., giving in) or disengagement (i.e., walking away; Laursen & Collins, 1994). Compared with conflicts between adolescents and their friends, conflicts between adolescents and their parents are more apt to involve neutral or angry affect and less likely to involve positive affect (R. Adams & Laursen, 2001).

Until recently, it was widely assumed that parent-child conflict followed the course of an inverted U-shaped curve across the adolescent period (e.g., Montemayor, 1983). A recent meta-analysis of studies of parent-adolescent conflict failed to support the commonly held view that parent-child conflict rises and then falls across adolescence, however (Laursen et al., 1998). Rather, a linear decline occurs in the frequency of parent-adolescent conflict in early and middle adolescence, and during this same period expressions of negative affect during conflict increases. Thus, the curvilinear pattern in conflict reported by some investigators may be the result of conflating conflict frequency (which may decline) and conflict intensity (which may rise). Also unclear is the extent to which changes in rate or intensity of conflict are associated with pubertal change as opposed to age (Laursen et al., 1998; Paikoff & Brooks-Gunn, 1991).

Although there is less consensus on the extent of changes in positive affect than on autonomy or conflict, the existing evidence suggests that subjective feelings of closeness and objective measures of interdependence decrease across the adolescent years (Collins & Repinski, 2001; Laursen & Williams, 1997), as does the amount of time parents and adolescents spend together (Larson, Richards, Moneta, Holmbeck, & Duckett, 1996). Relative to preadolescents, adolescents report less companionship and intimacy with parents (Buhrmester & Furman, 1987) and report lower feelings of acceptance by parents and less satisfaction with family life (Hill, 1988). Although perceptions of relationships remain generally warm and supportive, both adolescents and parents report less frequent expressions of positive emotions and more frequent expressions of negative emotions when compared with parents and preadolescent children. After a decrease in early adolescence, older teens report more positive affect during family interactions (Larson et al., 1996). It is important to note that children who had warm relationships with their parents during preadolescence are likely to remain

close and connected with their parents during adolescence, even though the frequency and quantity of positive interactions may be somewhat diminished (Collins & Laursen, 2004b).

### *The Influence of Parenting on Adjustment*

Drawing a distinction between *parenting style* and *parenting practices* helps to clarify the relation between parenting and adolescent adjustment (Darling & Steinberg, 1993). Parenting style refers to the overall emotional climate of the parent-child relationship, as indicated by variations in autonomy, harmony, and conflict. Parenting practices, in contrast, are specific, goal-directed attempts by the parent to socialize the adolescent in a particular fashion (e.g., toward high academic achievement or away from experimentation with alcohol). Practices are more or less independent from parenting style, in that similar practices can be carried out against very different stylistic backdrops. More important, the same parenting practice may have different outcomes in the context of one style than another (Darling & Steinberg, 1993; Steinberg, Lamborn, Dornbusch, & Darling, 1992).

Many researchers employ a typological approach to the study of parenting style in which families are categorized into one of several groups based on multiple dimensions of the parent-child relationship. The most influential and well-known approach (Maccoby & Martin, 1983; also see Baumrind, 1991) groups parents into four categories based on levels of responsiveness and demandingness. *Authoritative* parents are warm, firm, and accepting of the adolescent's individuality (Barber, 1994; Gray & Steinberg, 1999). Parents who are very demanding but not responsive are labeled *authoritarian*. Authoritarian parents place a high value on obedience and conformity and tend to favor more punitive, absolute, and forceful disciplinary measures. They tend not to encourage independent behavior and, instead, place a good deal of importance on restricting the child's autonomy. A parent who is very responsive but not at all demanding is labeled *indulgent* (or permissive). Indulgent parents place relatively few demands on the child's behavior, giving the child a high degree of freedom to act as she or he wishes. Parents who are neither demanding nor responsive are labeled *indifferent*. Indifferent parents minimize the time and energy that they must devote to interacting with their child. In extreme cases, indifferent parents may be neglectful.

A vast literature has linked higher levels of psychosocial competence to rearing by authoritative parents than to rearing by authoritarian, indulgent, or indifferent parents. Adolescents from authoritative homes are relatively more responsible, more self-assured, more adaptive, more creative, more curious, more socially skilled, and more successful in school. In contrast, adolescents from authoritarian homes are more dependent, more passive, less socially adept, less self-assured, and less intellectually curious; those from indulgent households are often less mature, more irresponsible, more conforming to their peers, and less able to assume positions of leadership; and those reared in indifferent homes are disproportionately impulsive and more likely to be involved in delinquent behavior and in precocious experiments with sex, drugs, and alcohol (Fulgini & Eccles, 1993; Kurdek & Fine, 1994; Lamborn, Mounts, Steinberg, & Dornbusch, 1991; Petit, Laird, Dodge, Bates, & Criss, 2001; Pulkkinen, 1982; Steinberg, 2001; Steinberg, Lamborn, Darling, Mounts, & Dornbusch, 1994). Although occasional exceptions to these general patterns have been noted, the evidence linking authoritative parenting and healthy adolescent development is remarkably strong, and it comes from studies of a wide range of ethnicities, social classes, and family structures, not only in the United States (e.g., Clark, Novak, & Dupree, 2002; Dornbusch, Ritter, Liederman, Roberts, & Fraleigh, 1987; Forehand, Miller, Dutra, & Chance, 1997; Hetherington, Henderson, & Reiss, 1999; S. Kim & Ge, 2000; Matza, Kupersmidt, & Glenn, 2001; Steinberg, Mounts, Lamborn, & Dornbusch, 1991) but in parts of the world as diverse as Iceland (Adalbjarnardottir & Hafsteinsson, 2001), India (Carson, Chowdhury, Perry, & Pati, 1999), China (Pilgrim, Luo, Urberg, & Fang, 1999), and Palestine (Punamaki, Qouta, & Sarraj, 1997).

Research also consistently indicates that adolescents who have experienced indifferent, neglectful, or abusive parenting disproportionately experience problems in mental health and development, such as depression and a variety of behavior problems, including, in cases of physical abuse, aggression toward others (Crittenden, Claussen, & Sugarman, 1994; Pittman & Chase-Lansdale, 2001; Sheeber, Hops, Alpert, Davis, & Andrews, 1997; Strauss & Yodanis, 1996). Severe psychological abuse (excessive criticism, rejection, or emotional harshness) appears to be linked to the most deleterious outcomes (Dubé et al., 2003; Haj-Yahia, Musleh, & Haj-Yahia, 2002; McGee, Wolfe, & Wilson, 1997;

Rohner, Bourque, & Elordi, 1996; Simons, Johnson, & Conger, 1994).

It is important to acknowledge possible bidirectional influence in these associations (W. Cook, 2001; C. Lewis, 1981; Stice & Barrera, 1995). Adolescents who are aggressive, dependent, or less psychosocially mature in other ways may provoke parental behavior that is excessively harsh, passive, or distant (Rueter & R. Conger, 1998). In contrast, adolescents who are responsible, self-directed, curious, and self-assured may elicit from their parents warmth, flexible guidance, and verbal give-and-take. In all likelihood, links between adolescent competence and authoritative parenting may be the result of a reciprocal cycle in which the child's psychosocial maturity leads to authoritative parenting, which in turn leads to the further development of maturity (J. Lerner, Castellino, & Perkins, 1994; Repetti, 1996; Steinberg, Elmen, & Mounts, 1989). One 9-year longitudinal study found that, for example, adolescents' and parents' negative feelings toward each other were reciprocally related over time. The more negative adolescents felt, the more this led to negative feelings on the part of their parents, and vice versa (K. Kim, R. Conger, Lorenz, & Elder, 2001).

Much research on parenting style addresses the independent, additive, and interactive effects of variations in autonomy, harmony, and conflict on adolescent adjustment. Although largely cross-sectional and, consequently, limited in its ability to inform questions of causality, studies of parent-adolescent relationships and adolescent adjustment have yielded remarkably consistent findings. Across a variety of outcomes, adolescents fare best in households characterized by a climate of warmth, in which they are encouraged both to be "connected" to their parents and to express their own individuality (Allen, Hauser, O'Connor, Bell, & Eickholt, 1996; Cooper, Grotevant, & Condon, 1983; Grotevant & Cooper, 1985; Hauser et al., 1991; Hauser & Safyer, 1994; Hodges, Finnegan, & Perry, 1999; McElhaney & Allen, 2001). Adolescents who report feeling relatively closer to their parents score higher than other adolescents on measures of psychosocial development, including self-reliance (Steinberg & Silverberg, 1986); behavioral competence, including school performance (Hill, 1987; Maccoby & Martin, 1983); and psychological well-being, including self-esteem (Harter, 1983). Adolescents who report feeling close to their parents also score lower than comparison groups on measures of psychological or social problems (e.g., drug use, depres-

sion, deviant behavior, and impulse control; Allen, Hauser, Eickholt, Bell, & O'Connor, 1994; Garber, Robinson, & Valentiner, 1997; Ge, Best, Conger, & Simons, 1996; Jessor & Jessor, 1977). The benefits of a balance between autonomy and connectedness also are evident in research on family decision making. Adolescents fare better when their families engage in joint decision making in which the adolescent plays an important role but parents remain involved in the eventual resolution, rather than unilateral decision making by the parent or adolescent (Lamborn, Dornbusch, & Steinberg, 1996).

Problems in psychosocial adjustment commonly occur when parents are either highly constraining or insufficiently involved. Adolescents whose parents are intrusive or overprotective, for example, may have difficulty individuating from them, which may lead to depression, anxiety, and diminished social competence (Holmbeck et al., 2000; McElhaney & Allen, 2001). Alternatively, those adolescents who are granted autonomy but who feel distant or detached from their parents score poorly on measures of psychological adjustment (Allen et al., 1996; Chen & Dornbusch, 1998; Fuhrman & Holmbeck, 1995; Lamborn & Steinberg, 1993; R. Ryan & Lynch, 1989). In short, the characteristics of parent-adolescent relationships moderate the impact of parental practices on adolescent behavior and adjustment.

Research findings on parent-adolescent conflict further illustrate this point. Parent-child conflict that occurs in the context of hostile and contentious interactions is associated with negative adolescent adjustment and behaviors. Apparently, the emotional climate of the relationship, rather than the conflict per se, may distinguish adaptive from maladaptive parent-adolescent quarreling (Smetana, 1995). Mild conflict between parents and adolescents actually may be functional in development, in that disagreements may be a mechanism through which adolescents signal changing self-conceptions and expectations for independence (Collins, 1995; Holmbeck & Hill, 1991; Steinberg, 1990). Conflict with parents also may facilitate the development of conflict-resolution skills, assertiveness, and role-taking skills (Cooper et al., 1983; Smetana, Yau, & Hanson, 1991). The positive effects of conflict, however, appear to occur only in parent-adolescent relationships that are also characterized by a high degree of cohesion or harmony (R. Adams & Laursen, 2001).

An important vehicle through which parents remain connected to adolescents without constraining them un-

duly is monitoring (Crouter & Head, 2002). Parental monitoring and supervision are correlated highly with positive adjustment and academic achievement among adolescents (Lamborn et al., 1991; Linver & Silverberg, 1997; Patterson & Stouthamer-Loeber, 1984). Stättin and Kerr recently have argued that the beneficial outcomes often attributed by researchers to effective parental monitoring may actually have little to do with monitoring and may merely be the end result of a parent-adolescent relationship in which the adolescent willingly discloses information to the parent (Kerr & Stättin, 2000; Stättin & Kerr, 2000). Indeed, a close examination of many widely used measures of parental monitoring reveals that researchers often conflate parental *monitoring* with parental *knowledge*, which can be gained through many means other than direct surveillance (e.g., voluntary disclosure by the adolescent). Although one recent analysis suggests that parental monitoring is a deterrent to adolescent problem behavior above and beyond that attributable to knowledge derived from other sources (Fletcher, Steinberg, & Williams-Wheeler, 2004), Stättin and Kerr's work points up the importance of distinguishing between what parents do and what they know. It is especially important that researchers interested in parental monitoring take care to ensure that the measurement of this construct is precise and that, perhaps, parental knowledge of their adolescent's behavior (and how the knowledge is obtained) be measured separately.

Findings on the significance of parenting during adolescence underscore the value of examining multiple parenting dimensions simultaneously to obtain a more accurate reading of the overall emotional climate of the parent-adolescent relationship. Parental attempts at control may be experienced differently in the context of a harmonious relationship than in the context of an adversarial one. Though once regarded largely as matter of parenting practices, the contributions of parents to adolescent development are now recognized as a complex interplay of parental actions, parent-adolescent relationships, and the larger contexts impinging on both.

### ***Ethnic Variations***

In the United States, the topic of ethnic differences in parent-adolescent relationships has received a great deal of attention in recent years, as researchers have attempted to keep pace with the changing demography of U.S. society. The studies generally have found that authoritative parenting is less prevalent among African

American, Asian American, or Hispanic American families than among White families, no doubt reflecting the fact that parenting practices are often linked to cultural values and beliefs (Dornbusch et al., 1987; Smetana & Chuang, 2001; Steinberg, Dornbusch, et al., 1992; Yau & Smetana, 1996). Nevertheless, even though authoritative parenting is less common in ethnic minority families, its links to adolescent adjustment appear to be positive in all ethnic groups (Amato & Fowler, 2002; Knight, Virdin, & Roosa, 1994; Mason, Cauce, Gonzales, & Hiraga, 1996; Steinberg, Dornbusch, et al., 1992; Walker-Barnes & Mason, 2001).

Research also has indicated that authoritarian parenting is more prevalent among ethnic minority than among White families, even after taking ethnic differences in socioeconomic status into account (Chao, 1994; Dornbusch et al., 1987; Steinberg, Lamborn, et al., 1992). In contrast to research on authoritative parenting, which suggests similar effects across ethnic groups, research on authoritarian parenting indicates that the adverse effects of this style of parenting may be greater among White youngsters than among ethnic minority youth (Chao, 1994; Dornbusch et al., 1987; Lamborn et al., 1996; Morrison Gutman, Sameroff, & Eccles, 2002; Ruiz, Roosa, & Gonzales, 2002; Schweingruber & Kalil, 2000; Steinberg et al., 1994).

At least two explanations have been offered for this finding. First, because ethnic minority families are more likely to live in dangerous communities, authoritarian parenting, with its emphasis on control, may be less harmful than in more positive settings and may even carry some benefits. Second, the distinction between authoritative versus authoritarian parenting may not always make sense when applied to parents from other cultures (Chao, 1994, 2001; Gonzales, Cauce, & Mason, 1996). For example, non-White parents frequently combine a very high degree of strictness (similar to White authoritarian parents) with warmth (similar to White authoritative parents; Formoso, Ruiz, & Gonzales, 1997; Rohner & Pettengill, 1985; Smetana & Gaines, 1999; Yau & Smetana, 1996). If researchers accustomed to studying White families focus too much on parents' strictness when observing family relationships, they may mislabel other ethnic groups' approaches to child rearing—which appear very controlling, but which are neither aloof nor hostile—as authoritarian when they are not (Gonzales et al., 1996).

Ethnic groups in the United States also differ in the expression of intimacy between adolescents and parents.

Some of these differences may have more to do with recency of immigration into the United States than with ethnicity per se. One study of late adolescents found that, for example, Vietnamese American and Chinese American individuals felt less comfortable talking to their parents about such intimate matters as sex or dating than did Filipino Americans or Mexican Americans, who in turn felt less comfortable than European Americans. The researchers speculated that these differences reflected ethnic differences in norms of formality in family relationships, especially in relationships between adolescents and their fathers (Cooper, Baker, Polichar, & Welsh, 1994). Other studies indicate that ethnic minority American adolescents, more than White adolescents, are likely to believe that it is important to respect, assist, and support their family (Fuligni, Tseng, & Lam, 1999), although ethnic differences in adolescents' *beliefs* and *expectations* appear to be more sizable than ethnic differences in how adolescents and their parents actually interact. Indeed, except for families who are recent immigrants to the United States, relations between American adolescents and their parents appear surprisingly similar across ethnic groups (Fuligni, 1998).

### *Relationships with Siblings*

Less is known about adolescents' relations with their brothers and sisters than with their parents. During adolescence relationships with siblings, and especially with younger siblings, generally become more egalitarian but also more distant and less emotionally intense (Buhrmester & Furman, 1990; Cole & Kerns, 2001). Despite these changes, the quality of sibling relationships between childhood and adolescence remains remarkably stable, and siblings who are relatively closer during middle childhood also are relatively closer as young adolescents (Dunn, Slomkowski, & Beardsall, 1994).

Early adolescents commonly describe their relationships with siblings and with parents similarly in terms of power differentials and the degree to which the relationship provides assistance and satisfaction (Furman & Buhrmester, 1985; Raffaelli & Larson, 1987). By contrast, sibling relationships are perceived as more similar to friendships than to parent-adolescent relationships with respect to the provision of companionship and the importance of the relationship (Furman & Buhrmester, 1985; Raffaelli & Larson, 1987). As children mature from childhood to early adolescence, conflict increasingly typifies sibling relationships (Brody, Stoneman, &

McCoy, 1994), with adolescents reporting more negativity in their sibling relationships compared to their relationships with friends (Buhrmester & Furman, 1990). Negative interactions between siblings are especially common in families under economic stress (K. Conger, R. D. Conger, & Elder, 1994). Like conflicts in parent-adolescent relationships, high levels of sibling conflict in early adolescence gradually diminish as adolescents move into middle and late adolescence. As siblings mature, relations become more egalitarian and supportive, and, as with the parent-adolescent relationship, siblings become less influential as adolescents expand their relations outside the family (Hetherington et al., 1999).

Several researchers have uncovered important connections among parent-child, sibling, and peer relationships in adolescence. Extensive findings imply that the quality of parent-adolescent relationships may influence the quality of relations among adolescent siblings, which in turn influences adolescents' relationships with peers (e.g., Brody et al., 1994; MacKinnon-Lewis, Starnes, Volling, & Johnson, 1997; Paley, Conger, & Harold, 2000; Reese-Weber, 2000), though the causal status of these interrelations has yet to be conclusively documented. Harmony and cohesiveness in parent-adolescent relationships are associated with less sibling conflict and more positive sibling relationships, whereas adolescents who experience maternal rejection and negativity are more likely to display aggression with siblings (e.g., Hetherington et al., 1999). Moreover, children and adolescents learn much about social relationships from sibling interactions, and they may bring this knowledge and experience to friendships outside the family (Brody et al., 1994; McCoy, Brody, & Stoneman, 1994; Updegraff, McHale, & Crouter, 2000). In poorly functioning families, aggression between unsupervised siblings may provide a training ground for learning, practicing, and perfecting antisocial and aggressive behavior (Bank, Reid, & Greenley, 1994; Slomkowski, Rende, K. Conger, Simons, & R. Conger, 2001).

The quality of sibling relationships has been linked not only to adolescents' peer relations but also to their adjustment in general (Seginer, 1998; Stocker, Burwell, & Briggs, 2002). Positive sibling relationships contribute to adolescents' academic competence, sociability, autonomy, and self-worth (e.g., Hetherington et al., 1999; Rowe, Rodgers, Meseck-Bushey, & St. John, 1989). A close sibling relationship can partially ameliorate the negative effects of not having friends in school

(East & Rook, 1992), and siblings can serve as sources of advice and guidance (Tucker, Barber, & Eccles, 1997; Tucker, McHale, & Crouter, 2001). At the same time, siblings are often similar in problem behaviors (K. Conger, R. Conger, & Elder, 1997; Slomkowski et al., 2001), such as early sexual activity, early pregnancy (e.g., East & Jacobson, 2001; East & Kiernan, 2001), drug use, and antisocial behavior (e.g., Ardel & Day, 2002; Bullock & Dishion, 2002; Rowe et al., 1989). These similarities raise the question of whether older siblings' problem behaviors are a risk factor for younger siblings.

As one might expect, unequal treatment from mothers or fathers often is associated with conflict among siblings (Brody, Stoneman, & Burke, 1987) and also with problematic individual outcomes such as depression and antisocial behavior (Reiss et al., 1995). Studies show that differences in siblings' real and perceived family experiences are related to different patterns of development (Anderson, Hetherington, Reiss, & Howe, 1994; Barrett Singer & Weinstein, 2000; K. Conger & R. Conger, 1994; Mekos, Hetherington, & Reiss, 1996). In general, better adjusted adolescents are more likely than their siblings to report that their relationship with their mother was close, their relations with brothers or sisters were friendly, they were involved in family decision making, and they were given a high level of responsibility around the house (Daniels, Dunn, Furstenberg, & Plomin, 1985). Studies show that youngsters, especially as they get older, generally appreciate the reasons why parents treat siblings differently and document that sibling relationships are strained only when this differential treatment is perceived as unfair (Feinberg, Neiderhiser, Simmens, Reiss, & Hetherington, 2000; Kowal & Kramer, 1997).

### Extrafamilial Relationships and Influences

Relationships with peers differ from those with family members in the distribution of power between participants and the permanence of the affiliation (Laursen & Bukowski, 1997). Peer relationships, moreover, are voluntary and transitory; participants freely initiate and dissolve interconnections. Neither party in peer relationships can impose the terms of social interaction on the other (Piaget, 1932/1965); whether an affiliation persists hinges on mutually satisfactory terms and outcomes (Laursen & Hartup, 2002). These distinctive features of relationships among peers provide potentially important

opportunities that differ from the socialization experiences that families provide and that are key to mastering skills for both independence and interdependence.

This section examines networks of relationships beyond the family. We emphasize the nature and significance of friendships and of romantic relationships during adolescence and also address the extent and implications of interrelations among personal relationships.

### Social Networks and Social Status

Adolescents typically affiliate with one or more peer groups, which are commonly distinguished as *cliques* (relatively small networks of friends or persons sharing common interests or activities) or *crowds* (loose aggregations based on members' common reputations for certain attitudes, interests, or behaviors). Once formed, these groups tend to remain relatively closed to newcomers, although boundaries may become more permeable in the senior high school years. According to recent estimates, almost half of high school students are associated with one crowd, about one-third are associated with two or more crowds, and about one-sixth do not fit into any crowd (Strouse, 1999).

Cliques exist in childhood and adulthood, as well as adolescence. Adolescent cliques, however, differ from both childhood and adult cliques in the bases for membership, as well as the degree of "cliquishness." Although common interests and shared activities are important determinants of clique membership at all ages, cliques during adolescence also are important in establishing individuals' status in the social hierarchy of the high school (Eder, 1985).

In contrast, reputation-based crowds do not emerge until the early or middle adolescent years and typically become much less prominent by late adolescence. The emergence, ascendance, and decline of crowds may be linked to the normative course of adolescent psychosocial development. For example, crowds may serve as an identity "way station" or placeholder during the period between individuation from parents and establishment of a coherent personal identity (Newman & Newman, 2001). Adolescents who feel relatively more confident in their identity may consider crowd affiliations less important than those who are more uncertain. By high school, many adolescents report that being part of a crowd stifles identity and self-expression (Larkin, 1979; Varenne, 1982)—a perception that may account partly for the instability in crowd identification during

middle and late adolescence. Research with a national sample showed that two-thirds of individuals changed crowds between grades 10 and 12 (Kinney, 1993; Strouse, 1999).

Little is known about the long-term implications of identifying with particular crowds, with the exception of youth who belong to delinquent crowds (e.g., B. Brown et al., 1993; Cairns & Cairns, 1994; Dishion, 2000; Patterson, DeBaryshe, & Ramsey, 1989). Some writers argue that the tendency of group members to exaggerate the positive features of their own group while disparaging the features of others groups may be beneficial to identity development, whereas others deplore the same process as perpetuating socially dysfunctional in-group versus out-group patterns (e.g., Stone & Brown, 1998). Crowd membership has been linked to academic success and failure, which may constrain later developmentally important opportunities (B. Brown et al., 1993). A possible, but little examined, moderating factor in these outcomes is whether the crowds are specific to school contexts rather than out-of-school settings (Kiesner, Poulin, & Nicotra, 2003). Though suggestive, findings on sequelae of crowd membership during adolescence require more extensive and differentiated studies than are now available.

### Friendships

The visibility of crowd memberships notwithstanding, friendships are arguably the most prominent and significant feature of social relationships during adolescence. Adolescents commonly report that friends are their most important extrafamilial resources and influences, and relationships with friends consistently are implicated in variations in adolescent competence and well-being (for reviews, see B. Brown, 2004; Hartup & Abecassis, 2002). Moreover, self-perceived competence in friendships is a significant component of overall competence during adolescence (Masten et al., 1995). Experiences with friends appear both to influence and moderate social adaptation and academic competence (Cairns & Cairns, 1994) and provide a prototype for later close relationships (Furman & Wehner, 1994; Sullivan, 1953).

#### *The Identity of Friends*

The broad outlines of friendship formation, processes, and links to individual development have been described extensively. Adolescents choose as friends other adoles-

cents who are similar to them on some dimensions and dissimilar on others. For example, European Americans and Asian Americans have friends who are similar in substance use and academic orientation but dissimilar in the importance given to ethnicity in self-definition, whereas African American adolescents show the reverse pattern (Hamm, 2000). It may be that affiliating with others who are somewhat dissimilar is more comfortable for asserting and developing one's own identity. Such affiliative preferences may be somewhat fluid as adolescents engage and resolve identity issues. This fluidity, as well as school transitions and more diverse involvement in school and extracurricular activities (e.g., choices of courses, sports, or other activities), almost certainly contributes to the considerable instability in friendships during adolescence (Hardy, Bukowski, & Sippola, 2002; Way, Cowal, Gingold, Pahl, & Bissessar, 2001). Changing friendship patterns can be beneficial if an adolescents' new associates are more prosocial or espouse more positive goals than former associates did (e.g., Berndt, Hawkins, & Jiao, 1999; Mulvey & Aber, 1988).

Though less often studied than same-sex friendships, cross-sex friendships are a common experience in adolescence, with slightly fewer than half (47%) of adolescents reporting a cross-sex friendship (Kuttler, La Greca, & Prinstein, 1999). Acknowledging mixed-gender friendships in social groups is more common in adolescence than in middle childhood, when gender segregation is the norm in mixed-gender groups (Maccoby, 1990). Affiliations with other-sex, as well as same-sex, friends are correlated with self-perceived competence (Darling, Dowdy, Van Horn, & Caldwell, 1999).

### *Concepts of Friendship*

The changing features of friendships during adolescence parallel increasingly complex and sophisticated beliefs about and expectations of friendships (Furman & Wehner, 1994; Selman, 1980; Youniss & Smollar, 1985). Adolescents increasingly regard companionship and sharing as a necessary, but no longer sufficient, condition for closeness in friendships; commitment and intimacy are expected as well, especially among females (Youniss & Smollar, 1985). For example, adolescents, more than children, view friends' behaviors and emotions as historical, biological, and social factors affecting the individual (Livesley & Bromley, 1973; Selman, 1980). This shift to more complex understanding of behavior between friends may account partly for adolescents' perceptions that their current friendship-making

abilities are inferior to their abilities in this domain in middle childhood (Barry & Wigfield, 2002).

Research on cognitive development and peer relationships has provided little compelling evidence regarding whether developmental changes in reasoning during early adolescence lead to changes in social competence or vice-versa or, even more likely, whether there is a reciprocal relationship between the two (for a review, see Eisenberg & Morris, 2004). For example, friendships become more intimate during adolescence in ways that imply improved perspective taking, abstract thinking, and meta-cognition (Savin-Williams & Berndt, 1990), but no study has yet made these connections explicit. Similarly, links between adolescents' understanding of the structure and organization of cliques and crowds undoubtedly depends on cognitive advances (B. Brown, 2004), although this relation has not been examined directly; neither do cross-sectional studies of individual differences in cognitive maturity typically inform questions about age differences, developmental change, or cause and effect.

Linking cognitive development to close relationships with peers is further complicated by the fact that adolescents' reasoning skills, like those of adults, often may be overridden in ambiguous or multifaceted situations or those to which stereotypes can be readily applied, so that both attentiveness to shared values and concerns can be undermined (Horn, 2003; Rest, 1983). Similarly, in studies of logical reasoning, easily accessible heuristics often trump logic (e.g., Klaczynski, 1997; Klaczynski & Gordon, 1996). Moreover, although adolescent changes are extensive and profound, conceptions of friendships now appear to remain malleable into the 20s. Conceptual refinements in late adolescence and the transition to early adulthood may reflect adjustments to the distinctive experiences of that period, which may require modifications to previously held expectations of friends (Baxter, Dun, & Sahlstein, 2001). Brain development that supports advances in executive regulatory functions and social information processing may account partly for the continued development of relationship-relevant cognitive skills as early adulthood nears (E. Nelson et al., 2005; Siegel, 1999).

### *Friendship Quality*

Developmental changes in understanding of friendships is only one contrast between adolescents' friendships and children's friendships (Rubin, Bukowski, & Parker, 1998). Mutuality, self-disclosure, and intimacy (defined

as reciprocal feelings of self-disclosure and shared activities) increase markedly (Furman & Buhrmester, 1992; Sharabany, Gershoni, & Hofmann, 1981) during adolescence. Intimacy in particular is related to satisfaction with friendships during early and middle adolescence (Hartup, 1996).

Paradoxically, conflicts also are more likely between friends than between acquaintances in both childhood and adolescence. Among adolescents, topics of conflict reflect current concerns, with older adolescents reporting more conflicts regarding disrespect in private interactions with peers, and young adolescents voicing more concern about instances of disrespect and undependability that occur in public (Shulman & Laursen, 2002). Still, compared to middle childhood conflicts with friends, conflicts decline during adolescence, and those that occur are increasingly likely to be resolved effectively and are less likely to disrupt relationships (Laursen & Collins, 1994; Laursen, Finkelstein, & Betts, 2001). Having primarily opposite-gender friends may signal social incompetence and rejection by same-gender peers for some adolescents, but may be a marker of a high level of social competence and acceptance in the peer group for others (Bukowski, Sippola, & Hoza, 1999). The quality of friendships of mixed-gender friendships appears to differentiate among these relationships more for boys than the converse. Boys describe their friendships with girls as more rewarding than their friendships with other boys, but girls do not report more satisfying friendships with boys than with other girls (J. Thomas & Daubman, 2001), perhaps because friendships with girls tend to be generally more intimate and supportive than friendships with boys (Kuttler et al., 1999).

### *Developmental Significance*

Interest in adolescents' friendships has thrived largely because consistent findings attest that friendships are developmentally significant features of adolescent experience (for reviews, see Hartup, 1996; Hartup & Abecassis, 2002). The line of reasoning that emerges from these findings is as follows: Friendships are primary settings for the acquisition of skills, ranging from social competencies to motor performance (e.g., athletics, dancing) to cognitive abilities (Hartup, 1996). Poor quality adolescent friendships (e.g., those low in supportiveness and intimacy) are associated with multiple outcomes, including incidence of loneliness, depression, and decreases in achievement in school and work settings (Hartup, 1996). Difficult, conflictful relations

with peers, especially if chronic in an individual's history, have been linked persistently to negative personal and social characteristics of the individuals involved (e.g., Abecassis, Hartup, Haselager, Scholte, & van Lieshout, 2002).

During adolescence, perceptions of parents as primary sources of support decline and perceived support from friends increases, such that friendships are perceived as providing roughly the same (Helsen, Vollebergh, & Meeus, 2000; Scholte, van Lieshout, & van Aken, 2001) or greater (Furman & Buhrmester, 1992) support as parental relationships. High-quality friendships become increasingly important as sources of support for adolescents' experiencing emotional problems. Recent findings have documented that adolescents receiving little support from parents and greater support from friends report more emotional problems (Helsen et al., 2000). These results are consonant with other findings showing stronger contributions of parental than peer relationships to increased risk for depression among youth at risk for affective problems (Aseltine, Gore, & Colten, 1994). Of the relatively few studies that address both parent and peer influences, however, few have considered possibilities other than simple additive ones. One exception to this shows that parental involvement with adolescents moderates the peer influences on drinking behavior (Wood, Read, Mitchell, & Brand, 2004). In an area long dominated by simplistic views of parent-peer cross-pressures on adolescent behavior, more nuanced views are both eminently plausible and badly needed.

### *Gender-Related Patterns*

Gender differences are integral to friendship expectations of both children and adolescents (Markovits, Benenson, & Dolenszky, 2001). Indeed, girls typically report greater companionship, intimacy, prosocial support and esteem support in their close friendships than boys do (Kuttler et al., 1999). Closeness to friends, however, may create a vulnerability that could account for some negative features of girls' relationships. For example, females' current friendships tend to be of shorter duration than males' friendships, and more females than males report both actions that have harmed existing friendships and histories of dissolved friendships (Benenson & Christakos, 2003). The greater emotional intensity of girls', as compared to boys', friendships and the resulting potential vulnerability when friendship ends have been hypothesized as risk factors for depression and as one explanation for the emergence of gender

differences in internalized distress during adolescence (Cyranowski et al., 2000).

### ***Summary Comment***

Despite its salience in research, the topic of friendships as a feature of interpersonal contexts during adolescence is still in an early stage. Much important descriptive work has been done, to be sure, but studies of explanatory processes are still lacking. Among the questions requiring more urgent attention are those involving group differences (e.g., gender and racial-ethnic variations in friendship) and individual differences (e.g., the friendships of high-functioning, well adjusted adolescents versus the relationships of adolescents who appear to be less well adjusted) in the nature and significance of close friendships.

### **Romantic Relationships**

Romantic interests are both normative and salient during the adolescent years. In the United States, 25% of 12-year-olds report having had a romantic relationship in the past 18 months; by age 18, more than 70% do (Carver, Joyner, & Udry, 2003). Zani (1991) reported similar rates of involvement for studies of European youth. Despite the obvious centrality of these relationships, however, research on adolescent romantic relationships was both meager and superficial until the last decade of the twentieth century. This section distills key points from this currently burgeoning area of study.

#### ***Contexts of Romantic Development***

Romantic feelings and the initiation of dating commonly have been attributed to hormonal changes. Most current findings imply that, however, the growing nature and significance of romantic relationships during adolescence and early adulthood stem as much from a culture that emphasizes and hallows romance and sexuality as from physical maturation. Social and cultural expectations, especially age-graded behavioral norms, independently influence the initiation of dating (Dornbusch et al., 1981; Feldman, Turner, & Araujo, 1999; Meschke & Silbereisen, 1997).

Relationships with peers are a primary context for the transmission and realization of these expectations (B. Brown, 2004; Giordano, 2003). Adolescents regard being in a romantic relationship as central to “belonging” and status in the peer group (Connolly, Craig, Goldberg, & Pepler, 1999; Levesque, 1993). The link

may be a transactional one: Peer networks support early romantic coupling, and romantic relationships facilitate connections with other peers (Connolly, Furman, & Konarski, 2000; Milardo, 1982; for reviews, see B. Brown, 2004; Furman, 1999; Giordano, 2003). Other studies have documented the impact of the extensiveness of peer networks for involvement in dating (Connolly & Johnson, 1996; Taradash, Connolly, Pepler, Craig, & Costa, 2001).

Mixed-gender peer groups appear to be especially significant settings for the development of romantic relationships. Several scholars have recently documented the role of these groups (Connolly, Craig, Goldberg, & Pepler, 2004; Connolly et al., 2000; Feiring, 1999; for reviews, see B. Brown, 2004; Collins & Van Dulmen, 2006b; Giordano, 2003). According to Connolly et al. (2004), among fifth and eighth graders, participation in mixed-gender peer groups normatively preceded involvement in dyadic romantic relationships. This progression partly reflects the tendency to incorporate dating activities with mixed-gender affiliations. For these young adolescents, group-based romantic activities were more stable than other dating contexts. At the same time, being with mixed-gender groups promotes proximity and common ground that enhance two adolescents’ attraction to each other (Connolly & Goldberg, 1999).

#### ***Developmental Course***

By middle adolescence, most individuals have been involved in at least one romantic relationship; and, by the early years of early adulthood, most are currently participating in an ongoing romantic relationship (Carver et al., 2003). Middle and late adolescents (approximately, ages 14 to 18) balance time spent with romantic partners with continued participation in same-sex cliques, gradually decreasing time in mixed-sex groups; by early adulthood, time with romantic partners increases further at the expense of involvement with friends and crowds (Reis, Lin, Bennett, & Nezelek, 1993).

Most current findings portray normative experiences of adolescent romance as part of a continuous progression toward the romantic relationships of adulthood. After age 17, adolescents are no more or less likely to be involved in a romantic relationship than at earlier ages (Collins & Van Dulmen, 2006a). Older adolescents, however, tend to emphasize personal compatibility rather than focusing solely on superficial features of appearance and social status (Levesque, 1993); and couple interactions often are marked by greater interdependence and more communal orientations than was the case in

early adolescent relationships (Laursen & Jensen-Campbell, 1999). In general, differences between mid-adolescents and 25-year-olds reflect increasing differentiation and complexity of thoughts about romantic relationships but continuity in relationship motives, concerns, and expectations. In a longitudinal analysis of relationship narratives (Waldinger et al., 2002), the structure and complexity of narratives increased between middle adolescence and age 25, whereas narrative themes were surprisingly similar across the 8- to 10-year gap between waves of the study. A desire for closeness was a dominant theme in the relationships of participants at both ages. Themes of distance also were present at both ages, although in adolescence this theme was characterized by actually being on one's own, whereas at age 25 the emphasis was on making autonomous decisions. Because U.S. respondents are highly likely to reflect the wish for independence throughout adulthood, these findings imply greater continuity than discontinuity between early adults and both foregoing and succeeding periods, although explicit comparisons have not yet been reported.

### ***Developmental Significance***

Accumulating findings imply that variations in qualities of dating and romantic relationships are associated with psychosocial development during adolescence (Furman & Shaffer, 2003). Variations in the *timing* of involvement in both romantic relationships and sexual activity also have been linked to adolescent behavior and development. Findings typically have identified early dating and sexual activity as risk factors for current and later problem behaviors and social and emotional difficulties (e.g., Davies & Windle, 2000; Zimmer-Gembeck, Siebenbruner, & Collins, 2001). At the same time, having a romantic relationship and having a relationship of high quality are associated positively with romantic self-concept and, in turn, with feelings of self-worth (Connolly & Konarski, 1994; Kuttler et al., 1999); longitudinal evidence indicates that, by late adolescence, self-perceived competence in romantic relationships emerges as a reliable component of general competence (Masten et al., 1995). Several writers have suggested that romantic relationships may be implicated in key processes of identity formation during adolescence, though no research currently supports this hypothesis (e.g., Furman & Shaffer, 2003; Sullivan, 1953). The findings linking adolescent romantic relationships and psychosocial development generally do not substantiate

causal connections between the two, though correlational findings document associations that should be explained. For example, longitudinal research with a German sample (Seiffge-Krenke & Lang, 2002) showed that quality of romantic relationships in middle adolescence was significantly and positively related to commitment in other relationships in early adulthood.

The developmental significance of romantic relationships depends more heavily on the behavioral, cognitive, and emotional processes that occur in the relationship than on the age of initiation and the degree of dating activity that a young person experiences (Collins, 2003). Interactions with romantic partners are associated with distinctive patterns of experience for adolescents. Adolescents in romantic relationships, for example, report experiencing more conflict than other adolescents (Laursen, 1995). Moreover, conflict resolution between late-adolescent romantic partners more often involves compromise than does conflict resolution in early adolescent romantic pairs (Feldman & Gowen, 1998). Mood swings, a stereotype of adolescent emotional life, are more extreme for those involved in romantic relationships (Larson, Clore, & Wood, 1999). Participants in the National Longitudinal Study of Adolescent Health who had begun romantic relationships in the past year manifested more symptoms of depression than adolescents not in romantic relationships (Joyner & Udry, 2000). This elevation may be due to breakups, rather than to involvement in a romantic relationship per se. Indeed, the most common trigger of the first episode of a major depressive disorder is a romantic breakup (Monroe, Rohde, Seeley, & Lewinsohn, 1999).

Little information is available on how time devoted to romantic relationships is spent or how teenage romantic partners behave toward one another. Without such information, it is difficult to identify possible functions of the relationships, whether positive or negative, for long-term growth (Collins, 2003).

### ***Individual Differences***

Variations in relationship expectancies reflect prior relationship experiences. Adolescents who have poor relationships with parents and peers appear to be at risk for later physical and relational aggression with romantic partners (J. R. Linder & Collins, 2005; J. L. Linder, Crick, & Collins, 2002). Moreover, the cognitive and behavioral syndrome known as *rejection sensitivity* arises from experiences of rejection in parent-child relationships and also in relations with peers and, possibly,

romantic partners. Rejection sensitivity in turn predicts expectancies of rejection that correlate strongly with both actual rejection and lesser satisfaction in subsequent relationships (Downey, Bonica, & Rincon, 1999). Similarly, individual differences in the history of attachment security in relationships with caregivers in early life and in accounts of those relationships in early adulthood are correlated with characteristics of romantic relationships in early adulthood (Collins & Van Dulmen, 2006b). Other individual differences play a role as well. Initial findings (e.g., Connolly & Konarski, 1994) imply that adolescent relationships parallel adult relationships in the relevance of individual partners' self-esteem, self-confidence, and physical attractiveness to the timing, frequency, duration, and quality of relationships (Long, 1989; Mathes, Adams, & Davies, 1985; Samet & Kelly, 1987).

### **Summary Comment**

B. Brown (2004) has observed that neither affiliations nor close relationships with peers, whether friends or romantic partners, can be regarded as uniformly positive or negative influences in adolescent development. This conclusion echoes Hartup's (1996) influential appraisal that the nature and extent of impact is not a main effect of whether an adolescent has mutual relationships with other adolescents, but is moderated significantly by the identity of the other and the quality of the relationships. This relatively recent realization promises both a more complex and more informative recognition of the relevance of peers and romantic partners to adolescent development.

### **Interrelations of Relationships**

Adolescents' relationships with family members and with peers become increasingly interrelated over time. Despite the stereotype of incompatible or contradictory influences of parents and friends, parent-child relationships set the stage for both the selection of friends and the management of these relationships (Parke & Buriel, 1998). Links between qualities of friendships and romantic relationships, as well as between family and romantic relationships, are equally impressive (Collins, Hennighausen, et al., 1997). At the same time, relationships with parents, friends, and romantic partners serve overlapping, but distinctive, functions. Typical exchanges in each of these types of dyads differ accordingly. Displaying safe-haven and secure-base behaviors with best friends is associated positively with displaying

these behaviors with dating partners. Perhaps, the growing importance of romantic relationships makes the common relationship properties across types of relationships more apparent than before. Equally likely, the parallels between early adults' relationships reflect their common similarity to prior relationships with parents and peers (Owens, Crowell, Treboux, O'Connor, & Pan, 1995; Waters, Merrick, Treboux, & Albersheim, 2000).

Similarity, however, is not the only indicator of relations among these relationships. For example, adolescents with insecure or otherwise unsatisfying relationships with parents initiate dating and sexual activity earlier than adolescents with more positive family relationships. The quality of these apparently compensatory early involvements, however, is typically poorer than that of extrafamilial relationships for youth with more beneficent family histories (Collins & Van Dulmen, 2006b). In comparison to childhood relationships, the diminished distance and greater intimacy in adolescents' peer relationships may both satisfy affiliative needs and also contribute to socialization for relations among equals. Intimacy with parents provides nurturance and support but may be less important than friendships for socialization to roles and expectations in late adolescence and early adulthood (Collins & Laursen, 2004a; Laursen & Bukowski, 1997). As noted earlier, research also points to important interrelations among adolescents' relationships with siblings and with friends. The nature and processes of these developmentally significant interrelations of relationships promise to become an increasingly prominent focus of future research.

## **SOCIAL INSTITUTIONS AS CONTEXTS FOR ADOLESCENT PSYCHOSOCIAL DEVELOPMENT**

Relationships with family members, friends, and romantic partners exist in a broader context of social institutions that also contribute to psychosocial development. These contributions are largely mediated through close relationships. These relationships also may moderate the impact of contexts on adolescents. Parent-adolescent and peer relationships in dangerous neighborhoods, for instance, appear to differ from those in safe ones, and the organization of schools with respect to age-grading and school transitions may strongly affect the structure, nature, and importance of peer relationships. This section outlines the role of neighborhoods, schools, and social

settings that potentially transform the interpersonal worlds of adolescents.

### Neighborhoods

Research on the ways in which neighborhoods influence adolescent development has expanded greatly since 1990 (Leventhal & Brooks-Gunn, 2004). The main challenge in research on neighborhood influences is demonstrating that neighborhood conditions affect adolescents' development above and beyond the influence of proximal contexts such as families and peer groups. These efforts typically require comparing adolescents whose family situations are similar, but who live in very different types of neighborhoods. In addition, a few researchers have tracked the psychological development and behavior of adolescents before and after their families moved from a poor neighborhood into a more advantaged one (e.g., Ludwig, Duncan, & Hirschfield, 2001).

Most research has focused on the effects of neighborhood poverty, although other characteristics of neighborhoods (e.g., the ethnic composition, crime rate, or availability of social service programs) potentially impinge on adolescents' relationships and development (Brooks-Gunn, Duncan, Klebanov, & Sealander, 1993; Coulton & Pandey, 1992; Duncan, 1994; Ensminger, Lamkin, & Jacobson, 1996; Sampson, 1997). Evidence from both cross-sectional and longitudinal studies documents the negative effects of poor neighborhoods on behavior and mental health, above and beyond effects attributable to family poverty or attending an underfunded school. Adolescents from impoverished urban communities are more likely than adolescents from equally poor households in better neighborhoods to bear children as teenagers, to become involved in criminal activity, and to achieve less in high school (Leventhal & Brooks-Gunn, 2004). Findings generally support the inference that it is the absence of affluent neighbors, rather than the presence of poor neighbors, which elevates risks for adolescents from impoverished communities (Duncan, 1994; Ensminger et al., 1996; Leventhal & Brooks-Gunn, 2004). Although virtually all neighborhood research has focused on urban adolescents, growing up in poor *rural* communities also appears harmful to adolescents' development and well-being (McLoyd, 1990), but whether the effects of urban and rural poverty reflect the same processes is not known.

Three different mechanisms have been suggested by which neighborhood conditions affect the behavior and

development of adolescents (Leventhal & Brooks-Gunn, 2004). First, neighborhood conditions shape the norms that guide individuals' values and behaviors. Poverty in neighborhoods breeds social isolation and social disorganization, undermining a neighborhood's sense of "collective efficacy" (the extent to which neighbors trust each other, share common values, and can count on each other to monitor the activities of youth in the community; Sampson, Raudenbush, & Earls, 1997). As a consequence, deviant peer groups more readily form and influence the behavior of adolescents in these communities. Rates of teen pregnancy, school failure, and antisocial behavior are all higher in neighborhoods in which collective efficacy is low (J. Ainsworth, 2002; N. Bowen, G. Bowen, & Ware, 2002; G. Bowen & Chapman, 1996; Brooks-Gunn et al., 1993; Herrenkohl et al., 2000; Paschall & Hubbard, 1998; Sampson, 1997; Sampson & Laub, 1994; Simons, Johnson, Beaman, R. Conger, & Whitbeck, 1996; Tolan, Gorman-Smith, & Henry, 2003). Some writers (e.g., Crane, 1991; Simons et al., 1996) further suggest that social problems are contagious under conditions of low collective efficacy. For example, adolescents who associate with delinquent peers are more likely to be drawn into criminal and delinquent activity (Simons et al., 1996). Similarly, adolescents who live in neighborhoods with high rates of teenage childbearing encounter relatively greater tolerance of this behavior, which in turn can affect their own attitudes toward premarital childbearing (Baumer & South, 2001; South & Baumer, 2000).

Second, stressors associated with neighborhood poverty undermine the quality of parenting in families, potentially affecting adolescent development adversely. Across all ethnic groups, poverty has been linked to harsh, inconsistent, and punitive parenting (Bradley, Corwyn, Burchinal, McAdoo, & García Coll, 2001; R. Conger et al., 1992; McLoyd, 1990; Patterson, Reid, & Dishion, 1992; Ramirez-Valles, Zimmerman, & Juarez, 2002; Simons et al., 1996). Ineffective parental supervision and low levels of adult social support, in turn, are associated with antisocial activity (G. Bowen & Chapman, 1996; Hoffman, 2003; Lynam et al., 2000; McCabe, Barnett, & Robbins, 1996). Furthermore, adolescents in poor neighborhoods frequently are exposed to chronic community violence, which increases the risk of behavioral and emotional problems (Biafora, Warheit, Vega, & Gil, 1994; DuRant, Cadenhead, Pendergrast, Slavens, & Linder, 1994; Osofsky, 1997; Stevenson, 1998; Vermeiren, Ruchkin, Leckman, Deboutte, & Schwab-Stone, 2002).

Third, adolescents in poor neighborhoods have access to fewer resources than do those who grow up in more advantaged communities. As a result, adolescents in poor communities have fewer opportunities to engage in activities that facilitate positive development and lower likelihood of receiving assistance when they are having difficulties (Leventhal & Brooks-Gunn, 2004); adolescents in communities with relatively greater resources, such as higher quality schools, are at lower risk for antisocial behavior (Kowaleski-Jones, 2000). Moreover, in neighborhoods with higher levels of resources and greater feelings of cohesion, adults' beliefs about teenagers tend to be more favorable, probably because the casual interactions between adults and adolescents in these settings are more positive than the interactions in less advantaged environments (Zeldin & Topitzes, 2002).

Although experts agree that neighborhoods exert an impact on adolescent behavior and development, the estimated strength of neighborhood influences is fairly modest once the likely contributions of other, more proximal influences are taken into account. Furthermore, most of the impact of neighborhoods on adolescent development appears to be indirect, transmitted through social relationships in families, peer groups, or schools (D. Jones, Forehand, Brody, & Armistead, 2002; Schwartz, Hopmeyer-Gorman, Toblin, & Abouezzeddine, 2003; Teitler & Weiss, 2000). Studying relevant mediating processes and those through which neighborhood conditions moderate the impact of relationships on adolescent development is likely to be more fruitful than searching for direct neighborhood effects. It is worth noting that the cumulative impact of multiple contexts appears to matter more than any single context alone in explaining why some adolescents are more successful than others (T. Cook, Herman, Phillips, & Settersten, 2002). Simply put, the greater number of positive features an adolescent's environment contains, the better off he or she will be; conversely, the more sources of contextual risk adolescents are exposed to, the greater their chances of developing problems (Gutman, Sameroff, & Eccles, 2002; Herrenkohl et al., 2000; D. Jones et al., 2002).

### Schools

Adolescents in industrialized societies typically change schools at least once during their teenage years, and researchers have devoted considerable attention to the nature and impact of school transitions. Research suggests that school transitions can disrupt the academic perfor-

mance, behavior, and self-image of adolescents, but this disruption generally appears temporary. Over time, most youngsters adapt successfully to changing schools, especially when other contexts—family and peer relationships, for example—remain stable and supportive and when the new school environment is well suited for adolescents (Anderman & Midgley, 1996; DuBois, Eitel, & Felner, 1994; Gillock & Reyes, 1996; Koizumi, 1995; Lord, Eccles, & McCarthy, 1994; Teachman, Paasch, & Carver, 1996; Wigfield & Eccles, 1994).

Not all students experience the same degree of stress when changing schools (Fenzel, 2001; Roeser, Eccles, & Freedman-Doan, 1999). Students who have more academic and psychosocial problems before making a school transition cope less successfully with it (Anderman, 1998; Berndt & Mekos, 1995; E. Carlson et al., 1999; Murdock, Anderman, & Hodge, 2000; Roeser et al., 1999; Safer, 1986). More vulnerable adolescents, those with fewer sources of social support, and those moving into more impersonal schools may be relatively more susceptible to the adverse consequences of changing schools. Poor inner-city youngsters appear to be especially likely to show transition-related negative decrements in self-esteem, achievement, classroom preparation, perceptions of the school environment, reports of social support, and participation in extracurricular activities (Eccles, 2004; Seidman, Aber, Allen, & French, 1996; Seidman, Allen, Aber, Mitchell, & Feinman, 1994). Interpersonal relationships play a role, as well. Adolescents who have close friends before and during the transition tend to adapt more successfully to the new school, although the benefits of staying with one's friends may accrue only to students who had been doing well previously; students who had been doing poorly adjust better if they enroll in a different school, away from their friends (Schiller, 1999).

One of the most commonly reported findings on adolescent school transitions is that students' academic motivation and school grades drop as they move into middle or junior high school (Eccles, 2004; Gentry, Gable, & Rizza, 2002; Gutman & Midgley, 2000; Murdock et al., 2000). Students' self-esteem also declines during this transition but increases somewhat during the early high school years. These findings suggest that the initial decline reflects students' temporary difficulties in adapting to the shift from an elementary to a secondary school environment (Wigfield, Eccles, Mac Iver, Reuman, & Midgley, 1991). Several features of secondary schools may be involved. Because scores on standardized achievement tests do not decline during this

same time, the decline in school grades may reflect changes in grading practices and student motivation rather than in students' knowledge or ability. Some difficulties may stem primarily from the failure of middle and junior high schools to meet the particular developmental needs of young adolescents. Eccles (2004; Eccles, Lord, & Midgley, 1991; Eccles et al., 1993; Roeser et al., 1999) has argued that junior high schools are larger and less personal than elementary schools and that, moreover, middle and junior high school teachers hold different beliefs about students than do elementary school teachers—even when they teach students of the same chronological age (Midgley, Berman, & Hicks, 1995). Teachers in junior high schools are less likely to trust their students and more likely to emphasize discipline, which creates a mismatch between what students at this age desire (more independence) and what their teachers provide (more control). Further, junior high teachers tend more than others to believe that students' abilities are fixed and not easily modified through instruction—a belief that interferes with their students' achievement (Eccles, 2004).

Eccles' findings are consonant with findings that adolescents attending more personal, less departmentalized schools do better than those in more rigid and more anonymous schools (Lee & J. Smith, 1993). Generally, changing schools also is easier on students who move into small rather than large institutions (Russell, Elder, & Conger, 1997). Moreover, studies of the immediate classroom environment indicate that the same factors that influence positive adolescent adjustment at home are important at school. Students achieve and are engaged more in school when they attend schools that are both responsive and demanding. In addition, academic functioning and psychological adjustment each affect the other, so that a school climate in which teachers are supportive and relationships between students and teachers are positive, but also demanding, enhances both adolescents' psychological well-being and their achievement (Blum & Rinehart, 2000; Eccles, 2004; Gutierrez, 2000; Phillips, 1997; Roeser & Eccles, 1998; Roeser, Eccles, & Sameroff, 1998). Both students and teachers are more satisfied in classes that combine a moderate degree of structure with high student involvement and high teacher support, a finding that has emerged in studies of both White and non-White students (Langer, 2001; Wentzel, 2002). Students in classes that are too task oriented, especially when they also emphasize teacher control, tend to feel anxious, uninter-

ested, and unhappy (Moos, 1978). Students in schools in which teachers are supportive but firm and maintain high, well-defined standards for behavior and academic work have stronger bonds to their school and more positive achievement motives; these beliefs and emotions, in turn, lead to fewer problems, better attendance, lower rates of delinquency, more supportive friendships, and higher scores on tests of achievement (Eccles, 2004; Roeser et al., 1998; A. Ryan & Patrick, 2001; Way & Pahl, 2001).

### The Workplace

Most American adolescents—a far larger proportion than elsewhere in the world—hold paid jobs during the school year. For example, about three-quarters of American high school juniors hold jobs during the school year, whereas only one-quarter of Japanese and Taiwanese juniors do (Larson & Verma, 1999). Paid employment during the school year is even rarer in most European countries and virtually nonexistent in many, such as France, Hungary, Russia, and Switzerland; in European countries where adolescents are employed during the school year, they tend to work very few hours each week and are employed in more informal jobs, like babysitting (Flammer & Schaffner, 2003). Although European adolescents are less likely than their American counterparts to hold paying part-time jobs during the school year, they are more likely to work in school-sponsored or government-sponsored apprenticeships (Hamilton & Hamilton, 2004; Kantor, 1994; Mortimer, 2003).

Most employed students spend considerable amounts of time in the workplace. Not surprisingly, the impact of paid employment on the psychosocial development of adolescents has been the focus of numerous studies (see Staff, Mortimer, & Uggen, 2004, for a detailed review). This research has addressed three broad questions: (1) whether working helps adolescents develop a sense of responsibility; (2) whether working interferes with other activities, such as school or extracurricular participation; and (3) whether working promotes the development of negative behaviors, such as drug and alcohol use. Most research has been cross-sectional, but several longitudinal studies of the impact of employment on adolescent development have distinguished between characteristics of adolescents that predict entry into the labor force versus characteristics that appear to develop as a consequence of employment. Generally, the effects of employment largely depend on the number of hours worked each

week rather than the type of job held. Several studies suggest deleterious consequences of employment when time at work exceeds 20 hours per week. In smaller doses, however, working seems to have neither a positive or negative effect on adolescents' psychological development (for a recent review, see Staff et al., 2004).

With respect to the questions that have driven research on adolescent work, research findings provide no support for the popular belief that holding a job fosters the development of responsibility or other positive aspects of psychosocial development (Mortimer & Johnson, 1998; Steinberg et al., 1993; Wright, Cullen, & Williams, 1997). Indeed, adolescents who have jobs are more likely than nonworkers to express cynical attitudes toward work and to endorse unethical business practices (Steinberg, Greenberger, Garduque, Ruggiero, & Vaux, 1982). Although working may help adolescents become more responsible when their work makes a genuine contribution to their family's welfare, as it often did during the Great Depression (Elder, 1974), most contemporary adolescents work mainly to earn their own spending money.

Regarding the impact of working on adolescents' involvement in other activities, most notably schooling, findings show unequivocally that adolescents who work long hours are absent from school more often, are less likely to participate in extracurricular activities, report enjoying school less, spend less time on their homework, and earn lower grades. Although the impact on students' actual grades and achievement test scores is small (Barton, 1989), students who work a great deal report paying less attention in class, exerting less effort on their studies, and skipping class more frequently (Steinberg & Dornbusch, 1991). These results occur both because youngsters who are less interested in school choose to work longer hours and because working long hours leads to disengagement from school—meaning that intensive employment during the school year most threatens the school performance of those students who can least afford to have their academic performance decline (Mihalic & Elliott, 1997; Schoenhals, Tienda, & Schneider, 1998; Steinberg & Cauffman, 1995; Warren, 2002).

Regarding the impact of working on negative behavior and adjustment, evidence suggests links between working long hours and increases in aggression, school misconduct, precocious sexual activity, and minor delinquency (Gottfredson, 1985; Rich & S. Kim, 2002; Wright et al., 1997). Smoking, drinking, and drug use are also higher among teenage workers than nonworkers,

especially among students who work long hours (e.g., Bachman & Schulenberg, 1993; Mihalic & Elliott, 1997; Mortimer & Johnson, 1998; Steinberg et al., 1993; Wu, Schlenger, & Galvin, 2003).

### Leisure Settings

Adolescents in industrialized societies have a considerable amount of time to devote to activities of their choosing. Although systematic research on the ways in which leisure influences adolescent development has begun only recently (J. Brown & Cantor, 2000; Larson & Verma, 1999; Roberts, Henriksen, & Foehr, 2004; Staff et al., 2004; Verma & Larson, 2003), it is apparent that, for U.S. adolescents, leisure typically occupies more waking hours (between 40% and 50%) than do school and work combined (between 35% and 40%; Larson, 2000). Teenagers spend more time in leisure activities than they do in school-related activities, more time alone than with members of their family, and considerably more time “wired” to music, the Internet, or television than “tuned into” the classroom (Csikszentmihalyi & Larson, 1984; Roberts et al., 2004; Shanahan & Flaherty, 2001; Staff et al., 2004).

Use of free time varies widely among individuals. In one study of American youth that tracked time use over the high school years (Shanahan & Flaherty, 2001), several distinct groups of students emerged. One especially busy group (about one-third of the sample in all grades) spent considerable time in a wide range of activities, including extracurricular activities, paid work, schoolwork, time with friends, and household chores. A second group, which made up about one-fourth of the sample, was similarly busy but did not hold a paying job. A third group, whose numbers increased from about 12% in the ninth grade to 20% in the 12th grade, devoted substantial time to a paying job but spent little time on other activities. A fourth group (roughly 20%) did not spend time in work or extracurricular activities but spent a substantial amount of time socializing with friends. Although adolescents' time use patterns changed somewhat with age, individuals who were busy at the beginning of high school typically were likely to be busy throughout high school. Overall, the results suggest that adolescents' free time is not best thought of as a “zero-sum” phenomenon, where involvement in one activity necessarily displaces involvement in another. Rather, there are very busy, well-rounded adolescents, who have substantial time commitments across many

different activities, and not-so-busy adolescents, who do not. Generally, the relatively busier adolescents also were better adjusted and more achievement-oriented than their classmates, but whether their better adjustment caused or resulted from their busy schedules could not be determined.

Adolescents choose their leisure activities, whereas their time at school and work mainly is dictated by others (e.g., teachers or supervisors); not surprisingly, studies show that adolescents report being in a better mood during leisure activities than during school or work (Csikszentmihalyi & Larson, 1984). Leisure activities that are both structured and voluntary (e.g., sports, hobbies, artistic activities, or clubs) seem to carry special benefits for adolescents' psychological well-being (Larson, 2000). When in school, adolescents report moderate levels of concentration but very low levels of motivation or interest in what they are doing. With friends and when participating in unstructured leisure activities (e.g., watching TV), teenagers report moderate levels of motivation and interest but low levels of concentration. It is only when adolescents are playing sports or involved in the arts, a hobby, or some sort of extracurricular organization that they report high levels of *both* concentration and interest. Participation in structured leisure activities, such as hobbies or sports, has been shown to be the most positive way for adolescents to spend free time, in terms of their psychological development (McHale, Crouter, & Tucker, 2001).

Researchers have spent considerable time studying links between extracurricular participation and psychological development, but firm conclusions are difficult because few studies separate cause and effect. For example, although researchers generally find that extracurricular participants have higher self-esteem than nonparticipants, it is not clear whether students with high self-esteem are simply more likely to volunteer for extracurricular activities, whether participation makes students feel better about themselves, or whether some other factor (e.g., having positive family relationships) is associated both with extracurricular participation and with better mental health (Gore, Farrell, & Gordon, 2001; Spreitzer, 1994). Findings from the few studies that tracked students over time imply that participation in an extracurricular activity—especially in athletics or fine arts—improves students' performance in school and reduces the likelihood of dropping out; deters delinquency, drug use, and other types of risk taking; and enhances students' psychological well-being and social

status (Broh, 2002; Eder & Kinney, 1995; Mahoney & Cairns, 1997; J. McNeal, 1995; Savage & Holcomb, 1999). Extracurricular activities are especially beneficial among adolescents whose network of friends also participates in the same activity—an indicator, perhaps, of membership in a peer group that is involved in prosocial activities that revolve around the school (Mahoney, 2000). Finally, extracurricular activities may foster psychosocial development because of the opportunities for relationships with adults such as coaches or mentors. Although this possibility has received scant attention from researchers, recent studies show that the development of close relationships with nonfamilial adults is a normative and beneficial part of adolescence in many communities (Beam, Chen, & Greenberger, 2002; Greenberger, Chen, & Beam, 1998; Rhodes, Grossman, & Resche, 2000).

The impact of the media on teenagers' behavior and development has been the subject of extensive debate but little conclusive scientific research. One formidable problem in interpreting studies of media use and adolescent development is the difficulty of disentangling cause and effect, because adolescents *choose* which mass media they are exposed to (Roberts et al., 2004). Thus, although studies have documented that adolescents who watch a lot of television and movies are significantly more troubled (e.g., bored, unhappy, and in trouble at home or school) than adolescents who watch less often, it is not known whether large doses of mass media cause problems; more plausibly, adolescents with more problems watch more TV, perhaps as a way of distracting themselves from their troubles (Roberts & Foehr, 2003). Similarly, although students who watch relatively more TV and videos and listen to relatively more music earn lower grades in school than their peers, it is impossible to say whether high media use leads to poor school performance, results from poor school performance, or is correlated with poor school performance because of some other factor (e.g., adolescents with poor family relationships both watch a lot of TV and do badly in school).

These inferential problems notwithstanding, a few generalizations about media usage and adolescent development have enough supportive evidence, however indirect, to generate some consensus among experts in the area. Most of the relevant research has focused on television, and the bulk of the research has focused on the three topics: sex, violence, and drugs. Exposure of adolescents to programs with sex, violence, and drug use is considerable (Roberts et al., 2004).

Studies that unequivocally demonstrate that exposure to messages about sex, violence, and drugs causes changes in adolescents' behavior, however, are rare. The strongest evidence is in the area of violence; numerous studies have shown that repeated exposure to violent imagery on television leads to aggressive behavior in children and youth, especially among those who have prior histories of aggression (e.g., Johnson, Cohen, Smailes, Kasen, & Brook, 2002). Exposure to violence has been linked conclusively—though not exclusively—to aggressive behavior toward others, heightened tolerance of violence, and greater desensitization to the effects of violence on others (Cantor, 2000; Roberts et al., 2004). Data linking exposure to messages about sex and drugs to actual sexual activity or drug use are less compelling than those linking violence and aggressive behavior (Strasburger & Donnerstein, 1999).

### Summary Comment

In general, research on institutional and leisure-time influences on adolescents and the relationships of which they are part documents forces that often determine the nature and extent of interpersonal influences in adolescent development. In some cases (e.g., the contributions of neighborhoods), contexts constrain or amplify dyadic and group effects. In others (e.g., leisure, media use), largely extrarelational experiences directly contribute to the behavior patterns and expectations that help to shape adolescents' orientations to current and future roles. Capturing these complex interrelations among levels of influence is a continuing challenge in research on adolescent development in interpersonal contexts.

## INTERPERSONAL CONTEXTS AND THE PSYCHOSOCIAL TASKS OF ADOLESCENCE

Adolescence has long been viewed as a period of tension between two developmental tasks: (1) increasing connections to others beyond the family and conformity to societal expectations, while simultaneously (2) attaining individual competence and autonomy from the influence of others. Implicitly, researchers have weighted questions of how adolescents separate themselves from others more heavily than questions of how they form connections and close relationships. Balance has been restored partially by recent research on intimate and romantic relationships in adolescence (e.g., Collins, 2003; Furman, Brown, & Feiring, 1999), but studies of auton-

omy and identity still far exceed studies of close relationships.

The focus of this section is independence and interdependence in relation to psychosocial development. An overarching issue is the contributions of interpersonal contexts to both of these psychosocial tasks during adolescence.

### Developing a Sense of Independence

The imbalance between the study of autonomy and the study of connectedness in adolescence has resulted from several factors. First, the study of human development has long been dominated by Western views of mental health and maturity, which emphasize the development of personal agency and self-definition over the growth of interpersonal competence and social interconnectedness (Baumeister & Tice, 1986). Second, the study of adolescence in particular has been characterized by the strong, enduring influence of psychoanalytic and neoanalytic theory, both of which have stressed the significance of adolescence as a period for the full maturation of ego skills, including those involving self-regulation (Blos, 1967, 1979) and the development of a sense of personal identity (Erikson, 1968). Finally, scholars of adolescence historically have attended particularly to the processes through which adolescents separate or distance themselves from authority figures, especially parents (Collins, Gleason, et al., 1997; Steinberg, 1990). As a result, adolescence continues to be cast as a critical period for the development of autonomy, and researchers remain intensely interested in questions of how and along what timetable individuals establish independence.

Independence is a multifaceted construct that refers, somewhat loosely, to a lengthy list of phenomena that vary in their interrelatedness. The definition of adolescent autonomy suggested by Douvan and Adelson in 1966 remains a helpful starting point for discussing what it means to become "independent." These writers identified three broad types of autonomy: *emotional autonomy*, which refers to the subjective feelings of independence, especially in relation to parents; *behavioral autonomy*, which refers to the capacity for independent decision making and self-governance; and *value autonomy*, which refers to the development of an independent world view that is grounded in a set of overarching principles and beliefs.

This subsection emphasizes research on emotional and behavioral autonomy. Research on the development

of value autonomy in adolescence, generally discussed with reference to moral development, has been extensively reviewed elsewhere (Eisenberg & Morris, 2004; Rest, 1983). However, the development of independent religious and political beliefs in adolescence has received only scant attention from developmental psychologists in recent years and more concerted study is needed.

We begin with three introductory observations about the study of independence in adolescence. First, although the development of independence is usually cast as an individual accomplishment (i.e., the adolescent becomes "an autonomous person"), the development of autonomy almost always implies independence *from or in relation to* some person (e.g., a parent), group, or institution. Consequently, the development of autonomy necessarily involves both a change in individual capacity (e.g., in the ability of the adolescent to make independent decisions) and a change in the individual's relationships with other individuals or institutions that deliberately or unintentionally influence or control the adolescent's feelings, behavior, or beliefs (e.g., in the extent to which the adolescent is permitted or encouraged by parents to make independent decisions or by the law to engage in autonomous decision making; Collins, Gleason, et al., 1997). Because of this, studying the development of independence in adolescence necessarily requires attention to the social context in which it takes place.

Second, independence is both a process and an outcome. In the realm of emotional autonomy, one can think of individuation not only as the process through which adolescents reformulate views of themselves, their parents, and the parent-child relationship but also as the end state of emotional maturity that emerges from this reformulation (Josselson, 1980). In the realm of behavioral autonomy, one can think of the renegotiation of family rules and regulations as the process through which adolescents establish more freedom from parental control and also as the family's acceptance of a new, more egalitarian division of authority between adolescent and parent that results from this renegotiation (Collins, 1995). And in the realm of value autonomy, one can study the process through which adolescents come to question the values and beliefs handed down by parents or other authorities and the adolescents' adoption of a system of moral, religious, or political beliefs based on their own views (Eisenberg & Morris, 2004). Relative to research on independence as an outcome, research on independence as a process is relatively sparse; consequently, we know far more about the characteristics of adolescents

who are individuated, capable of independent decision making, or principled in their beliefs, than we do about the interpersonal and intraindividual transformations that facilitated these outcomes.

Third, it is important to note that independence, as defined here, is valued differently in different cultural contexts (Feldman & Quatman, 1988). Among cultural and socioeconomic groups that value individual autonomy more than demonstrations of collective responsibility (e.g., middle-class European Americans), the capacity to function without depending on parents, to make personal decisions that contradict the desire of the group, and to voice one's own opinions, even if they challenge those of one's elders, is seen as a highly desirable trait, and adolescents who do not demonstrate sufficient emotional or behavioral autonomy are viewed as psychosocially immature. Among groups in which attending to the good of the larger collective is more important than the exercise of personal choice (e.g., middle-class Japanese, working-class Mexican Americans), however, establishing emotional independence from parents, making decisions without the input of one's elders, and endorsing values or beliefs that go against those of one's family often are seen in a negative light (e.g., Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000).

One interesting but relatively unstudied question is whether the correlates and consequences of independence in adolescence vary across groups that differ in their views of its value. For example, whereas individuation tends to be associated with higher self-esteem among American youth, it is associated with lower self-esteem among Asian adolescents (Chun & MacDermid, 1997). A related question concerns the ways in which adolescents, especially those whose families are recent immigrants, are affected by growing up in a social context in which they are encouraged by some individuals (e.g., teachers or peers) to behave independently but expected by others (e.g., parents or extended family) to sacrifice personal autonomy for the sake of the larger group. Generally, families who have emigrated from a culture that is relatively slower to grant adolescents autonomy to a culture where autonomy is granted sooner follow timetables for adolescent independence that fall somewhere between the two extremes. This tendency has been documented in studies both of Chinese immigrants in America and Australia (Rosenthal & Feldman, 1990) and of East German immigrants in the former West Germany (Silbereisen & Schmitt-Rodermund, 1995).

Recognizing that the development of independence is simultaneously an individual and interpersonal phenomenon poses methodological difficulties. Often, researchers assess the capacity for self-regulation or some other sort of independent functioning, ignoring the fact that manifestations of autonomy (whether emotional, behavioral, or cognitive) typically take place in interpersonal contexts. An illustration comes from research on developmental changes in resistance to peer influence in which adolescents typically respond to a series of hypothetical dilemmas requiring them to choose between a course of action that is self-determined and one that is demanded by their friends. In this paradigm, individuals who less often endorse the course of action recommended by the peer group are characterized as relatively more autonomous. Findings from research in which autonomy is operationalized in this way imply that the development of autonomy follows a J-shaped function, with resistance to peer influence declining between the ages of 10 and 14 or so and then increasing into late adolescence (Berndt, 1979; Steinberg & Silverberg, 1986).

It is tempting to conclude from this research that middle adolescence is a time of heightened susceptibility to peer influence (and, thus, diminished behavioral independence). This may be the case, but interpreting the findings of studies like these is difficult without information about developmental changes in the real or perceived degree of coercive pressure exerted by adolescent peer groups. Individuals' capacity to maintain autonomy in the face of peer pressure actually may remain constant during adolescence, whereas the amount of pressure from peers to comply with the group's norms and preferences may increase. If so, changes in the strength of peer group pressure, and not in individuals' capacity to resist it, may account for apparent declines in behavioral independence around age 14. Adolescents' likelihood of capitulating to peer-group influence may be a joint product of their capacity for autonomous behavior and the peer group's tolerance of individual members' independent decision making. Few studies, however, have been designed to distinguish between these contrasting processes (but see B. Brown, Clasen, & Eicher, 1986).

Similar conceptual and methodological challenges inhere in the study of emotional and value autonomy. Adolescents' subjective sense of independence, especially in the context of the parent-adolescent relationship, inevitably is influenced by the extent to which

their parents encourage, accept, or hamper emotional autonomy. Some parents become distressed by their teenager's striving for emotional independence, whereas others relish this same development (Silverberg & Steinberg, 1990). Yet, measures of emotional autonomy that simply assess the adolescent's subjective feelings of independence from parents do not ordinarily distinguish between individuals who have achieved this state with their parents' blessings or assistance and those who have had to struggle to establish their independence. It is not known whether this distinction makes a difference (e.g., whether the mental health correlates of emotional autonomy vary as a function of the degree to which the adolescent's independence was facilitated, tolerated, or fought by his or her parents). Similarly, some adolescents who have developed an independent world view may have achieved this degree of ideological autonomy through parental encouragement of independent thinking, whereas others may have had to struggle to assert their independent opinions. Research on adolescent autonomy would benefit from more systematic efforts to understand the processes through which emotional, behavioral, and value autonomy develop and from investigations that examine the relation between aspects of adolescent adjustment and variations in the process as well as outcome of the adolescent's move toward independence.

Emotional and behavioral autonomy undoubtedly are interrelated, although little is known about whether and how changes in adolescents' subjective feelings of independence affect, or are affected by, changes in capacities for independent behavior. For example, are adolescents who see themselves as emotionally autonomous from parents more likely than other adolescents to demonstrate independent decision making in the peer group? Similarly, do experiences in independent decision making outside the family promote the development of emotional autonomy in relation to parents? The notion that growth in one aspect of independence necessarily translates into growth in another is hardly self-evident. Indeed, one interesting possibility is that emotional autonomy from parents, especially when gained at a relatively early age, results in becoming more, not less, susceptible to the influence of peers and, accordingly, less behaviorally independent in that context.

### *Emotional Autonomy*

The development of emotional autonomy involves increases in adolescents' subjective sense of his or her

independence, especially in relation to parents or parental figures. At least in the early stages of adolescence, feeling emotionally autonomous is achieved in part by separating oneself from and arguing with one's parents; through this process, the relationship is transformed and the adolescent develops both a new behavioral repertoire and a new image of his or her parents (Collins, 1995; Steinberg, 1990). In this sense, the development of emotional autonomy is not primarily an intrapsychic transformation in which the adolescent comes to see him- or herself as more grown up, but an interpersonal transformation, in which patterns of interaction between the adolescent and parents shift through a process of mutual (if not always willing) renegotiation. At the end of this transformative process are three interrelated outcomes: a changed adolescent, who now views him- or herself in a different light; a changed parent, who now views his or her child (and perhaps him- or herself) in a different light; and a changed parent-child relationship, which is likely to be somewhat more egalitarian (Collins, 1995).

The starting point for most discussions of emotional autonomy and its development is the psychodynamic perspective on adolescence. In this perspective, the development of emotional independence during adolescence is conceptualized as independence *from* parents, parent-adolescent conflict is seen as a normative manifestation of the detachment process, and parent-adolescent harmony, at least in the extreme, is viewed as developmentally stunting and symptomatic of intrapsychic immaturity (A. Freud, 1958). Orthodox analytic views of the detachment process gave way in the last quarter of the twentieth century to more tempered, neo-analytic theories that cast the development of emotional independence in terms of the adolescent's *individuation* or *sense of identity* rather than limiting the phenomenon to his or her detachment from parents. The development of emotional autonomy begins with individuation from parents (Blos, 1967, 1979) and ends with the achievement of a sense of identity (Erikson, 1968).

Theory and research recently has shifted toward the idea that emotional autonomy results from a progressive negotiation between adolescent and parents over issues related to the granting and exercise of adolescent autonomy (Collins, 1995; Collins, Gleason, et al., 1997). Thus, the process of individuation is less about the adolescent's attempt to separate from his or her parents than about a transformation in the implicit and explicit assumptions and beliefs that shape interactions among

family members. This is not to say that all elements of this negotiation process are conscious or deliberate, the involved parties are always agreeable participants, or the everyday experience of renegotiating the terms of the parent-adolescent relationship is necessarily pleasant.

This new view of emotional autonomy, however, emphasizes the different ways in which adolescents and parents construe their relationship, the different expectations that they bring to the kitchen table, the different frames they use to interpret their experiences with one another, and the ways in which these cognitions shape patterns of interaction among family members (Collins, 1995; Larson & Richards, 1994; Smollar & Youniss, 1985). Accordingly, assessments of emotional autonomy have relied both on self-report measures of individuation (e.g., Lamborn & Steinberg, 1993; R. Ryan & Lynch, 1989; Steinberg & Silverberg, 1986) in which adolescents are asked questions about their perceptions of themselves (e.g., "I go to my parents for help before trying to solve a problem myself"), their parents (e.g., "My parents hardly ever make mistakes"), and the parent-adolescent relationship (e.g., "There are some things about me that my parents do not know"), and also on observational techniques, in which interactions between parents and adolescents are recorded and subsequently coded for displays of assertiveness and individuality on the part of the adolescent and for evidence of the facilitation or hindrance of the adolescent's assertion of autonomy by his or her parents (e.g., Hauser et al., 1991). Currently, the most widely used coding system for this purpose is that developed by Hauser, Allen, and their associates (Allen, Hauser, Bell, et al., 1994; Allen, Hauser, Eickholt, et al., 1994; Allen, Hauser, O'Connor, & Bell, 2002; Allen et al., 1996; Hauser et al., 1991; Hauser & Safyer, 1994).

Empirical research on the development of emotional autonomy implies a reciprocal process of intraindividual and interpersonal change in which the adolescents' growing sense of emotional independence affects, is affected by, and manifests itself in their relations with others. Several conclusions have emerged from work in this area. First, over the course of adolescence, individuals' subjective sense of independence increases significantly, as indicated by feelings of separateness from their parents and changes in their perceptions of them, with older adolescents less likely than preadolescents to idealize their parents or believe in their omnipotence (Steinberg & Silverberg, 1986). Notably, although this process begins early in adolescence, typically with the deidealization of parents and challenges to parental au-

thority, it unfolds over the entire adolescent period, and fully mature images of one's parents do not begin to appear until very late in adolescence, around the time that the adolescent is likely to be in the midst of the identity crisis described by Erikson (Smollar & Youniss, 1985).

Second, numerous studies show that the development of emotional autonomy is a far more gradual and far less dramatic phenomenon than originally suggested in "storm and stress" perspectives on adolescence (Collins & Laursen, 2004b; Steinberg, 1990). Detachment from parental ties is neither the norm, nor is it associated with positive adjustment or psychological well-being (Allen et al., 1996; Chen & Dornbusch, 1998; Frank, Avery, & Laman, 1988; Fuhrman & Holmbeck, 1995; Lamborn & Steinberg, 1993; Mahoney, Schweder, & Stättin, 2002; R. Ryan & Lynch, 1989). No studies suggest that active rebellion or unrelenting oppositionalism is necessary to later healthy psychosocial development, and many studies indicate that the overt repudiation of parents by the adolescent likely forecasts problems, not success, in the development of emotional independence (Fuhrman & Holmbeck, 1995; Steinberg, 1990). Furthermore, although the development of emotional autonomy is not characterized by individual psychological upheaval or excessive familial turbulence, it may be associated with mild distress among parents, especially mothers. This issue has not been studied, however, in samples other than White, working- and middle-class families (Silverberg & Steinberg, 1987, 1990; Steinberg, 2001; Steinberg & Silverberg, 1987).

Third, whereas the process of individuation appears to be especially significant during early adolescence, identity development is salient in late adolescence and early adulthood. Indeed, research on identity development indicates few age differences in early, or even middle, adolescence; rather, the end of the adolescent decade appears to be the critical time for the development of a coherent sense of identity (Archer, 1982; Nurmi, 2004; Waterman, 1982). Thus, the process of discovering *that* one has a separate identity (the process of individuation) precedes the process of discovering *what* that identity is (the process of identity development). Middle adolescence is important as the time during which the psychosocial concerns of adolescence shift from individuation from parents to the establishment of a sense of identity. Peers, in close relationships as well as in groups, undoubtedly play a crucial role in this transition (B. Brown, 2004). No research, however, has examined possible connections between the

processes of individuation in early adolescence and identity development in late adolescence.

Fourth, the most visible autonomy-related transformations in family relations, such as the widely reported increase in bickering and squabbling over matters of parental authority, occur relatively early in the period (Steinberg, 1981). The timing of these changed family patterns suggests that interpersonal changes that reflect the development of emotional autonomy precede some of the intrapsychic changes associated with gains in self-governance, which may not take place until the middle portion of the period, or in the development of a sense of identity, which takes place relatively late in adolescence. Although more longitudinal studies of the links between intrapsychic and interpersonal aspects of emotional autonomy are needed, one plausible hypothesis is that changes in the parent-adolescent relationship lead to, rather than follow from, changes in the adolescent's subjective sense of self-reliance (Holmbeck & Hill, 1991; Steinberg, 1990). In other words, the interpersonal may drive the intrapsychic, rather than the reverse.

Finally, there are sizable individual differences in the extent to which significant others in the adolescent's life permit or encourage the development of emotional independence, and these differences are meaningfully related to measures of adolescent psychosocial adjustment, especially in the realms of self-reliance, self-perceptions, and mental health. Many studies, involving both observational and self-report measures, indicate that the development of emotional independence is facilitated by parents who are warm but not intrusive. This recurring finding is consistent with the view that adolescents are more self-confident and less prone to depression and other forms of internalization when they feel close to parents and simultaneously feel free to individuate from them (Allen, Hauser, Eickholt, et al., 1994; Grotevant & Cooper, 1986; Hodges et al., 1999). In contrast, positive mental health and the development of emotional autonomy are linked negatively to parenting that is either excessively controlling (which may be experienced by the adolescent as passive aggression) or overtly hostile (Allen, Hauser, Eickholt, et al., 1994; Holmbeck et al., 2000; McElhaney & Allen, 2001; Pavlidis & McCauley, 1995). Extreme psychological control, including various forms of love withdrawal and guilt induction, has been shown to be especially incompatible with the development of emotional autonomy (Barber, 1996; Pomerantz, 2001). The same factors that

are associated with the development of healthy individuation—parental warmth, involvement, and the tolerance of expressions of individuality—also appear to contribute to the development of a healthy sense of identity, lending further support to the notion that these phenomena are interrelated (Grotevant & Cooper, 1986; Perosa, Perosa, & Tam, 1996).

### **Behavioral Autonomy**

Behavioral autonomy encompasses multiple capacities involved with self-reliance, but the construct of behavioral independence has appeared in two very different forms in research on adolescence (see Hill & Holmbeck, 1986). In one, behavioral autonomy refers to the capacity for competent self-governance in the absence of external guidance or monitoring, as when, for example, an adolescent is able to function on his or her own without parents in a new or challenging situation or behave ethically when outside the purview of adult supervision. In the other, behavioral autonomy also refers to the capacity to function independently in the face of *excessive* external influence, when, for example, the adolescent must be able to resist peer pressure to behave in a way that goes against his or her better judgment or personal preferences. Both of these situations require self-reliance, but whether these very different aspects of behavioral independence (i.e., the ability to function responsibly without guidance or in the presence of strong external influence) develop concomitantly has not received adequate research attention, nor has the broader issue of whether the expression of behavioral autonomy is stable across contexts. It is quite easy to imagine, for example, a young person who functions competently while alone but who behaves irresponsibly when in the presence of peers or one who is slavishly dependent on parents when around the house but who stands up for herself when with friends.

Research on the development of behavioral autonomy has for the most part been conducted in the broader framework of socialization research, guided mainly by social learning theory. Investigators have studied features of family contexts that covary with responsible independence, manifested in self-reliance, personal accountability, and appropriate responses to social influence. Two specific lines of work have dominated: studies of the development of responsibility (e.g., Cauffman & Steinberg, 2000; Greenberger & Sorenson, 1974; Lamborn et al., 1991; Steinberg et al., 1994) and studies of resistance to peer pressure, especially in antisocial situations (Berndt, 1979; B. Brown et al., 1986; Erick-

son, Crosnoe, & Dornbusch, 2000; Krosnick & Judd, 1982; Steinberg & Silverberg, 1986). According to these socialization models, parents facilitate the development of behavioral autonomy in four chief ways: (1) by serving as models of competent decision-makers; (2) by encouraging independent decision making in the family context; (3) by rewarding independent decision making outside the family context; and (4) by instilling in the adolescent a more general sense of self-efficacy through the use of parenting that is both responsive and demanding (Darling & Steinberg, 1993). Unfortunately, the sizable intercorrelations among these features of parenting make it impossible to specify which of these processes is most important.

As with research on emotional autonomy, behavioral autonomy sometimes has been examined as a quality of the adolescent's psychological capability or functioning (e.g., studies of age or gender differences in self-reliance) and sometimes as a quality of the adolescent's relationships with parents (e.g., studies of independence seeking or independence granting) or peers (e.g., studies of resistance to peer influence). When conceptualized as an individual phenomenon, assessment generally has taken four forms:

1. Adolescent self-report of global tendencies, using personality inventories that pose direct questions about self-reliance or personal responsibility (e.g., Greenberger & Sorenson, 1974)
2. Adolescent self-report of his or her performance of specific tasks indicative of independent functioning (e.g., the completion of school assignments, money management, punctuality at work; e.g., Mortimer, 2003)
3. Adolescent responses to hypothetical dilemmas that ask the individual to report how he or she would behave in various situations (e.g., when tempted to do something antisocial) and under varying social conditions (e.g., with peers versus alone; e.g., Ford, Wentzel, Wood, Stevens, & Siesfeld, 1990)
4. Assessments of the adolescent's independence made by parents or teachers (a method more popular in the past than currently; e.g., Bronfenbrenner, 1961)

Studies of behavioral autonomy as a quality of the parent-child relationship generally rely on questionnaires requiring parents and, independently, adolescents to report on how familial decisions are made (e.g., unilaterally by parents, jointly, or unilaterally by the adolescent; e.g., Dornbusch et al., 1987).

The fact that expressions of behavioral autonomy likely vary as a function of who else is present at the time makes it difficult to draw generalizations about the developmental course of behavioral independence as an overall capacity. Most studies that ask adolescents to gauge their own level of self-reliance (e.g., Steinberg & Silverberg, 1986) find a linear increase in this trait over the course of adolescence, but it is not clear whether adolescents' own appraisal of their capacity for responsible autonomy is consistent with their actual performance across varied situations. For example, whereas the period between age 11 and 14 is characterized by gains in subjective reports of responsibility, the same period is characterized by a decline in resistance to peer influence. Indeed, even in research on susceptibility to social influence, studies indicate different developmental timetables with respect to resistance to parental influence (which tends to increase linearly over the course of adolescence) and resistance to peer influence (which follows an U-shaped pattern, declining between ages 11 and 14 but increasing thereafter; Berndt, 1979). Although few studies have charted developmental changes in parental autonomy-granting, early adolescence is likely to be an important time for changes, with most parents relinquishing unilateral control over an increasingly wider array of everyday issues involving the adolescent and most families undergoing the sorts of transformations in family relations described in the previous section on emotional autonomy. Because they appear to progress along similar developmental timetables, adolescents' reports of their own sense of self-reliance may more closely reflect their assessment of their growing emotional and behavioral independence in relation to their parents rather than changes in their relations with peers.

The period between early and middle adolescence, from around age 13 until 15, appears to be an important transitional time in the development of behavioral autonomy, because adolescents become increasingly motivated to seek independence from parents during this period, while not yet having the psychosocial maturity for mature self-regulation when alone or in the company of their friends. Recent advances in developmental neuroscience have led several writers to link findings from studies of brain maturation to findings from studies of self-governance (e.g., Steinberg et al., in press). Changes in the limbic system that impel the adolescent toward sensation seeking and risk taking, both of which require greater independence from parental control, pre-

cede the maturation of the prefrontal cortex, which undergirds various aspects of executive function, affecting self-regulation, impulse control, planning, and foresight. This disjunction creates a gap that some writers have likened to "starting the engines with an unskilled driver" (C. Nelson et al., 2002, p. 515). This gap between the degree of autonomy adolescents seek and are granted, on the one hand, and their actual capacity for self-governance, on the other, may leave individuals prone to poor judgment, so that they place themselves in difficult or challenging situations before having developed the capacity for mature self-regulation (Steinberg & Scott, 2003).

Several investigators have examined ethnic and cross-cultural differences in adolescents' and parents' expectations for behavioral autonomy. Feldman and her colleagues, for example, have examined this issue by asking parents and adolescents from both Asian and Anglo cultural groups to fill out a "teen timetable"—a questionnaire that asks at what age one would expect an adolescent to be permitted to engage in various behaviors that signal autonomy (e.g., "spend money however you want," "go out on dates," "go to rock concerts with friends"; Feldman & Wood, 1994). In general, Anglo adolescents and their parents living in America, Australia, or Hong Kong have earlier expectations for adolescent autonomy than do Asian adolescents and parents from these same countries (Feldman & Quatman, 1988; Rosenthal & Feldman, 1990). Because of this, adolescents from Asian families may be less likely to seek autonomy from their parents than are their Anglo counterparts. In general, adolescents' mental health is most positive when their desires for autonomy match their expectations for what their parents are willing to grant (Juang, J. Lerner, McKinney, & von Eye, 1999). Not surprisingly, adolescents believe that individuals should be granted autonomy earlier than parents do (Ruck, Peterson-Badali, & Day, 2002).

Studies of expectations for behavioral autonomy have failed to find consistent sex or birth-order differences in age expectations for behavioral independence, contrary to the popular belief that boys expect more autonomy than girls or that later-born adolescents are granted earlier freedom because their older siblings have paved the way. Sex and birth-order differences in the extent to which parents *grant* autonomy do exist, though the pattern varies depending on the particular constellation of sons and daughters in the household and the parents' attitudes toward sex roles. Although parents are generally

thought to be more controlling of daughters than sons, this is relatively more likely in households where parents have traditional views of gender roles (Bumpus, Crouter, & McHale, 2001). Gender differences in the extent to which adolescents are granted independence appear to be especially pronounced in African American households. Relative to other ethnic groups, African American boys are given relatively more freedom but girls are given less (Bulcroft, Carmody, & Bulcroft, 1996). Contrary to expectation, parents grant more autonomy to first-borns than to second-borns, especially when the first-born is a girl and the second-born is a boy (Bumpus et al., 2001). Adolescents' expectations for autonomy may be highly influenced by the ways in which peers are treated by parents. Consistent with this, adolescents who "feel" older seek more independence than their same-aged peers who "feel" younger (Galambos, Kolaric, Sears, & Maggs, 1999).

### Summary Comment

The purportedly individual process of developing independence is embedded in the interpersonal contexts of family and peer relationships. Though rarely conceptualized as a systemic phenomenon, the emergence of evidence on the likely interacting processes of brain development, transformations in parent-child relationships, and the ascendance of extrafamilial networks implies that a developmental systems perspective is the minimum adequate conceptual framework for studying the development of autonomy.

### Developing a Sense of Interdependence

Interdependence is the norm in societies throughout the world. The emphasis on independence in industrialized cultures is relative not absolute (Goodnow, 2002; Goodnow, Miller, & Kessel, 1995). Adolescents in most cultures strive to be connected with others, whether as members of pairs, families, or larger groups. The significance of interdependence for developing adolescents is apparent in several ways. Adolescents in diverse industrialized societies generally now enjoy more discretionary time than in other historical periods; in many cultures (e.g., East Asian countries or Hispanic communities in the United States), a large proportion of the time not devoted to schooling is spent with family members (Cooper, 1994; Larson & Verma, 1999; Rothbaum et al., 2000). Although European American middle-class ado-

lescents in the United States spend less time with family members during adolescence than before, the amount of time actually spent talking with family members declines negligibly over these years (Larson et al., 1996) and appears to exceed the time that non-Western youth typically spend talking with their families (Stevenson et al., 1990; B. Whiting & Edwards, 1988). In addition, time with peers increases gradually during adolescence (Larson & Richards, 1991), and most adolescents claim to have several good friends and one or more best friends (Hartup & Abecassis, 2002). The centrality of interdependence is also apparent in the importance adolescents assign to interpersonal competence during the adolescent years. Longitudinal findings indicate that, by late adolescence, self-perceived competence in close relationships (e.g., with romantic partners) emerges as a reliable component of self-perceptions of general competence (Masten et al., 1995).

Developmental task analyses imply that achieving interdependence in adolescence is part of a process begun at birth (Buhrmester & Furman, 1987). *Attachment* to caregivers forms a substrate on which other attachments can be built, and the processes of forming and transforming attachments continues into adulthood as a component of interdependence. Same-gender peer relationships during childhood provide initial experiences of *intimacy*, but intimate relationships with opposite-sex peers typically first develop during adolescence (Savin-Williams & Berndt, 1990; Sullivan, 1953). Some rudiments of *sexuality* are present in infancy and childhood, but sexual activity itself generally begins during adolescence, bringing with it issues of relationships, social and personal responsibility, health, and safety (Brooks-Gunn & Paikoff, 1997; Simon & Gagnon, 1969; Udry, 1990). Interdependence is thus both a multifaceted construct comprised of several closely related but not redundant competencies, and an ongoing process in which each person affects, and is affected by, the other. Attachment, or the capacity to form interpersonal bonds, is a—perhaps the—foundational skill involved in developing interdependence.

The focus of this section is the three psychosocial goals comprising the task of interdependence: (1) attachment, (2) intimacy, and (3) sexuality. With respect to each we ask, first, what is the nature of the psychosocial task? Second, what is its developmental course? Third, how are the tasks related to the maturational and social issues that frame adolescent experiences? Fourth, what experiences, especially in interpersonal relation-

ships, facilitate or hamper the achievement of interdependence during adolescence?

### *Attachment*

The construct of attachment in infant-caregiver relationships refers to a relatively unique or distinct connection, which supports infants' efforts to feel safe from threatening conditions and to be regulated emotionally. These internal emotional experiences are manifested in the organization of the infant's behavior to maintain proximity with the caregiver, especially in novel or threatening circumstances. Infants may feel secure with multiple partners, though these may vary in the degree to which the infant feels secure in them (Cassidy, 1999; Weinfield, Sroufe, Egeland, & E. Carlson, 1999). According to M. Ainsworth (1989), infant behaviors with attachment partners are prototypes of attachments at every age, including those that occur outside of the biological family. These relationships illustrate four defining criteria for differentiating attachment relationships from other close relationships: proximity seeking, secure-base behavior (free exploration in the presence of the other person); safe-haven behavior (turning first to the other person when facing a perceived threat); and distress over involuntary separations (see Waters & Cummings, 2000, for a discussion of the significance of secure-base behavior after childhood).

Two largely compatible explanations have been offered for links between attachments with caregivers and those in later extrafamilial relationships. One is a carry-forward model, in which functions and representations of caregiver-child attachment relationships (*internal working models*) organize expectations and behaviors in later relationships (e.g., Waters & Cummings, 2000). Research findings document correspondences between early insecure attachment and poor peer relationships in adolescence (e.g., Weinfield, Ogawa, & Sroufe, 1997) and between security, as assessed in the Adult Attachment Interview, and peers' reports of resiliency, undercontrol, hostility, and anxiety (Kobak & Sceery, 1988). A second explanation is that relationships with caregivers prior to adolescence expose individuals to components of effective relating, such as empathy, reciprocity, and self-confidence, which shape interactions in other, later relationships (e.g., Collins & Sroufe, 1999; Sroufe & Fleeson, 1988). In turn, childhood and adolescent friendships serve as templates for subsequent close relationships outside of

the family (Furman & Wehner, 1994; Sullivan, 1953; Youniss, 1980). For example, recent findings substantiate links between representations of romantic relationships and representations of other close relationships, especially relationships with friends; and these interrelated expectancies parallel interrelations in features like support and control (Furman, Simon, Shaffer, & Bouchee, 2002; Furman & Wehner, 1994). Studies of the same individuals from birth to age 19 suggest that these two pathways may be part of a single process. In longitudinal studies, representations of attachment throughout childhood and also social behavior during the same period both have been predicted by early attachment relationships, and interactions between behavior and representations across time in turn have been found to predict social competence at age 19 (Carlson, Sroufe, & Egeland, 2004).

Maintaining interdependence in adolescence and early adulthood, however, involves relative redistributions of relationship functions. Adolescents' perceptions of parents as primary sources of support generally decline, whereas perceived support from friends increases, such that friendships are seen as providing roughly the same (Helsen et al., 2000; Scholte et al., 2001) or greater (Furman & Buhrmester, 1992) support as parental relationships. This process especially implicates friends and romantic interests, the individuals with whom early adults most like to spend time (proximity seeking) and with whom they most want to be when feeling down (safe-haven function; M. Ainsworth, 1989; Cassidy, 2001; Waters & Cummings, 2000). This shift in attachments requires a cognitive and emotional maturity that rarely is achieved before late adolescence (M. Ainsworth, 1989). In the process, attachment is transformed from caregiving of one partner by the other to that of mutual caregiving between the two partners (Allen & Land, 1999; Cassidy, 2001; Waters & Cummings, 2000). Although parents are just as likely as friends to be the primary source from which late adolescents and early adults seek advice and on which they depend (Fraley & Davis, 1997), Hazan and Zeifman (1994) have suggested that the apparent overlap among relationships at this time implies that components of attachment relationships (namely, maintaining proximity, using the other as a safe haven, and using the other as a secure base) also become characteristic of relationships with extrafamilial partners.

The significance of attachment for individuals and their relationships both before and during adolescence is

apparent in longitudinal findings. For example, secure early attachment in caregiving relationships predicts the features of relationships with extrafamilial partners during adolescence (Sroufe & Fleeson, 1988). Similarly, early attachment security predicts competence with peers both during middle childhood (the elementary school years) and during adolescence. The combination of early experiences of caregiving and competence in peer relationships in preschool and middle childhood predicts adolescent competence more strongly than any of these assessments alone (Sroufe, Egeland, & Carlson, 1999). Likewise, early caregiving experiences significantly predict hostility in interactions with romantic partners in early adulthood over and above the contributions of proximal relationships with peers and parents (Collins & Van Dulmen, 2006b).

Attachments assessed during adolescence and early adulthood also predict quality of relationships. Representations of attachment in earlier life, as assessed by the Adult Attachment Interview (AAI; Main, Kaplan, & Cassidy, 1985; see also Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993) have been linked significantly to characteristics of relationships with parents in adolescence and early adulthood (Becker-Stoll & Fremmer-Bombik, 1997). Researchers also have documented remarkable correspondence between AAI classifications and an individual's actual manifestations of security in relationships with their caregiver in infancy, as assessed by the Strange Situation (Waters et al., 2000). Exceptions to this general continuity also are consistent with the hypothesis that current functioning reflects a combination of relationship history and current experiences (Carlson et al., 2004; Sroufe, Egeland, Carlson, & Collins, in press; for a critical perspective, see M. Lewis, Feiring, & Rosenthal, 2000). For example, Weinfield, Sroufe, and Egeland (2000) reported that disruptive life events often undermine continuity from early attachment assessments to early adult attachment assessments in a risk sample, whereas Waters et al. (2000) found significant continuities in a largely stable middle-class sample. Finally, individuals' security in caregiver relationships during infancy significantly predicted representations of romantic relationships, as assessed by the Current Relationships Interview (CRI; Crowell & Owens, 1996), at age 21. Other things being equal, a foundation of interdependence in early life appears to be a significant forerunner of continued interdependence in one's closest relationships in adolescence and adulthood.

Whether adolescent attachments contribute uniquely to future adaptation and well-being is still largely unknown. Suggestive recent findings, however, come from a 2-year longitudinal study implying considerable stability of attachment beginning in 9th and 10th grades (Allen, McElhaney, Kuperminc, & Jodl, 2004). More extensive evidence is accumulating slowly, partly because few valid, reliable measures of adolescents' current attachments exist. Conceptually sound, well-validated measures of attachment, such as the AAI (Main et al., 1985), are of questionable validity for some samples of adolescents. Moreover, some instruments carry the label "attachment," but do not systematically assess M. Ainsworth's (1989) criteria for distinguishing attachment relationships from other close relationships. Nor have these instruments been validated longitudinally against attachment measures that do address these criteria, such as the Strange Situation or the AAI (Crowell, Fraley, & Shaver, 1999). The most widely used such instrument, Armsden and Greenberg's Inventory of Parent and Peer Attachment (IPPA, 1984), reliably measures certain features of relationships that overlap with the features of secure attachments, such as degree of mutual trust, quality of communication between partners, and degree of anger and alienation. Although IPPA scores cannot substitute for valid measures of attachment, the scores have yielded interesting age-related patterns that are relevant to interdependence during adolescence and even into early adulthood. For example, in a recent study linking IPPA scores with measures of romantic relationships, relationship quality with mothers and decreasing quality of relationships with father during adolescence were associated with greater expectations of rejection in relationships with friends and romantic partners (Ho, 2004). Other researchers have documented significant positive correlations between poor quality relationships with parents and peers, as assessed by the IPPA, and aggression and victimization toward partners in romantic relationships in early adulthood (J. L. Linder et al., 2002).

### *Summary Comment*

Achieving the psychosocial tasks of interdependence thus implies building on earlier relationship patterns to form and maintain further stable interdependencies during and beyond adolescence. Attachment perspectives have yielded compelling evidence that interpersonal contexts are significant not only in achieving adoles-

cents' interdependence goals but also in providing a foundation for competent independent functioning as well (Allen & Land, 1999; R. Thompson, 1999).

### Intimacy

Intimacy has been defined in several ways. In the widely accepted definition proposed by Reis and Shaver (see also Reis & Patrick, 1996):

Intimacy is an interpersonal process within which two interaction partners experience and express feelings, communicate verbally and nonverbally, satisfy social motives, augment or reduce social fears, talk and learn about themselves and their unique characteristics, and become "close" (psychologically and often physically). (1988, p. 387)

As a psychosocial task of adolescence, intimacy refers to experiencing this mutual openness and responsiveness in at least some relationships with age-mates. Interdependence is a necessary, but not sufficient, condition for intimacy. If interdependence declines, intimacy may be less likely or less satisfying (Prager, 2000; Reis & Patrick, 1996; Reis & Shaver, 1988).

The development of capabilities for intimacy during adolescence undoubtedly builds on the hallmark physical, cognitive, and social changes of the period. Concepts of friendship first incorporate notions of intimacy in early adolescence (Furman & Bierman, 1984). In contrast to the relatively large number of studies linking these changes to the growth of independence, few studies have examined their links to changing patterns of intimacy with peers. Nevertheless, many scholars speculate that adolescents become increasingly capable of intimate relationships as more sophisticated understanding of social relations emerges and as adolescents' ability to infer the thoughts of feelings of others sharpens (e.g., Selman, 1980).

The interpersonal roots of emerging intimacy during adolescence have been studied more extensively. Generally, findings confirm links between the quality of adolescents' relationships (i.e., the degree of openness and support experienced with close associates) and the nature of family relationships in earlier periods, as well as changes in the abilities of relationship partners during adolescence (Collins & Van Dulmen, 2006a). For example, in one longitudinal study parent involvement during childhood predicted closeness to parents during adolescence, with stronger links between childhood father involvement in childhood and closeness to father at age 16 for girls than for boys (Flouri & Buchanan, 2002). Fur-

thermore, the degree of flexible control, cohesion, and respect for privacy experienced in families has been linked positively to intimacy in late-adolescent romantic relationships, with especially strong associations emerging for women (Feldman, Gowen, & Fisher, 1998). In contrast, degree of negative emotionality in parent-adolescent dyads predicted degree of negative emotionality and poor quality interactions with romantic partners in late adolescence (K. Kim et al., 2001). This association appears to be mediated by negative affect and ineffective monitoring and discipline in parent-adolescent relationships (R. Conger, Cui, Bryant, & Elder, 2000).

In relationships with peers, larger amounts of time with peers and correspondingly less time with adults during adolescence may contribute to the development of intimacy by increasing comfort with peers and encouraging self-disclosure, as well as openness to others' self-revelations. Shared interest in mastering the distinctive contexts and social systems of adolescence also stimulates a desire to communicate with peers, and biological changes associated with puberty also may occasion more frequent discussion with peers, who may offer a more comfortable arena than parent-child relationships for discussing issues of physical changes, sex, and dating. Opportunities for intimacy may be one reason why friendships occupy increasing amounts of time during adolescence. The superficial sharing of activities that sufficed between childhood friends is supplanted, during adolescence, by the potential for mutual responsiveness, concern, loyalty, trustworthiness, and respect for confidence between adolescent friends (Furman & Bierman, 1984; Newcomb & Bagwell, 1995). According to Sullivan (1953), the theoretical fountainhead of research in the area, friendship in preadolescence and adolescence meets a basic psychological need to overcome loneliness, an idea that is similar to Baumeister and Leary's (1995) recent proposal that humans have an evolved need to belong. In Sullivan's view, same-sex peers develop the psychological capacity to achieve intimacy by overcoming loneliness through close friendships with same-sex peers (*chumships*).

Increases during adolescence in mutuality, self-disclosure, and intimacy with friends (defined as reciprocal feelings of self-disclosure and engagement in activities) have been documented in several studies (Furman & Buhrmester, 1992; Sharabany et al., 1981). Sharabany et al. (1981) reported, from age 10 to age 16, adolescents increasingly reported frankness, spontaneity, knowing, and sensitivity toward friends. Trust

and loyalty, as well as taking and imposing, were characteristics of communication with friends throughout this age range.

Gender differences in both extent and significance of intimacy are both common and widely discussed. During adolescence, girls' friendships consistently involve more knowing and sensitivity, more giving and sharing, and more taking and imposing than boys' friendships do (e.g., Sharabany et al., 1981; Youniss & Smollar, 1985). McNelles and Connolly (1999) found that with increasing age both girls and boys in grades 9, 10, and 11 in a Canadian sample increasingly engaged in discussion and self-disclosure with close friends and were equally successful in sustaining shared affect between them. In this study, the two genders differed primarily in the manner in which intimacy was established, with boys more often manifesting intimacy in the context of shared activities than girls did and girls more likely than boys to attain intimacy through discussion and self-disclosure. One interesting by-product of this gender difference is the relatively greater tendency for adolescent girls to engage in "co-rumination," which may leave them more susceptible than boys to the development of depressive symptomatology (Rose, 2002).

Intimacy in opposite-sex friendships, although not uncommon among late adolescents (Kuttler et al., 1999), emerges relatively late. Sharabany et al. (1981) found that not until the 9th and 11th grades were opposite-sex friendships rated very high in intimacy. Little is known about the intimacy of these friendships relative to those of same-gender pairs (but see Sippola, 1999, for relevant evidence), the typical role of intimacy in networks of same-gender and opposite-gender friends, or the developmental significance of placing high relative importance on opposite-gender over same-gender friendships.

Adolescent friendships appear to provide critical interpersonal experiences for both genders that both shape later close relationships and support individual psychosocial growth (Furman & Wehner, 1994; Sullivan, 1953). Qualities of friendships in middle and late adolescence appear to be linked to concurrent qualities of romantic relationships (Collins & Van Dulmen, *in press*; Furman et al., 2002). Representations of friendships and romantic relationships are interrelated as well. Displaying safe-haven and secure-base behaviors with best friends is correlated positively with these behaviors in dating relationships (Treboux, Crowell, Owens, & Pan, 1994). Perhaps the growing importance of romantic

relationships calls attention to the commonalities across types of relationships. It is equally likely that the parallels between early adults' relationships reflect their common similarity to prior relationships with parents and peers (Collins & Van Dulmen, 2006a; R. Conger et al., 2000; Owens et al., 1995; Waters et al., 2000). The nature and processes of these developmentally significant relations among relationships is a promising area for further study.

Intimacy also may enhance other aspects of psychosocial development. In particular, intimacy with peers has been implicated in identity development. In an influential early essay, Elkind (1967) depicted the opportunity to share perceptions and feelings with other adolescents as one of the main ways in which adolescents overcome egocentric beliefs that others are preoccupied with their behavior (the imaginary audience) or that their experiences are unique (the personal fable). Erikson (1968) regarded intimacy in early adulthood as emerging from identity achievement, which enables individuals to engage in sharing with others without feeling excessively vulnerable personally. Little evidence bears on either Elkind's or Erikson's predictions. Some studies have shown that young adults who are relatively advanced in identity achievement, as assessed in Marcia's (1980) classification scheme, also are more likely than those in less advanced classifications to have formed intimate relationships (Dyk & G. Adams, 1990; Fitch & G. Adams, 1983; Orlofsky, Marcia, & Lesser, 1973; Tesch & Whitbourne, 1982). Although these correlational findings do not address the causal implications of Erikson's developmental formulation, multiple findings imply that high-quality friendships—those that are intimate and in which the adolescent feels supported and cared for—are associated with a range of positive outcomes, including school engagement and positive self-esteem and mental health, and poor-quality relationships consistently are associated with the converse (e.g., Berndt & Keefe, 1992; Dubow, Tisak, Causey, Hryshko, & Reid, 1991; for reviews, see B. Brown, 2004; Hartup, 1996).

### **Summary Comment**

Intimacy as an aspect of interdependence, though rooted in key family experiences and same-sex friendships prior to adolescence, is largely an emergent of adolescent development. Research findings, however, have revealed more about the observable characteristics of

adolescent friendships than about the meaning of deeper, less discernible qualities like intimacy. As interest in close relationships grows in diverse fields, not just in developmental psychology, renewed focus on the nature and course of intimacy as a human capacity undoubtedly will require more concerted attention.

### **Sexuality**

The psychosocial task of sexuality refers to adjusting to a sexually maturing body, managing sexual desires, forming sexual attitudes and values and learning about others' expectations, experimenting with sexual behaviors, and integrating these dimensions into one's sense of self (Crockett, Raffaelli, & Moilanen, 2003). As with other aspects of physical and psychological change during adolescence, psychosocial sexuality reflects complex exposure to social roles, behaviors, mores, and values, as well as biological changes. The focus of this section is social, attitudinal, and emotional aspects of sexuality rather than sexual behavior per se (e.g., patterns of sexual behavior, rates of sexual intercourse, or contraceptive use; for a recent comprehensive review of these topics, see Savin-Williams & Diamond, 2004).

Key elements of sexual response are present well before gonadal puberty. For example, sexual attraction is evident in diverse societies by the age of 10, the age at which adrenal puberty (adrenarche) occurs (Herdt & McClintock, 2000). The main developmental issues of psychosocial sexuality during the adolescent period, thus, are not biological ones but social ones. Pubertal changes and their endocrinological antecedents mainly affect the frequency and intensity of sexual arousal in both sexes. These latter sequelae are highly correlated with sexual activity of various kinds among both females and males, although their significance is moderated by social relationships and social context, especially among females (B. Miller et al., 1998).

Sexual fantasizing typically appears earliest and remains the most common adolescent sexual experience (Halpern, Udry, Campbell, & Suchindran, 1993; Katchadourian, 1990). Erotic fantasies appear to be followed by the initiation of masturbation, "making out," and sexual intercourse of various kinds (B. Miller et al., 1998; E. Smith & Udry, 1985). This sequence appears to be typical of European American youth, whereas the order in which these sexual experiences occur is less predictable for African American youth (E. Smith & Udry, 1985). Ethnic and racial differences are espe-

cially marked in the prevalence of intercourse and in the speed with which adolescents progress to intercourse from other sexual activity (Blum et al., 2000; Katchadourian, 1990).

Other generalizations about the normative development of psychosocial sexuality are difficult, because expectations, attitudes, and values vary considerably across cultural, societal, and ethnic-racial contexts (Brewster, 1994; Eyre, Auerswald, Hoffman, & Millstein, 1998; Eyre, Read, & Millstein, 1997; Paige & Paige, 1985; T. Smith, 1994; J. Whiting, Burbank, & Ratner, 1986), and even across neighborhoods (Billy, Brewster, & Grady, 1994; Ku, Sonenstein, & Pleck, 1993; for reviews, see Brooks-Gunn & Paikoff, 1997; Crockett et al., 2003; Savin-Williams & Diamond, 2004). For example, societal indicators of sexual behavior, contraceptive practices, sexually transmitted diseases, and early pregnancy among the United States and other Western nations parallel variations between those countries in prevalent attitudes about the desirability and appropriateness of sexual experimentation during adolescence and the proper goals of sexuality education (Fine, 1988), the impact of family relationships on sexual behavior (e.g., Weinstein & Thornton, 1989; for a review, see B. Miller, Benson, & Galbraith, 2001), and processes and peer norms of sexual behavior (e.g., Billy & Udry, 1985; for a review, see Crockett et al., 2003).

In the United States, social and cultural expectations account partly for changes in attitudes and values regarding sexuality since the middle of the twentieth century: (a) An increased proportion of both males and females now express approval of premarital intercourse when it occurs in the context of an affectionate relationship; and (b) a larger proportion of females now engage in sexual activity during the middle adolescent years than had done so in past decades (Moore & Rosenthal, 1993). Though often attributed to a "sexual revolution," the changes have occurred so gradually that the term *sexual evolution* may be more appropriate.

Social and interpersonal processes undoubtedly also contribute to persistent differences between the genders and between adolescents with heterosexual versus homosexual preferences in component tasks of achieving maturity in psychosocial sexuality. Evidence on these comparisons is not adequately balanced in that studies of girls' subjective experiences of sexuality are more numerous than studies of boys' experiences and many more studies focus on heterosexual adolescents than on

homosexual or bisexual youth. Nevertheless, contrasting challenges are apparent. For example, girls, who are judged more harshly than boys for engaging in some types of sexual activities, are more likely than boys to express ambivalence about their sexuality and to fear harsh judgments if they are viewed as sexually active (Graber et al., 1999; Hillier, Harrison, & Warr, 1997; Moore & Rosenthal, 1993). Similarly, in contrast to females with heterosexual orientations, females with preferences for same-gender partners appear to experience more fluidity in their sexual-identity labels during adolescence (Diamond, 2000; for other research on bisexual attractions, see Weinberg, Williams, & Pryor, 1994).

Understanding the development of psychosocial sexuality is complicated further by the sizable individual differences in attitudes and values pertaining to relationships and sexual expression. Evidence of such differences comes from research showing that a sample of Australian adolescents could be differentiated according to five “styles” of psychosocial sexuality: (1) sexually naive, (2) sexually unassured, (3) sexually competent, (4) sexually adventurous, and (5) sexually driven (Buzwell & Rosenthal, 1996). These clusters varied correspondingly in tendencies toward sexual risk taking, a finding which implies that appropriate differentiation might be needed for interventions such as sex-education programs and campaigns to reduce the risk of teenage pregnancy or to promote safe sexual practices. Gender and sexual-orientation variations also are apparent. Females generally appear to emphasize emotional aspects of relationships as contexts for sexual behavior, whereas males more often emphasize physical satisfaction and release (Moore & Rosenthal, 1993), though within-gender views are highly variable (S. Thompson, 1995). Similarly, current evidence implies that the risk of social and emotional isolation in sexual relationships may be relatively greater for gay, lesbian, and bisexual adolescents of both genders than for adolescents with heterosexual orientations. Sanctions against explicit displays of same-sex romance in adolescence may make the maintenance of a more “normalized” emotional relationship difficult because sexual-minority youth often find it difficult to engage in many of the social and interpersonal activities that their heterosexual peers are permitted to enjoy (Diamond & Savin-Williams, 2003).

Further sources of individual variation in the development of psychosocial sexuality include significant others, especially relationships and processes involving family members, best friends, and romantic partners.

Longitudinal and cross-sectional evidence alike implicates positive parent-adolescent relationships in delayed initiation of intercourse, less frequent intercourse, and fewer sexual partners (e.g., Feldman & Brown, 1993; K. Miller, Sabo, Farrell, Barnes, & Melnick, 1998; for reviews, see Brooks-Gunn & Paikoff, 1997; B. Miller et al., 2001; Savin-Williams & Diamond, 2004). Peers, especially best friends, also contribute to individual differences in sexual expectations, attitudes, and behaviors, albeit more so among girls than boys (e.g., East, Felice, & Morgan, 1993; Whitbeck, Conger, & Kao, 1993). For European American males, though apparently not for African American males, a similar association may reflect selection of friends with similar activities and values (e.g., Bauman & Ennett, 1996; Billy, Rodgers, & Udry, 1984; Rowe et al., 1989).

Sexuality most often has been regarded as a source of developmental difficulties and risks during adolescence. This assumption stems partly from a concern about the impact of precocious sexual experience on normative developmental timetables and abilities and prevailing moral values regarding sexuality outside of marriage, especially for the very young, and partly from concerns about sexual exploitation, pregnancy, and health risks from early sexual activity (Brooks-Gunn & Paikoff, 1997; Savin-Williams & Diamond, 2004). Most studies have emphasized these and other dysfunctional outcomes; research findings consistently have shown that adolescents who become sexually active at a young age (typically, initiating intercourse before age 16) generally exhibit relatively greater risk for problematic outcomes, compared to adolescents who defer sexual activity. Indeed, early onset of sexual activity, rather than sexual activity per se, appears to account for the association between sexual activity and problematic psychosocial development. The link almost certainly is mediated by relative psychosocial immaturity and by a general orientation to unconventionality among early active teenagers (Jessor, Costa, Jessor, & Donovan, 1983). As a group, these adolescents tend to be less achievement oriented, more alienated from their parents, and more likely to exhibit other problem behaviors such as drug or alcohol abuse (e.g., Davies & Windle, 2000; Neeman, Hubbard, & Masten, 1995; B. Thomas & Hsiu, 1993; Zimmer-Gembeck et al., 2001).

Several theoretical formulations, bolstered by supportive findings from empirical research, view these associations as part of a cluster of behaviors defined as problems because they represent “transition prone-

ness," or a pattern of earlier-than-usual transitions to behaviors that are typically expected of adults but not of adolescents (e.g., Bingham & Crockett, 1996; Capaldi, Crosby, & Stoolmiller, 1996; Costa, Jessor, Donovan, & Fortenberry, 1995; Jessor, Donovan, & Costa, 1991; Tubman, Windle, & Windle, 1996). This inference is bolstered by findings that later initiation of intercourse and less frequent intercourse for those who do begin early are inversely related to both religiosity (Rostosky, Wilcox, Comer Wright, & Randall, in press; Whitbeck, Yoder, Hoyt, & Conger, 1999) and high levels of educational aspirations and achievement (Jessor et al., 1983; Ohannessian & Crockett, 1993; Whitbeck et al., 1999). In a 4-year longitudinal study, self-restraint at age 10 to 11 predicted having had fewer sexual partners at the later time (Feldman & Brown, 1993). By contrast, sexual activity is associated with risk proneness (Rawlings, Boldero, & Wiseman, 1995). Contrary to common expectations, however, correlations between delayed intercourse and self-esteem generally have been negligible (e.g., Crockett et al., 1996; Whitbeck et al., 1999), although more depressed girls are at risk for higher levels for sexual activity (Whitbeck et al., 1999).

One concern about early sexual behavior is that a premature focus on sexual expression may interfere with successful integration of physical sexuality with attitudinal, emotional, and identity components. For example, Maccoby (1998) has observed that sexually adventurous female adolescents, unlike their male counterparts, may experience social condemnation, peer derision, and stereotyping that interfere with more positive developmental opportunities. Savin-Williams (1996) has suggested that negative social sanctions, stigmatization, and personal identity struggles may account partly for current findings showing a high rate of attempted suicide, emotional distress, school problems, and alcohol and drug abuse among self-identified gay, lesbian, and bisexual youth. Although some researchers question the validity of these findings (Savin-Williams, personal communication, October 22, 2004), many adolescents, regardless of sexual orientation, report negative experiences stemming from perceived pressure to engage in sexual activity, which they did not desire or for which they felt unready. These individuals disproportionately reported guilt and self-doubt following sexual experimentation, which colored feelings about subsequent sexual experiences (Moore & Rosenthal, 1993; Savin-Williams, 1996; Zani, 1991).

Unfortunately, relatively little research has been devoted to examining the hypothesized psychological advantages of integrating physical and psychosocial aspects of sexuality during adolescence, especially for sexual-minority youth. Contemporary views regard mature sexuality in the psychosocial sense as developmentally healthy rather than problematic (e.g., Brooks-Gunn & Paikoff, 1997; Carpenter, 2001; Savin-Williams & Diamond, 2004; Tolman, 1994; Tolman, Spencer, Rosen-Reynoso, & Porche, 2004). Accordingly, many observers have advocated that public school sex-education efforts include more detailed and comprehensive programs that directly address issues of attitudes, values, and responsible sexual decision making (including decisions to abstain from sexual activity), in contrast to the largely ineffective current models based exclusively on abstinence (Landry, Kaeser, & Richards, 1999). Some experts are cautiously optimistic that a combination of school-based sex education and community-based health clinics could reduce the rate of teenage pregnancy by providing the information about contraception, sex, and pregnancy that sexually active adolescents need (e.g., Frost & Forrest, 1995; Tiezzi, Lipshutz, Wroblewski, Vaughan, & McCarthy, 1997). Even more broadly based programs may be needed, as in one highly effective combination of service learning with classroom discussions about life options (Allen, Philliber, Herrling, & Kuperminc, 1997). Efforts like these integrate sexuality into a framework of healthy interdependence (i.e., focused on the relational aspects of sexuality) and independence (i.e., focused on responsible and self-governed sexual behavior).

### *Summary Comment*

Interdependence implies a cluster of interrelated psychosocial competencies. Thus far, researchers have focused primarily on the separate tasks of attachment, intimacy, and sexuality but have given little attention to the interrelations among them. Isolated findings suggest that, for example, questions about the role of attachment in the development of intimacy (e.g., Cassidy, 2001; Collins & Sroufe, 1999) and the degree to which sexuality is integrated with intimacy and commitment in early adulthood (e.g., Bogaert & Sadava, 2002; Collins, Henrichsen, & Sroufe, 1998) deserve further attention. These and other questions regarding the extent of such linkages and the processes by which they occur promise to illuminate the nature of adolescent development in relational contexts.

## CONCLUDING THEMES

Research on adolescence, which was moribund halfway through the twentieth century, now is a vital and productive area of developmental psychology. Professional organizations are flourishing, and scholarly journals and multiple major volumes of reviews (e.g., G. Adams & Berzonsky, 2003; R. Lerner & Steinberg, 2004) attest to the quantity and quality of archival research and the desire of scholars and scholars-in-training for authoritative sources in the field. In a sense, the study of adolescence has attained its majority.

As in other vital subfields of psychology, research on adolescence reflects significant theoretical and empirical themes in psychology generally and developmental psychology in particular. One such theme, the importance of contextual as well as traditionally intraindividual forces in human functioning, has become a hallmark of research on adolescence during the past 2 decades (e.g., Grotevant, 1998; Larson & Wilson, 2004; R. Lerner & Steinberg, 2004). Initially focused largely on institutional, economic, and cultural conditions, contemporary interest in context is now realizing the vision of developmental systems theorists (e.g., Bronfenbrenner, 1979; Magnusson & Stattin, 1998; Sameroff, 1983). The emphasis has shifted from external, often distal forces as moderating influences on intrapersonal processes to processes by which intraindividual processes are engaged in dynamic interplay with both proximal (e.g., interpersonal) and distal (e.g., economic systems) environments.

This chapter underscores how this more inclusive view is expanding understanding of the nature and significance of psychological functioning during adolescence. Extensive findings substantiate long-standing speculations that perceptions and expectancies emanating from society and culture, via interactions with salient members of social networks, mediate the psychological and behavioral impact of pubertal changes. Expanded knowledge of brain development and function is clarifying many previously veiled processes that contribute to this interactive nexus of influences. Likewise, the extent and nature of interrelated social processes in diverse interpersonal contexts, from those typifying relationships with parents and siblings to those more typical of expanding networks of peers, is moving the field beyond simplistic notions of the distinctiveness and separateness of family and extrafamilial influences that characterized the writings of adolescent researchers for three quarters of a century (Collins & Laursen, 2004a).

Full-fledged realizations of developmental systems formulations in research designs and statistical analyses remain a goal for the future, but an appreciation of the extensive interconnections among individual and contextual factors has contributed greatly to the creative thrust in contemporary research with adolescents.

Although the overall level of activity and the gains accrued from studying phenomena of adolescence are impressive, some topics have received less attention and less rigorous investigation than others. Consequently, some fundamental facets of growth and change in adolescence are understood only marginally better today than at the time of the publication of the previous edition of this *Handbook*. Whereas the study of social influences has advanced remarkably, cognitive development and intellectual performance in adolescence have been addressed in relatively few recent studies. Similarly, emotional development and self-regulation, both key elements in the transition from childhood to adulthood, have attracted only tangential attention from adolescence researchers. These topics represent a growing interest in the development of positive competence as a complement to the long-standing emphasis on deficits in competence as factors in maladaptation during and beyond adolescence. Several of the key psychosocial tasks that for decades have served as theoretical and conceptual hallmarks of adolescence, such as the development of the capacity for mature intimacy in close relationships, are the focus of only a minority of the research findings reported each year. Autonomy and identity arguably are exceptions to this generalization, but even when these widely studied aspects of adolescent functioning are brought into research, the purpose is to assess an adolescent's current status rather than to examine the nature and course of development toward mature functioning during adolescence and beyond.

This unevenness in research emphases challenges researchers to complement the vigorous attention to contexts of adolescent development with renewed attention to developmental issues. From questions of how adolescents function differently in relationships with different partners, in varying ethnic or cultural milieu, or in relatively disadvantaged versus relatively more advantaged environments, research should move to questions of how variations in self-regulatory competence or in capacities for seeking gratification for one's partner as well as oneself in sexual relationships emerge from characteristic interpersonal experiences in families, peer networks, school, and community experiences. Such questions push

the boundaries of widely used research designs and statistical methods, but rapidly emerging innovations in the field imply that many current limitations may be overcome in the near future (R. Lerner & Steinberg, 2004).

In addition to greater emphasis on developmental processes, more attention to psychological processes generally would enhance research on adolescence. At present, studies focus heavily on individual and relational correlates of antecedent and contemporaneous aspects of development (e.g., behavior problems in relation to parental styles or peer-group values) or as contributors to later competence (e.g., parent-adolescent interactions as predictors of later interactions with dating partners). Relatively few studies examine the mediating processes that account for these links (for exemplary exceptions, see B. Brown et al., 1993; E. Carlson et al., 2004; R. Conger et al., 2000; K. Kim et al., 2001). Greater attention to biopsychosocial processes derived from current theories would move research beyond the descriptive level toward more comprehensive understanding of adolescent functioning.

The goal of research on adolescence is the same in the 1st decade of the twenty-first century as it was 100 years ago: to illuminate the nature and significance of the multiple transitions embedded in achieving maturity. For the most part researchers have set their sights on documenting *which* persons and circumstances influence adolescents most and *to what extent* these influences account for variability in the maturity of adolescents. The advances of recent decades have come primarily from the realization that the candidate variables of interest extend to the diverse interpersonal, institutional, societal, and cultural contexts in which adolescents encounter opportunities, demands, resources, and obstacles relevant to psychological maturation. In the next decade, a more comprehensive understanding of the nature and course of achieving maturity promises to come from extending the question of *which* influences to questions of *how* and *through what processes* adolescents develop the capacities for healthy independence and healthy interdependence in a complex world.

- Brain. *See also* Biology
  - complexity of brain-behavior relations, 181–184
  - hormones and, 896
  - maturation, 169–170
  - organization of the cerebral hemispheres, 895
  - regional brain function, 896

## 1116 Subject Index

- Brain (*Continued*)  
    regional brain structures, 895–896  
    wave 5 in the brain stem auditory evoked potential (BAER), 207  
Bullying and victimization, adolescence, 593–594
- California Child Q-Set, 307, 308  
Categorization, social, 910–912  
Category Test, 739  
Causality, 234  
Character, building, 796–799  
Child Behavior Checklist (CBCL), 63–64  
Child care, non-family, 745  
Childhood Temperament Questionnaire, 105  
Child Psychopathy Scale (CPS), 737  
Children's Behavior Questionnaire (CBQ), 105, 117, 119, 128, 139, 145  
Circular models, 374  
Clothing/appearance/mannerisms, gender and, 881, 883  
Coalitional group domain, socialization processes, 378, 383–386, 399–400  
Cognition:  
    adolescent development, cognitive change, 1007–1009  
    focus on, 11–13  
    gender and cognitive skills, 873–874  
    motivation and, theories linking, 950  
    prosocial development, cognitive correlates, 683–686  
    socialization processes, and mediating role of the child's cognitive representations of the social world, 412  
Cognitive developmental approaches:  
    gender development, 894, 906–914  
    context, 912  
    gender constancy, 907–908  
    gender schema theory (GST), 908–912  
    review of the evidence, 907–908  
    social categorization, 910–912  
    peers, 582–584  
    Piagetian perspective, 582–583  
    Vygotsky's perspective, 583–584  
    prosocial development, 649–650  
    socialization processes, 370–371  
Cognitive-emotional processes as mediators, antisocial behavior, 756–765  
    latent knowledge structures, 763–765  
    mediation of life experience through acquired processing patterns, 763  
    social information processing, 759–763  
    social-situational factors altering cognitive-emotional processes, 757–759  
Colorado Childhood Temperament Inventory (CCTI), 116, 120, 304  
Combined Temperament and Personality Scales (CTPQ), 106  
Communication:  
    emotional (*see* Emotion)  
    gender differences, 882–883  
    nonverbal, 883  
    styles, 882–883  
Communitarian spirit, 797–798  
Community factors, antisocial behavior, 743–744  
Competence, experience-based; changes in, 662  
Competence-related beliefs:  
    change in the mean level of children's, 952–953  
    changes in children's understanding of, 953–955  
    factor structure of children's, 952  
    gender differences in, 963–964  
    motivation and, 952–955  
Complete androgen insensitivity syndrome (CAIS), 891–892  
Conceptual self, 79  
Conduct disorder:  
    antisocial behavior, 730  
    defined, 721  
    stimulant medication and, 765  
Conflict:  
    emotional development and family, 278  
    socialization processes and, 408–409  
Congenital adrenal hyperplasia (CAH), 890–891  
Conscience, 70–77  
    intuitive morality of early childhood, 70–71  
    moral development and, 802–803  
    moral emotion, 71–73  
    relational influences, 73–76  
Conscientiousness, 308, 316–320  
    early childhood antecedents, 318  
    lower-order traits, 317–318  
    underlying processes, 318–320  
Context, culture as, or context as, 839–842  
Contextual influence, types and examples of, 14–15  
Contingent causality models, 375–376  
Continuity:  
    empirical and theoretical limits on, 141–142  
    homotypic, 338  
    hypothesis, temperament and, 136  
Control:  
    autonomy and, 394–398  
    beliefs, 955–956  
    motivation and, 937–938, 955–956  
    socialization processes and, 394–398  
    theories, 937–938  
Controversial children, 610  
Conversations about emotional responses, 259–260  
Co-parenting, 448–449  
Coping strategies:  
    attachment and, 277–278  
    developmental change in, 276–277  
    effective/ineffective, 274–275  
    emotional development, 271–279  
    emotion regulation, 271–272  
    with family, 274–275  
    family influences on, 277–279  
    with peers, 274–275  
    temperament and, 132, 272–274  
Core relational themes, 234  
Corporal punishment, 401–402  
Cortisol reactivity, temperament and, 124–125  
Crying contagion, neonatal, 240–241  
Culture/ethnicity:  
    acculturation/assimilation, 468–469, 472  
    achievement values and goals, 967  
    adolescent development and, 1019–1020  
    aggression/antisocial behavior and, 723, 743  
    children/families of color in the United States, 465–469  
    children's competence, control, and attribution beliefs, 966–967  
    conceptual and methodological issues, 466–468  
    as context, or context as context, 839–842  
    definition of culture, 236–239  
    discrimination in classrooms, 978–979  
    emic developmental research issues, 474–476  
    children as family workers, 475  
    dual frames of reference, 475–476  
    language and cultural brokers, 474–475  
    emotional development and, 235–239  
    ethnic differences in our own culture, 559–561  
    goals and, 405  
    individualism versus collectivism, 403–405  
    morality and, 811–819, 838–846

- culture as context or context as context, 839–842
  - emotional forms, intuitions, and rapid processing, 816–817
  - justice and interpersonal responsibilities, 817–819
  - social communication and cultural coherence, 813–814
  - social practices and cultural coherence, 814–816
  - tradition, social hierarchy, heterogeneity, and social opposition, 842–843
- motivation and, 964–968
- parental practices, 236–237
- peer relationships, 579–580, 612
- perspectives on ethnic influences on family socialization, 486–487
- prosocial development, 662–665
- school experiences, 982–984
- self and:
  - cross-cultural comparisons, 558–559
  - ethnic differences in our own culture, 559–561
- socialization concerns in ethnic minority families, 476–487
  - African American families, 476–478
  - American Indian families, 478–481
  - Asian American families, 482–483
  - Latino families, 483–486
- socialization of children of color, 469–487
  - acculturation, 472
  - bicultural adaptation, 472–474
  - families of color, 469–470
  - generational differences in family ecologies, 470–472
  - socialization processes and, 372–373, 403–409
  - temperament and, 214–215
- Current Relationships Interview (CRI), 1042
- Demographic features, family, 665–666
- Dimensions of Temperament Survey (DOTS), 139, 140, 147
- Discipline/punishment, 400–402, 668–670, 747–749
  - control, appropriate versus inappropriate, 669–670
  - corporal, 401–402
  - hierarchical power domain (reward and punishment), 400–402
  - inconsistent, 747–748
  - physical punishment and punitiveness, 748–749
  - power-assertive, punitive techniques, 668–669
- Discomfort in infancy, and personality development, 305
- Disgust, 229
- Dispositional factors, antisocial behavior, 734–737
  - personality, 736
  - psychopathy, 736–737
  - temperament, 734–736
- Dissemblance, emotional:
  - ability to implement, 268
  - cognitive representation, 270
  - components of, 267–270
  - knowledge, 267–268
  - motivation, 268–270
    - avoidance of negative situational outcomes or enhancement of positive situational outcomes, 268–269
    - observance of norms and conventions, 269–270
    - protection of self-esteem, 269
    - relationship maintenance/enhancement, 269
- Diversity, 3, 13. *See also* Culture/ethnicity
- Dynamical systems approach, emotional development, 233–235
- Early Adolescents Temperament Questionnaire (EATQ), 145
- Eating disordered behavior, 539–540
- Ecological factors and social stressors, antisocial behavior and, 743–746
  - community factors, 743–744
  - culture, laws, and policies, 743
  - media violence, 745–746
  - non-family child care, 745
  - within-family factors, 744–745

  - self and, 6
  - sex and, 7
  - socialization and, 5–8
  - temperament and, 4–5, 107, 110–111, 146–149
- Emotional development in childhood and adolescence, 248–284
  - emotional autonomy, 1035–1038
  - emotion regulation, 248–249
  - skill(s) of emotional competence, overview of, 249–250
  - skill 1: awareness of our emotions, 250–254
    - awareness of multiple emotions, 253–254
    - self-conscious emotions, 251–253
  - skill 2: ability to discern and understand others' emotions, 254–258
    - facial expressions and emotion-eliciting situations, 255–256
    - problematic outcomes and understanding others' emotional states, 258
    - social competence and discerning others' emotional states, 257
    - taking into account unique information about the other, 256–257
    - understanding others' feelings and cognitive development, 255–258

Emotional development in childhood and adolescence (*Continued*)  
 skill 3: use of a vocabulary of emotion and expression,  
 258–262

ability to use concepts, lexicon, and scripts relevant to  
 emotion and expression, 258–262

conversations about emotional responses, 259–260

development of emotion lexicon, 259

emotion script learning, 261–262

structural analysis of emotion-descriptive language, 260–261

skill 4: capacity for empathic and sympathetic involvement,  
 262–265

disposition for overarousal, 263

early parental attunement, 263–264

influence of socialization, 264–265

skill 5: skill in differentiating internal emotional experience

from external emotional expression, 266–271

ability to implement emotional dissemblance, 268

avoidance of negative situational outcomes or enhancement of  
 positive situational outcomes, 268–269

cognitive representation, 270

components of emotional dissemblance, 267–270

knowledge, 267–268

motivation, 268–270

observance of norms and conventions, 269–270

protection of self-esteem, 269

relationship maintenance/enhancement, 269

skill 6: adaptive coping with aversive emotions and distressing  
 circumstances, 271–279

coping strategies, 275–277

development of emotion regulation and coping, 272

effective and ineffective coping and emotion regulation with  
 peers/family, 274–275

emotion regulation, 271–272

family influences on children's coping, 277–279

influence of temperament, 272–274

skill 7: awareness of emotion communication in relationships,  
 279–282

interpersonal closeness, 280–281

secret keeping and secret sharing, 280

social roles and emotion communication, 281

skill 8: capacity for emotional self-efficacy, 282–284  
 personality, mood, and emotion processes, 282–284

Emotional development in early life, 239–248

phase 1 (prenatal to 6 weeks): initial reactions to emotion  
 signals, 240–241

neonatal crying contagion, 240–241

neonatal responsiveness to emotion prosody, 240–241

phase 2 (6 weeks to 9 months): pre-referential communication,  
 241–243

evidence for rudimentary emotional exchange and its  
 constituents, 241–242

weaknesses in evidence for discrimination of discrete  
 emotional signals, 242–243

phase 3 (9 months to 18 months): behavioral regulation and  
 referential communication, 243–246

affect specificity, 245–246

development of affective sharing by the infant, 246

effects of emotional communication in older infants, 244

onset of emotional communication involving environmental  
 objects, 244

primacy of facial versus vocal signals, 244–245

referential specificity, 245

retention of valenced effects of emotional communication, 246

phase 4 (18 months/2 years and beyond): rise of other-conscious  
 emotions, 246–248

affect specificity, 246–247

development of other-conscious emotions, 247–248

Empathy:

moral development, and primacy for, 800–802

prosocial development, and responding related to, 661–662,  
 686–688

Employment:

adolescent, 1030–1031

job loss and unemployment, 464

maternal employment and children's development, 462–463

personality and success in, 341–342

quality of parents' work, and family socialization, 463–464

women's and men's employment patterns and family  
 socialization, 461–464

Environmental construal, 328–329

Environmental elicitation, 327–328

Environmental inputs to development, focus on, 13–15

Environmental manipulation, 330

Environmental objects, onset of emotional communication  
 involving, 244

Environmental selection, 329–330

Ethnicity. *See* Culture/ethnicity

Ethology, 584–585

Eugenics movement, 173

Event-related potential (ERP), 207

Event representation, social, 35

Evolutionary psychology perspectives:

adolescent development, 1013–1014

gender, 888–889

morality, 802

personality development, 339

prosocial development, 651–652

Executive functions, antisocial behavior and, 738–739

Experience-based competence, changes in, 662

Extraversion, 308, 311–313

early childhood antecedents, 312

lower-order traits, 311–312

versus shyness and behavioral inhibition, 127–129

underlying processes, 312–313

Faces, infant preference for, 28

Facial expressions, emotional development and:

emotion and, 230–231

emotion-eliciting situations, 255–256

primacy of facial versus vocal signals, 244–245

Facial skeleton, temperament and, 209

Family:

adolescent development and, 1015–1017

alternative structure (single and gay/lesbian parenting), 901–902

antisocial behavior and, 744–750

abusive parenting, 749–750

family coercion and inconsistent discipline, 747–748

mother-infant attachment relationships, 746–747

parental warmth and proactive teaching, 747

physical punishment and punitiveness, 748–749

emotional development and, 274–275, 277–279

gender socialization in, 898–902

encouragement of gender-typed activities and interests,  
 898–899

encouragement of gender-typed personal-social attributes,  
 899–900

parental attitudes and values, 901

role models in the home, 900–901

sibling effects, 902

moral development and, 830–832

prosocial development and, 665–683

demographic features, 665–666

expression of emotion and conflict in the home, 675–677

inductions, 667–668

- parental control, appropriate versus inappropriate, 669–670
- parental discipline, power-assertive, punitive techniques, 668–669

  - adjustment and, 134–152
    - continuity hypothesis, 136, 141–142
    - direct linkage, 136, 138–141

## 1128 Subject Index

### Temperament (*Continued*)

- fearfulness, 149–152
- moderated linkage, 142–143
- negative emotionality, 146–149
- pathoplasty model, 135–136
- predictions, 135–151
- processes linking temperament and adjustment, 137
- scar hypothesis, 136
- self-regulation, 143–145
- spectrum/continuity hypothesis, 136
- theoretical expectations, 136–138
- vulnerability model, 135
- adult, 102–103
- antisocial behavior and, 734–736
- attachment and, 210–211
- biological perspectives, 209–216
- childhood, 101–102, 104, 105–106
- defined, 99–101
- development and, 125–132
  - activity level, 128–129
  - attentional orienting and effortful control, 129–132
  - attention and distress, 130–131
  - contributions of temperament to development, 126–127
  - extraversion/surgency versus shyness and behavioral inhibition, 127–129
  - future research directions, 153
  - two control systems, 131–132
- dimensions of:
  - differentiating in future research, 152
  - in infancy and childhood, 104
- emotional development and influence of, 272–274
- ethnicity and, 214–215
- friendship and, 619
- future directions, 152–153
- historical perspective on research, 101–103
- infants, 104–105
- measurement approaches, 113–118
  - attempts to make parent and observer perspectives more similar, 118
  - caregivers' vantage point versus bias and inaccuracy, 115–116
  - components-of-variance approach to validity, 116–117
  - digital versus analog validity, 115
  - error sources, 114
  - future directions, 152–153
  - home observation measures, 114
  - laboratory measures, 114
  - parent reports/questionnaires, 114–118
- metaphor of seasons/weather, 273
- moral affects and, 215–216
- neural models of, 106–113
  - affiliativeness/agreeableness, 111
  - anger/irritability, 110
  - attentional networks, 112–113
  - attention as control system, 107
  - emotion as information-processing system, 107
  - fear and behavioral inhibition, 108–109

- negative emotionality or general distress proneness, 110–111
- optimal levels of stimulation and distress to overstimulation, 109–110
- positive emotionality/approach and extraversion, 107–108
- parent reports/questionnaires, 114–118
- peer relationships and, 617–619
- personality and, 100–101, 132–134, 302–303
- psychobiological research approaches, 119–125
  - approach/withdrawal and hemispheric asymmetry, 122
  - autonomic reactivity and self-regulation, 122–124
  - behavioral genetics, 119–120
  - cortisol reactivity, 124–125
  - electrodermal reactivity, 122–123
  - heart rate and vagal tone, 123–124
  - molecular genetics, 120–125
- psychopathology and, 211–214
- structure of, 104–106
- taxonomy of personality traits and, 310–326
  - agreeableness, 320–323
  - conscientiousness, 316–320
  - extraversion, 311–313
  - neuroticism, 313–316
  - openness to experience/intellect, 323–325
- Temporal self, 80
- Toddler Behavior Assessment Questionnaire (TBAQ), 117, 119, 128, 143, 304
- Transactional models, socialization processes, 374
- Transitions:
  - family, 464–465
  - school, 981–985

Unfamiliarity. *See* Reaction to unfamiliarity; Strange Situation

Vagal tone, temperament and, 123–124

### Values:

- gender, 883–886
- goals and, 692
- prosocial development and, 692

Verbal ability, antisocial behavior and, 737–738

Verbal Fluency, 738

### Violence:

- growth of serious, 727–728
- media, 745–746
- in romantic relationships, 728

Vulnerability, personality and, 347

Vulnerability model, temperament and, 135

Wave 5 in brain stem auditory evoked potential (BAER), 207

Willfulness, 321

Wisconsin Card Sorting Task, 738

Women. *See also* Gender

- aggression in, 730–731
- egalitarian attitudes, 885–886
- prejudice against, 885

Working models, antisocial behavior, 764

Workplace. *See* Employment
