Socialization research began with the assumption that the process was based more or less entirely on the tuition of the young by those who were invested in the child's and/or their own welfare, and the child's successful acquisition of relevant knowledge and skills. More recently, developmentalists have come to two new realizations. First, the brain contains the blueprints that determine the routes by which and the ease with which socialization occurs (and thus may be thought of as "experience-expectant"). Socializing experiences act to modify not only the cognitive, socioemotional, and behavioral competencies of the developing individual but also the corrected design of the brain (which thus may be thought of as "experience-dependent"). Second, social context has a significant impact on the effect of socializing experiences. What socialization is and how it works depends on both the immediate social context and the long-term cultural context. Although there are many continuities across time and cultures with respect to socialization, there are also many variations, reflecting the fact that

*socialization* is an umbrella term that refers to a suite of processes that serve many different purposes. A related realization is that the domain in which socialization takes place (e.g., protection, tuition in the rules of group life, collaborative work to accomplish a shared task, or the exertion of control over a child whose actions may be dangerous to others) also determines the impact of particular socialization experiences.

Socialization can produce either benefits or costs for both the young and others in their environment. On the one hand, it can function to foster children's individual success in managing their lives and their shared management of life challenges with others in their world. Thus, it includes their ability and motivation to acquire individual and culturally shared competencies at a social, emotional, and cognitive level. On the other hand, socialization may create threats to these ends. Parents, or other agents of socialization, may lack the knowledge, investment, or competency to assist the young in ways that add to the individual and common good. Finally, there are necessary conflicts between the motives of the young and their elders. Such conflicts may occur at points of transition in their individual and shared lives, for example, when the young seek increasing autonomy or when parents have priorities that are discrepant from those of their children. Celebrities receiving awards credit their parents with their successes. Prison inmates curse their parents as causal in their downfall. To some extent, these variations reflect post hoc biases in causal reasoning. At the same time, the reality is such that parents—in collaboration with others—may indeed expand or limit the child's positive possibilities.

Socialization research has been guided by many different theoretical perspectives. It began with psychoanalytic notions about the conflict between the wishes of the individual and the demands of society and moved to a variety of learning theory conceptualizations reflecting approaches dominant across the field of psychology at the time. Increasing attention to cognitive processes (including the developing abilities of individuals to cognitively represent themselves and their social world) and to the role of emotion expression and emotion regulation resulted in work on the part of social and developmental psychologists to determine the way in which social cognitions and emotions were linked. Although attachment theory remained formally apart from traditional theories of socialization, it became increasingly evident that the foundation for socialization provided by the attach-

ment relationship between child and primary caregiver could not be ignored. With the emergence of neuroscience, theorists and researchers began to explore additional pieces of the socialization puzzle, suggesting ways in which socialization processes are routed through and influenced by the central nervous system and associated neurohormonal processes. In addition, cultural psychologists alerted them to the fact that differing societal beliefs and goals affect the practices in which agents of socialization engage in different cultural contexts and the meaning assigned to these practices.

At the same time, researchers began to understand that a complete understanding of the socialization process was not possible without a consideration of the complexity of those who were doing the socializing. Parents, for example, have their own set of expectations and predilections—the ways in which they think about the parenting relationship—that affect the way they approach the tasks of socialization. Initially these expectations and predilections were seen to be deliberate and reflective but increasingly it became clear that at least some of them occurred automatically and with little awareness. Parenting approaches affect the responses of the child, which feed back to affect parental expectations and predilections by confirming and expanding them or, at times, contradicting them. Thus, any discussion of socialization is now seen to require attention not only to the processes involved in children's socialization but also to biological and cultural processes involved in the production of caregiver socialization practices and to the ways in which children and caregivers have a mutual and reciprocal impact on each other.

We begin this chapter with a consideration of the changing nature of the content, theoretical perspectives, and models in the field of socialization. We then move on to give attention to (a) the biological platform on which socialization is built, (b) the sociocultural processes that organize the socialization experiences of the young, and (c) the ways in which biological and sociocultural history combine to influence the child's life outcomes. Finally, we integrate our view of the current status of socialization theory and consider what we believe to be its future directions.

The approach that we follow is not without limitations. The research cited is necessarily representative rather than exhaustive. In addition, attention is focused on socialization processes that involve children and adolescents. Socialization continues during the lifetime, but the present discussion is limited to the age grouping of

interest in this *Handbook*. The early years are those in which socialization produces its greatest effects. Finally, central attention is given to socializing relationships between parents and children. Socialization involves a wide spectrum of influences. Beyond parents, for example, there are the powerful influences of peers who come to expand the lens through which children understand and manage their world. But parents, we believe, are primary for a number of reasons, including the fact that they and their children are unique in being part of a biologically intertwined system that strongly supports the socialization process.

In this first section, we review the theoretical approaches that have been taken to socialization and then highlight changing emphases in the field. The latter include shifting models in the exploration of causal processes in socialization and the emerging view of socialization as variable across domain and context.

## THEORETICAL APPROACHES AND CHANGING EMPHASES

There have been several classical approaches to socialization and caregiving relationships. These include psychoanalytic theory, attachment theory, and social learning theory.

### Psychoanalytic Theory

The first formal approach to understanding socialization emerged from psychoanalytic theory, which viewed the child as hedonistic, with expression of aggressive and sexual impulses needing parental and societal intervention to create a civilized human being (Freud, 1965). The importance of early experience was underlined in the premise that patterns of responding learned when individuals solved conflicts between gratification of bodily desires and the demands of society formed prototypes for later personality functioning (Erickson, 1959), including characteristic ways of dealing with dependency, aggression, gender roles, and conscience. Freud's concept of incorporation or internalization was particularly influential in guiding subsequent thinking about socialization. Thus, children were assumed to resist the imposition of societal values that threatened their autonomy but to repress their hostile feelings because of fear of punishment in the form of abandonment

or loss of love. To maintain the repression, as well as elicit parental approval, they identified with or internalized the values and rules of their parents. Here was the basis for self-punishment and guilt as well as an answer for the puzzling question of how individuals behave in socially acceptable ways without constant surveillance. The concept of internalization also laid the groundwork for a position that values are transmitted in their totality rather than modified or constructed by their recipients.

### Attachment Theory

Psychoanalytic theory was adapted and modified in subsequent approaches to understanding socialization. In attachment theory, for example, there was a sharp break in the notion of a conflictual relationship between society and child, which was replaced by a more positive view of the adaptive quality of parent-child relationships. Bowlby drew from ethology and evolutionary biology to argue that, over evolutionary time, relationships between caregivers and their offspring had taken shapes that fostered both the survival and the adaptive skills of the young. The first steps toward that goal took the form of actions, on both sides, which ensured proximity and protection of the young, as well as facilitating compliance with the directives of caregivers (Stayton, Hogan, & Ainsworth, 1971). Retained from the psychoanalytic perspective was a strong concern with the impact of early experiences on later development. That concern is at the core of proposals that the attachment patterns developed in early life are carried forward in the form of working models (mental representations of the caregiving relationship that include both cognitive and emotional components). These working models subsequently influence individuals' close relationships, including the relationship with their own offspring (e.g., Bowlby, 1980; Bretherton, 1980). With attachment theory came, as well, a change in content studied. Of primary interest was the quality of the relationship formed between caregiver and child, a relationship based on the biological need for the provision of protection and comfort as opposed to the linkage between the satisfaction by a caregiver of an oral or hunger drive as posited by psychoanalytic theory (hence the distinction between attachment and dependency). Ultimately, attention turned to the role of attachment in the way in which children learned to regulate their negative emotions (e.g., Cassidy, 1994), which is a further extension of content.

## Social Learning Theories

Psychoanalytic theory contributed to the thinking of social learning theorists who combined the rich clinical material of psychoanalysis with the basic principles of learning theory to produce a dynamic but empirically testable view of socialization (e.g., Sears, Maccoby, & Levin, 1957; Sears, Rau, & Alpert, 1964). The approach involved a set of processes that relied heavily on primary and secondary or learned drives that had their origin in maternal reduction of primary drives, such as hunger and thirst, similar to the psychoanalytic focus on hunger but different from the attachment theory focus on protection. These learned drives included dependency—the need to be near the mother and identification—the need to be like the mother (including the reproduction of her values and beliefs). The theory accounted in learning terms for the transmission and internalization of values and promoted research on topics relevant to socialization such as techniques of discipline. Studies of parenting suggested that, for example, reasoning and withdrawal of love worked well, particularly if they occurred in a context of warmth (Sears et al., 1957). The explanation was that they, unlike punishment or assertion of power, took advantage of the reinforcement that came from reproducing the (withdrawn) behavior of a warm and loving agent of socialization.

In a further refinement of social learning theory, Bandura and Walters (1963) presented a “sociobehavioristic” approach that eschewed psychoanalytic notions as well as reliance on the concept of acquired drives. They argued that the social nature of human functioning needed greater emphasis, focusing on the acquisition of novel responses through observational learning, and arguing that this, as opposed to learning through reinforcement, was the central and most important form of learning. Internalization of societal standards comes about through self-regulation, with the suggestion that people maintain their beliefs and values despite changing external circumstances because they judge their own actions—judgments learned through observation and direct learning (Bandura, 1977). Bandura (1977) also moved away from the notion of wholesale incorporation of parental values when he argued that children select from the conflicting information they receive to establish their own standards of behavior, with selection depending on a number of variables including differences in perceived competence between the model and the self and the degree to which behavior is seen to arise from

children’s efforts rather than being a function of events over which they have no control.

Emerging separately from the social learning approaches of Sears and Bandura was Patterson’s social interactional perspective (e.g., Patterson, 1980, 1982, 1997). Patterson maintains that the reinforcement contingencies embedded in social interactions are the important determinants of children’s behavior and has shown in a series of finely detailed studies how some mothers have difficulty obtaining compliance from their children because of their negative reinforcement of those children’s coercive behavior. Thus, Patterson (1997) suggests that “problem families function as simple short-term maximizing systems that inadvertently contribute to their own long-term misery” (p. 209). Moreover, when positive reinforcement by peers is added to this pattern of parenting, the outcome is high levels of aggressive behavior (Snyder & Patterson, 1995). Missing in Patterson’s approach is the concern with internalization that plays such a prominent role in other approaches to socialization, with Patterson (1997) arguing that reinforcement contingencies that control coercive behaviors are embedded in social exchanges and that these events are highly unlikely to be actively processed. Thus, behaviors during conflict are overlearned and shaped without awareness. In a similar vein, Patterson and Fisher (2002) question what is to be gained by developmental models that hypothesize events such as internalized values as mediators between parenting practices and child outcomes.

## Parenting Attitudes and Styles

Early theories of socialization emphasized parent actions as predictors of child outcomes. Some researchers, however, came to believe that parenting attitudes might prove to be better predictors of child socialization outcomes. Again, ideas emerged from psychoanalytic approaches. Horney (1933) and Levy (1943), for example, explored socialization through the study of unconscious emotional reactions, such as overprotection or excessive parental control, which determined parenting behavior and therefore children’s social, emotional, and cognitive outcomes. Over time, parent attitudes came to be considered as straightforward events that were accessible to conscious awareness rather than as reflections of unconscious processes. Their content was also expanded to include concepts such as warmth versus coldness, acceptance versus

rejection, and autonomy versus control (e.g., A. Baldwin, 1955; Schaefer, 1965). Parental attitudes were seen to provide the emotional climate in which parental values and beliefs are transmitted and so they provided a context in which that transmission occurred and presumably affected its success. In addition to dimensions of parenting style, some socialization researchers focused on categories of parenting style, providing a qualitative assessment that captured the complexity and subtlety of combinations of parenting dimensions. The most enduring and influential of these categorical systems is Baumrind's (e.g., 1967), in her division of parents into three groupings: (1) authoritarian, characterized by rigid psychological control; (2) authoritative, marked by firm control, warmth and responsiveness to the child's needs; and (3) permissive.

### Cognitive Approaches to Socialization

In the 1960s, there was an emergent interest in experimental psychology in the role of cognitions, an interest that redirected the field of psychology away from a predominant focus on behavior. The new approach focused on the ways in which information is processed in response to relevant stimuli, along with the ways in which such processing serves to guide subsequent responses. However, the guise that cognitive formulations took varied across fields and theorists. Social psychology had a long history of concern with such constructs as social perception, causal reasoning (attribution theory), motivation for cognitive consistency, and so forth. Bandura (1986) formally adopted the title of "social cognitive theory" for a model that had employed cognitive constructs such as attention and imaginal encoding from the very beginning. M. Hoffman (1970) elaborated on the social learning theorists' analysis of discipline techniques in a cognitive developmental approach. The approach emphasized the use of "other-oriented" discipline (providing a rationale that focused on the impact of the child's antisocial actions on others) as particularly effective for moral development. This pattern of discipline was contrasted to power assertion (use of the parent's superior power to exert control), which predicted low levels of moral maturity, and love-withdrawal (withholding approval or affection when the child misbehaves), which was not consistently related to moral maturity.

The inclusion of cognitive constructs in the field of socialization took many different forms. As one varia-

tion, researchers often gave consideration to the role of the child's cognitive development in their responses to socialization experiences. In doing so, they were concerned with the changing abilities of the child as a processor of information. In addition, the child, at all ages, came to be understood as acquiring social knowledge structures. Bowlby, for example, borrowed from the developing interests in cognitive processes to talk about the ways in which the young carry forward their early history with parents as "internal working models." Beginning in the 1980s, Dodge, Coie, and their colleagues (see Coie & Dodge, 1998, for an overview) applied a cognitive approach to children's antisocial responses, with a particular focus on attributional biases that led to the interpretation of the ambiguous actions of others as reflecting hostile intentions. From a social information-processing framework, children were seen as approaching social situations with a history of social experiences represented in memory. Their consequent behavior was determined by the way they encoded, represented, and processed events as a function of interactions between biology, memorial events, and cues in the immediate social situation. In a reconceptualization of parental discipline practices and children's internalization of values, Grusec and Goodnow (1994) emphasized two features of children's cognition that were important in this process. The first was their accurate perception of the parental message and the second was their perception of such features of discipline as its fairness and its noncoerciveness that made acceptance of the message more likely.

Systematic consideration of parental cognitions emerged in the early 1980s (although it was predated by earlier work on parenting attitudes). Parke (1978) pointed out that, up to that point, most analyses of mother-infant interaction had credited the mother with the same degree of cognitive complexity as the infant. Realization that the understanding of socialization processes was seriously limited by failure to consider the important role of parental cognitions led to a reframing of this area of research. The 1980s saw an upsurge of research activity designed to clarify linkages between children's actions, parental thinking, parent actions, and child outcomes (e.g., Bugental & Johnston, 2000; Goodnow & Collins, 1990; S. Miller, 1995; Sigel, McGillicuddy-DeLisi, & Goodnow, 1992). Parental cognitions also appeared in the work of attachment theorists who focused on the way in which caregivers think about their ability to provide protection for their children (e.g., George & Solomon, 1996).

The approach taken to parental cognitions has followed two complementary pathways. The first focuses on parental cognitions as stable knowledge structures or schemas (as described by Bugental, 1992, and Grusec, Hastings, & Mammone, 1994); as such, they represent implicit cognitions that operate automatically, effortlessly, and outside of awareness (Bugental, Lyon, Cortez, & Krantz, 1997; Greenwald & Banaji, 1995). Parental cognitions as stable knowledge structures are learned as summary representations of parents' own past history as a child (e.g., George & Solomon, 1996; Zeanah, Benoit, Hirschberg, Barton, & Regan, 1994) or they may reflect a shared cultural history (e.g., Bornstein et al., 1998). The second approach to parental cognitions focuses on parental cognitions as event-dependent and data driven; as such, they involve reflective appraisal of ongoing events in the caregiving relationship (see Bugental, Johnston, New, & Silvester, 1998, for a review of these two approaches to parental cognitions).

## CURRENT DEVELOPMENTS: BIOLOGICAL AND CULTURAL PERSPECTIVES

Two new areas of focus have emerged in recent years, as socialization researchers have responded to increasing interest in biology and culture. No real understanding of any psychological phenomenon is possible without knowledge of how these two interact repeatedly to arrive at the outcome of interest.

### Biological Perspectives

In the past decade, the integration of biological and social processes has emerged across a variety of areas, where it has been recognized that these processes act in a complementary fashion. It has been proposed that when these processes are considered together, new insights may be afforded regarding the mechanisms involved in complex interpersonal interactions (Cacioppo, Berntson, Sheridan, & McClintock, 2000). In addition, there has been increased communication and cross-referencing between investigators concerned with parenting relationships among humans and those concerned with nonhuman models. The combined perspectives have provided new insights into many aspects of socialization. These perspectives, discussed in turn, include developmental neuroscience, evolutionary psychology, and behavior genetics.

Developmental neuroscience has moved into a position of central importance as researchers consider me-

diating processes in parent-offspring interactions (Carter, 1998; Fleming, 1990; Fleming, Corter, Stallings, & Steiner, 2002; Liu et al., 1997; Meaney, Aitken, Bodnoff, Iny, & Tatarewicz, 1985). In addition, there has been increasing interest in the long-term influences of socialization practices on the regulation (or dysregulation) of the child's neurohormonal responses (e.g., Bugental, Martorell, & Barraza, 2003; Gunnar, 2000). Behavioral neuroscientists working predominantly with nonhuman models have shown an increased interest in applying their findings to human processes, and social scientists have increasingly discovered that these findings help to inform their understanding of human relationships (e.g., Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000).

As a second shift, a bridge has emerged between the traditional interests of socialization or developmental researchers and those of evolutionary psychologists who focus on parental investment theory (Trivers, 1974). These fields have moved together in a shared concern with the experiences of children who are thought of as "costly" from an evolutionary standpoint and "at risk" in developmental psychology (e.g., Bugental & Beaulieu, 2004; Geary, 2000; Geary & Bjorklund, 2000; Hertwig, Davis, & Sulloway, 2002). These theoretical approaches converge to provide predictions with regard to both the negative and positive outcomes for such children as a function of the costs or benefits they provide to parents in the latter's reproductive success. More generally, increasing reference is being made to an emerging field of evolutionary developmental psychology (e.g., Bjorklund & Pellegrini, 2000, 2002; Geary & Bjorklund, 2000). Evolutionary psychology has focused attention on the domain-specific nature of adaptations. Consistent with this perspective, socialization may be conceptualized as involving distinctive algorithms in accomplishing different goals or tasks (Bugental, 2000).

Also seen are continuing shifts in the contribution of developmental behavior genetics to the socialization process. Traditional approaches have focused on the main effects of genes on children's social, emotional, and cognitive responses. More recently, interest has centered on the interplay between genetic and environmental influences (e.g., Collins et al., 2000). Evidence is mounting in support of evocative gene-environment correlations—the ways in which genetically based characteristics of the child come to influence the socializing environment, which feeds back to influence the child's behavior. As a

case in point, O'Connor, Deater-Deckard, Fulker, Rutter, and Plomin (1998) found that children who were at genetic risk for antisocial behavior (an assumption based on the prebirth behavior of their biological mothers) were more likely to elicit coercive parenting from their adoptive parents—a pattern that fostered increases in antisocial behavior of children. Evocative gene-environment correlations have also been found for other socializing influences; for example, the mutual responsiveness shown between parents and very young children (Deater-Deckard & O'Connor, 2000), or the negative conflict shown between parents and adolescents (Neiderhiser, Reiss, Hetherington, & Plomin, 1999).

As another causal route, genetic differences between children may serve to moderate the effects of the socializing environment; for example, Caspi et al. (2002) found that the long-term effects of maltreatment are moderated by genetic patterns. Those children whose genotype conferred high levels of monoamine oxidase A (MAOA; an enzyme that metabolizes neurotransmitters, such as serotonin, and thus renders them inactive) were more likely than children without this genetic pattern to respond to maltreatment with antisocial problems. The evidence that genotypes can moderate the child's sensitivity to environmental insults is significant; more generally, Belsky (e.g., Belsky in press; Belsky, Hsieh, & Crnic, 1997) and colleagues have proposed that there are genetic variations in children that lead to differential susceptibility to their parenting experience. This line of research has led to important insights regarding the types of parenting that are more or less effective with children with different temperament patterns (e.g., Bates, Pettit, Dodge, & Ridge, 1998; Kochanska, 1997). In addition, increased consideration is being given to the ways in which environments influence gene expression (e.g., Brown, 1999; Bruer & Greenough, 2001). For example, a very stressful early environment may lead to the expression of genes that control the presence of cortisol receptors in the brain; the resultant changes in children's response reactivity may act back to influence the nature of their social environment. Early experience in the home environment not only may foster problematic gene expression but also hold the possibility for fostering adaptive gene expression in response to environmental challenges. Newer concern with the two-way effects of genetic and experiential influences counter the earlier concerns expressed by many socialization theorists (e.g., Baumrind, 1993; L. Hoffman, 1985) concerning earlier genetic approaches that focused on just one side of the picture.

In summary, developmental neuroscience, evolutionary psychology, and behavior genetics all converge in their focus on the brain. Evolutionary psychology, combined with developmental neuroscience, tells much about the experience-expectant brain. Concerns with gene expression tell about the experience-dependent brain. Developmental neuroscience offers information regarding the couriers and routes through which socializing influences occur. In doing so, these disciplines simultaneously inform understanding of problematic and adaptive socialization of the young.

### The Cultural Perspective

Major changes in the orientation of socialization researchers are also evident in a dramatically increasing interest in the impact of context and culture on socialization outcomes. Earlier approaches to the study of culture's impact focused on cross-cultural comparisons as a way of validating the universality of psychological theories or of obtaining a wider variation in variables of interest than would be otherwise possible (e.g., Barry, Child, & Bacon, 1959; Whiting, 1976). More recently, the focus has been on how psychological events can be understood as a reflection of shared cultural meanings and practices, with attempts to find new ways of thinking about psychological functioning that cannot be accounted for in existing theories (J. Miller, 2002). Culture has also been expanded to include not only socialization in different self-contained groups but also socialization in the context of ethnic and minority groups existing in a larger and different cultural context (primarily in North America) and interactions between socioeconomic status and cultural context.

Harkness and Super (2002) note that studies of culture and socialization, regardless of disciplinary paradigm, have in common four assumptions. First, settings, such as types of dwellings and expectable activities for members of the group, are important because they determine the boundaries of children's experience as well embody cultural meanings. Second, the activities and routines that occur in different settings instantiate themes that matter to agents of socialization and thereby communicate cultural messages. Third, there are themes in a culture such that the same ideas or images occur in the meanings that are inherent in settings and activities; as well, the way settings and activities are organized for younger members of the group reflects an integrated system on the part of socialization agents. And, finally, what agents of

socialization do to children is affected not only by the cultural experiences of the agents themselves but also by characteristics of children with whom they interact, with these characteristics including temperament differences, skill potentials, and species-specific potentials for growth, transformation, and the organization of experience into meaning (Super & Harkness, 1997). One way in which these ideas have been formalized is in “ecocultural” (Weisner & Garnier, 1992) or “developmental” niches. Super and Harkness (1997), for example, suggest that children are socialized in a developmental niche that includes the physical and social settings of daily life, culturally regulated customs of child rearing, and cultural belief systems or “ethnotheories” of caregivers. These features are coordinated, they are influenced by outside events, and they are affected by the child’s individual characteristics to yield particular socialization outcomes.

Cultural psychologists argue that cultures can be understood as created, sustained, and communicated in everyday practices and behavioral routines (Goodnow, Miller, & Kessel, 1995) and that development occurs through participation in activities rather than through the acquisition of knowledge and skills (Rogoff, Pardies, Arauz, Corres-Chavez, & Angelillo, 2003). Fiske, Kitayama, Markus, and Nisbett (1998) write that socialization involves the incorporation of cultural models, meanings, and practices into basic psychological processes, which maintain or transform the cultural system. Moreover, behavioral responses cannot be understood without knowledge of the culturally based meaning they have and the cultural practices to which they are linked (J. Miller, 2002).

These various proposals have affected and will continue to affect the way researchers construe the developmental process. The work of cultural psychologists has underlined the importance of context and meaning for socialization theorists and led to the realization that the central focus on a few specific socialization practices (e.g., reinforcement, discipline, modeling), characterizing much of the history of research in the area, has limited understanding and needs considerable expansion.

#### **CROSS-CUTTING THEMES: DIRECTION OF EFFECT IN SOCIALIZATION RELATIONSHIPS AND SITUATIONAL SPECIFICITY OF SOCIALIZATION**

Before moving to a detailed discussion of biology and culture in the remainder of the chapter, we discuss two

issues that must be addressed in any conceptualization of the socialization process. They both reflect changes in the way researchers have thought about socialization as a process whereby the agent of socialization transmits standards, rules, and procedures to the child but the nature of the standard, rule, procedure, and so on is irrelevant in the transmission process.

#### **Direction of Effect in Socialization Relationships**

A continuing concern in the field of socialization has been with the direction of effects in relationships. Developmentalists have moved away from very simple models that fail to capture the complex nature of causal processes toward the increasing use of models that are concerned with the interplay of causal forces of many types. Models have moved from the depiction of unidirectional causality (socializing agent to child, or child to socializing agent) to bidirectional causality (interdependence in the effects of causal influences in socializing relationships). As a new direction, contingent causality is being explored in socialization processes; in such models, causal influences are seen as contingent on context. Despite the increasing sophistication of socialization models, empirical research has not kept pace with the emerging models. The preponderance of socialization research (in both the questions asked and the methods of analysis) continues to employ unidirectional models (as noted by Collins et al., 2000, and Kuczynski, 2003).

The earliest way of thinking about socialization processes by philosophers, educators, and social scientists was unidirectional—influence flows from parents and society to children. As described by Hirschfeld (2001):

Socialization has been seen as a causal process in which knowledge is acquired from communal living in a particular social environment. In this view, structure and organization in cultural learning flow from society to child, and consequently from adult to child. . . . Children are treated largely as if they were passive receptacles into whom culture is poured or on whom it is impressed. (p. 109)

The pervasiveness of this view has been documented in comprehensive reviews (e.g., Corsaro, 1997). This view was virtually unchallenged until Bell’s highly influential critique (1968). In reviewing what was known about the influence process that occurred between

parents and children, Bell made a compelling case that children have just as much (if not more) influence on parents than parents do on children. Children strongly influence their own environments, either by serving to “trigger” parental responses or by selecting some environments more than others (e.g., Scarr & McCartney, 1983).

Ultimately, it came to be accepted that the influence process between socializing agents and children was bidirectional in nature. As well described by Kuczynski (2003), bidirectional models come in many different forms. As a variant of Kuczynski’s categorization, we consider ways of conceptualizing socialization that follow from (a) transactional models, (b) circular models, (c) ecological models, (d) systems models, and (e) contingent causality models.

### *Transactional Models*

The earliest break from unilateral models came with the introduction of the notion of socialization transactions by Sameroff (1975). From this perspective, there are continuous reciprocal interchanges between parents and children. Thus, the parent responds to the child’s behavior at one point in time, and the parent’s response to the child’s behavior comes to influence the child’s response in the future. Consequently, socializing relationships undergo constant transformation. However, continuous transactional processes are not easily measured. As a result, research following from this approach typically approximates the tenets of the model by measuring a series of unidirectional influences; for example, the influence of the child on the parent at one point in time, followed by the influence of the parent on the child at a later point in time. Causal inference in such models is possible when interventions lead to differences in parental behavior (as a result of an experimental manipulation), which influence child outcomes. LaFreniere and Capuano’s (1997) intervention with the mothers of anxious-withdrawn preschool children provides an illustration: This intervention led to reductions in maternal intrusiveness, which was associated with increases in children’s social competence.

In biological approaches that focus on the interrelationship of physiological processes and social interactions, transactional models fit well with the evidence. For example, the regulatory systems of mothers and infants are linked, with the internal states of each open to regulation by the presence or responses of the other (e.g., Hofer, 1987). As is noted later, animal models

often contribute to understanding such transactional systems in that experimental variations can be produced at various points in the relationships making causal inference possible. Transactional models are also consistent with emerging work in the field of developmental behavior genetics, with demonstrations of the two-way influence processes found between genes and environment, for example.

### *Circular Models*

Circular models represent a variant of transactional models (Kuczynski, 2003). In such models, the parent and child relationship involves a recursive interactional loop that has no beginning or end. As is true for other transactional models, such processes are not easily measured: It is only possible to enter the loop at defined points, and the direction of effects is not easily ascertained. The notion of circularity does, however, have good explanatory value in accounting for observations of socializing interactions. This has been particularly notable in explaining the “vicious circles” described by Patterson and his colleagues (e.g., Patterson, Reid, & Dishion, 1998). These investigators have found repeated evidence for reciprocal influence processes between mothers and aggressive children. In these families, the mother often begins an interchange with an aversive demand, the child counterattacks, the mother backs off, and the child terminates the counterattack. As the mother’s influence attempts fail, her confidence declines, and thus her ability to elicit compliance is further eroded. In similar fashion, longitudinal research conducted by Eisenberg and her colleagues (Eisenberg et al., 1999) found bidirectional effects between children’s negative emotionality and parents’ use of punitive tactics.

### *Ecological Models*

In ecological approaches to socialization, consideration has been given to bidirectionality, not only in the family, but also between the family and the larger social networks in which the family is rooted. The earliest ecological model in the field of socialization emerged with Bronfenbrenner’s conceptualizations (1979). The term *ecology* was used to describe the various levels of socializing influence—from the forces operating in the nuclear family to extended family or friends, neighborhoods, and larger community structures. The descriptive adjective “geographical” was applied to this

approach (Goodnow et al., 1995) as a way of highlighting the metaphor contained in an ecological model. In models of this kind, the socializing role of parents may follow from their role as guides or managers (e.g., Parke & Bhavnagri, 1989): Rather than serving as direct sources of influence, parents may act to manage or create environments, which, in themselves, serve as socializing influences.

### *Family Systems Models*

A systems model of family processes make uses of principles drawn from general systems theory (as reviewed by Cox & Paley, 1997). In this approach, the focus is on the mutual influences that occur between family members and between subsystems in the family. For example, the parent-child relationship is understood in the context of the relationship between parents. Thus, the term *co-parenting* is used to describe the activity of joint caregivers, with effectively functioning co-parenting units in which the caregivers together convey a context of solidarity and support between them, a consistent set of rules, and a secure home base (McHale et al., 2002). Family processes are conceptualized as organized systems whose properties are not derivable from knowledge about the individuals or family subsystems. For example, it has been suggested that children's emotional security cannot be understood outside the context of the family; in particular, it has been suggested that the child's sense of security will be damaged by destructive conflict between parents (e.g., Cummings & Wilson, 1999). This approach has stressed consideration of the role of fathers (as well as mothers) if a full understanding is to be obtained of children's development (Cox, Paley, & Harter, 2001).

Finally, the approach has stressed the extent to which families can reorganize adaptively in response to challenges and transitions external to the family (e.g., the child's entrance to school). All components in the socializing system (the individuals in it, the social networks in which it is embedded, along with other aspects of the larger environment) are understood to be in constant change, in particular, at points of transition (e.g., Cowan & Cowan, 2000; Fogel & Branco, 1997; Valsiner & Cairns, 1992). Effective parenting is understood to involve collaboration in response to these changes, conflicts, and contradictions (e.g., Holden & Ritchie, 1988). As a constraint posed by this approach, the measurement of reciprocal processes between family subsystems

poses a challenge to existing statistical methods—a challenge receiving increased attention (Kenny, Korchmaros, & Bolger, 2003).

### *Contingent Causality Models*

Conditional causality models focus on the “if-then” nature of socialization processes: Socializing forces, rather than being understood primarily as additive or reciprocal effects, are understood to involve contextual contingencies. This type of model has served to influence thought emerging from different theoretical perspectives. Concerns with the fit between socializing style and child temperament represent the earliest use of a conditional causality model (Thomas & Chess, 1977). From this framework, it was proposed that effective socialization was contingent on the match between parental practices and the characteristics of a particular child. More recently, a number of investigators (e.g., Kim, Conger, Lorenz, & Elder, 2001; Kochanska, 1995; Patterson & Sanson, 1999; Stoolmiller, 2001) have expanded this approach, showing how various features of children's temperament, such as fearfulness or irritability, interact with the socialization practices to which they are exposed.

In another line of work, research concerned with the organizing effects of parenting contexts and parental goals has stressed the appropriate variations in parental practices across settings (e.g., Dix, 1992; Grusec & Goodnow, 1994; Grusec, Goodnow, & Kuczynski, 2000; Hastings & Grusec, 1998). From this point of view, parents' understanding of a particular child's characteristics and perspective and the characteristics of the immediate situation, rather than the use of specific strategies or styles, determines their effectiveness (Grusec et al., 2000). Thus, maternal perspective-taking ability has been linked to mother-adolescent conflict intensity (Lundell, Grusec, McShane, & Davidov, 2004; Smetana, 1996) and mothers' knowledge of their children's reactions to different discipline interventions has been linked to their children's compliance (Davidov & Grusec, 2005). Similarly, parents' knowledge of their adolescents' thoughts and feelings during conflicts predicts positive outcomes (Hastings & Grusec, 1997). In addition, socializing practices appropriately vary with shifts in parental goals or aims (e.g., child safety or compliance; Grusec et al., 2000).

From a very different perspective, parental investment theory proposes that the level of parental care provided to

the young is contingent on the resources available to the parents (Mann, 1992; Trivers, 1974), combined with the costs imposed by provision of care to a particular child (e.g., the costs of providing care to an at-risk child versus other children). Thus, a high-risk child might be neglected by parents who lack resources (i.e., economic, cognitive, or social) but receive exceptionally high levels of care by parents who have adequate access to resources (Bugental & Beaulieu, 2004).

Finally, biological approaches include many instances of conditional causality in social relationships. For example, reference is often made to “switching mechanisms” (Zupanc & Lamprecht, 2000) in which a pattern of social response (e.g., manifestation of parental behavior) is “turned on” in response to hormonal change. As another example, the hormonal changes that occur during pregnancy are associated with increased interest in care of the young (among both mothers and their partners).

In summary, models of causality in socializing relationships have moved away from simple concern with unidirectional effects (parent to child, child to parent) to models that consider the role of reciprocal influences, along with the role of context. Children are increasingly understood as engaged in continuous transactions in their socializing environment, an environment that includes not only their families but also more extended social networks, the larger community, and the resources available to the family in that community. In addition, interest has emerged in models suggesting a contingent relationship between socialization and context: The outcomes of the same socializing practices are expected to differ (qualitatively as well as quantitatively) as a function of contextual variables.

### **Situation-Specific Socialization**

In the history of socialization theory, different perspectives have been taken on the cross-contextual continuity of socialization. An earlier view focused on general processes that were believed to operate across ages, settings, and cultures. This view was centered in a learning theory approach that focused on domain-general processes. From this perspective, the child is socialized by a set of processes that are equally applicable across context. Although variations might be expected in quantitative processes (e.g., variations in the intensity of rewards and punishments across ages), variations were not predicted for the qualitative nature of socialization across contexts. The perspective was

intrinsically appealing in that it offered a guidebook for parents (or those concerned with facilitating or understanding optimal parenting) regarding the socialization processes that worked. The durability of Baumrind’s (e.g., 1967, 1971) approach to socialization is a case in point.

Challenges to this view have emerged from different theoretical perspectives. Increased attention has been directed to the possibility that socialization involves processes that are qualitatively distinct across context or domain. Researchers in some areas have suggested that the processes of interest to them are controlled by mechanisms that are specific to a particular response system or a particular type of social relationship. Language acquisition (following the work of Chomsky, 1988) is one such area, with the thesis that children are innately wired to develop language. Attachment processes (following the work of Bowlby, 1973) is another area with its focus on maternal protection as a foundation of personality. Research concerned with empathy and sympathetic distress (following the lead of M. Hoffman, 1981) is a third area in its emphasis on the importance of other-oriented induction—reasoning that addresses the impact of the child’s negative actions on others.

In this section, we review the various ways in which single process theories have come to be questioned. We begin with some of the earliest challenges and end with a relatively recent and systematically organized challenge that has been spearheaded by evolutionary psychology.

### ***Privileged Learning***

The earliest challenges to general learning theory came from within the field itself. Researchers from this theoretical perspective were faced with limits on the extent to which the postulated learning mechanisms were true for all situations. For example, evidence emerged that some types of learning appeared to be privileged: Learning occurred with exceptional ease and was highly resistant to attempts to override it. Garcia’s classic research showing that food aversion can be learned by nonhumans in a single episode provides a case in point (as summarized in Garcia & Koelling, 1996). Seligman (1970) described these predispositions as “prelearning.” He proposed that organisms are differentially prepared to associate different kinds of events, with food aversion as an example of those very easily acquired and the establishment and maintenance of responses incompatible

with species-specific responses extremely difficult to learn (Breland & Breland, 1966).

### *Challenges from Attachment Theory*

Early challenges to the continuity of socializing processes also arose in the study of attachment relationships where the processes suggested by learning theorists as organizers of socialization did not appear to operate in any simple fashion. Thus, contrary to what would be predicted by learning theory, babies whose mothers responded most quickly and frequently to their crying in the first 3 months of life cried less at the end of their 1st year of life (Ainsworth, Blehar, Waters, & Wall, 1978). Although the provision of food is a benefit of the attachment relationship, it does not serve as a basis for selective attraction to attachment figures or for strengthening of the attachment relationship (Harlow, 1973; Harlow & Harlow, 1965). Instead, such attraction is organized around the species-specific stimulus features that have been associated with mothers across the relevant evolutionary history. In addition, infants show privileged learning in identifying the characteristics of their own mother. In similar fashion, shared play activity serves as a benefit that is often associated with early parent-child relationships but is not associated with attachment: The young seek contact with attachment figures when they are in a state of distress but may seek out a variety of others for social play (e.g., Bretherton, 1985; Higley et al., 1992).

Some investigators have focused specifically on the distinctiveness of the function of attachment. For example, MacDonald (1992), arguing from an evolutionary perspective, suggested that attachment relationships are organized by fear responses (fear of separation), whereas affectional relationships are organized on the basis of emotional warmth. Goldberg, Grusec and Jenkins (1999) pointed out that the key function of attachment is the safety of the young and that the fundamental element in the production of secure attachment revolves around provision by a caregiver of protection and comfort in response to infant distress as opposed to sensitive responding to other forms of affect.

### *Peers versus Parents as Agents of Socialization*

Another challenge to the notion of single-process explanations of socialization came from developmental psychologists who were concerned with peer relationships. From these earliest concerns (Piaget, 1948), it has been suggested that the influence process between peers dif-

fers from that between parents and children. In accord with Piagetian views, Youniss, McLellan, and Strouse (1994) suggested that "[p]eer relationship[s] are marked by use of symmetrical reciprocity and guided by the overarching principle of cooperation by equals" (p. 102), an organizational principle that differs from the unilateral authority or power asymmetry that is more characteristic of adult-child relationships.

### *Domains of Social Knowledge and Judgment*

Concern with variations in socialization processes also emerged with respect to the demonstration of distinctions children make in their judgments about social concepts. Specifically, Turiel and his colleagues (see Turiel, 1998) proposed that there are distinctions shown between morality and conventionality across cultures and that these emerge very early in the course of development. Morality involves universal concerns with justice, welfare, and rights whereas conventionality involves consensually agreed-on behavioral routines that are important for the organized functioning of group life. Although both domains are understood as legitimately subject to regulation by those in authority (e.g., parents in the home environment and teachers in the school environment), the moral domain is seen to be obligatory and unalterable, whereas the social conventional domain can be altered by agreement or consensus.

Building on these concepts, Smetana and her colleagues (e.g., Nucci & Smetana, 1996; Smetana, 1997; Smetana & Asquith, 1994) have been concerned with the changing or nonchanging ways that parents and children understand and negotiate moral, conventional, prudential (e.g., safety maintenance and property protection), and personal (e.g., choice of friends) domains across the course of development. Thus, parental regulation and enforcement are always considered legitimate with respect to the moral domain but grow somewhat less so with respect to the social conventional domain. The big difference comes in what is deemed by adolescents to be increasingly under their personal jurisdiction and therefore not subject to parental control. Even sharper disagreement occurs over issues that combine conventional and personal considerations. Keeping one's room clean and neat may be seen as involving the conventional domain by parents, with the room seen as part of the entire house. The same activities may be seen as involving the personal domain by adolescents, with the room seen as their territory (Smetana & Daddis, 2002).

### *Parenting Goals*

A number of socialization theorists have been concerned with the role of parental goals as sources of variability in their socialization practices across contexts. Parental goals serve to moderate the ways in which parents behave (including their affective responses) on different occasions. From this perspective, parents will employ different tactics in different settings depending on what they hope to achieve. Attention has been directed to the specific nature of parental goals (e.g., Dix, 1992; Hastings & Grusec, 1998). So, for example, Dix (1992) suggested that parenting practices vary on the basis of the activation of (a) parents' personal goals (goals that are relevant to efforts to obtain child obedience), (b) parents' empathic goals (goals focused on satisfying children's emotional needs), and (c) parents' socialization goals (goals based on the motivation for children to learn culturally defined values). Hastings and Grusec (1998) focused on shifting parental practices as a function of a similar clustering of goals: (a) parent-centered goals (fostering power assertion), (b) relationship-centered goals (fostering warmth, negotiation, and cooperation), and (c) child-centered goals (fostering reasoning).

### *Features of the Child as Determinants of Socialization Effectiveness*

In addition to observing that agents of socialization may have different outcomes they wish to achieve, socialization theorists have also had to incorporate the differential susceptibility of different kinds of children to socialization experiences in different domains. Thus, the impact of particular socialization practices depends on a number of variables including the social behavior in question (e.g., violations of moral or social conventions), the age and sex of the child, the sex of the parent, and, as noted earlier, the child's temperament and mood (Grusec & Goodnow, 1994).

### *Domains of Social Life*

A number of theoretical approaches have emerged that are specifically concerned with the nature and functioning of the different domains of social life. Domains may be conceptualized as representing bodies of knowledge that act as guides to partitioning the world and that facilitate the solving of recurring problems faced by organisms in that world (Hirschfeld & Gelman, 1994). These approaches, which have typically been in-

fluenced by evolutionary psychology, propose that different social domains are organized by distinctive algorithms, and that they operate in the accomplishment of social tasks that have had adaptive significance across cultures and species. The greatest utility of this approach for socialization theory follows from the implicit need for different types of parental practices in different social domains.

Although different theorists have developed different taxonomies, five domains have regularly been represented (four are directly relevant to the discussion of socialization processes; Bugental, 2000):

1. *Protective care*: Interaction in this domain is organized by mechanisms (e.g., proximity-maintenance) that provide for the safety and feeding of dependent offspring.
2. *Coalitional groups*: Interaction in this domain is organized to facilitate the establishment and maintenance of shared benefits from an in-group and shared defense against threat from outsiders.
3. *Hierarchical power*: Interaction in this domain involves the management of control between individuals who differ in social dominance and resource holding potential.
4. *Reciprocity/mutuality*: Interaction in this domain involves the regulation of matched benefits between functional equals.
5. *Mating*: Interaction in this domain serves to facilitate the selection and protection of access to high-value sexual partners.

## **BIOLOGICAL PROCESSES THAT CREATE THE PLATFORM FOR SOCIALIZATION**

In this section, we review the biological mechanisms that can be thought of as creating the platform for the processes that are involved in socialization. At one level, there are shared genetic influences that reflect the brain's "best guess" as to the kinds of social experiences the young will have. In addition, there are genetic variations in children in the extent to which they are receptive to socialization (considered later in our integration of biological and sociocultural theories). We organize our understanding of the biological platform for socialization in four social domains that appear to have distinctive features (introduced in Bugental & Goodnow, 1998).

## Processes in Different Domains

For each domain, we describe (a) the basic tasks of the domain, (b) the ways in which parents and the young are biologically prepared for the domain, and (c) the ways in which interaction in a domain serves to accomplish proximal tasks (e.g., time-limited tasks characteristic of a particular stage of development) as well as providing experiences beneficial for tasks that emerge at later ages.

### *Protective Care Domain*

The protective care domain is the domain that most uniquely involves parents and the young in a relationship. Although there are variations in the extent to which such a relationship may be established with other caregivers, mothers are the most extensively prepared for this relationship as a result of biological processes. Fathers (among those species that involve cooperative care) are also prepared for this relationship, as a result of biological processes, but somewhat differently and more variably than are mothers.

The provision of care to the young must be thought of as conditional in nature: Parents invest more in those offspring who are more likely to serve their reproductive interests; that is, they are more likely to invest in those children who are likely to grow up to have healthy children of their own (Bugental & Beaulieu, 2004; Wilson & Daly, 1994). In addition, parents (without conscious awareness) weigh their investment in one child against their investment in other offspring (or potential offspring in the future). Parents also invest more in the young when they have the resources to do so (e.g., access to food and economic resources or access to supportive others who will facilitate the process of parental care).

To some extent, the processes involved in protective care serve the shared interests of parents and their offspring. For the infant, the relationship is a safety-maintenance system that is essential for survival and normal development. For the parents, the relationship, in promoting the survival and healthy development of the young, enhances the replication of their own genes. At the same time, the protective care system also involves tasks that are not shared between parent and child (Trivers, 1974; Wilson & Daly, 1994). Human offspring have a very long period of dependency and therefore there is a need for an extended period of parental care: The infant's best interests are served by obtaining the largest share possible of the parent's provision of care; in contrast, the parents' best interests are best served by dividing their care provi-

sion across their offspring (and thus optimizing their own reproductive success). Their interests may be thought of as competing. Mothers may have many children, and the level of care provided for one child must be balanced against the level of care provided for other children. Children, however, cannot choose alternative caregivers; as a result, they are prepared to initially maintain contact with the individual (or individuals) who are available to them in a caregiving role.

**What Are the Tasks of the Protective Care Domain?** The proximal tasks of the protective care domain are (a) maintenance of safety and nourishment (provisioning) of the young before they are able to do so for themselves and (b) comforting of the young following stress. The long-term tasks of this domain are (a) facilitation of the stress regulation ability of the young and (b) facilitation of the child's understanding of and competence in the caregiving relationship.

**How Are the Young Prepared for the Protective Care Domain?** The protective care system (regulated by attachment processes) represents a co-evolved system that involves the distress system of the young and the protective system of the caregiver (Bowlby, 1969; Panksepp, 1996). Under naturally occurring circumstances, the reunion of mother and infant not only allows safety but also, simultaneously, nursing access. However, attachment processes are linked to stimulus features of the mother rather than to provision of nourishment (e.g., Harlow, 1973).

*Experience-Expectant Responses of the Young.* Because the protective care domain needs to be operational at birth, most of the timing mechanisms that regulate it are online immediately (or in some cases, even prior to birth). Very early in life (beginning on the 1st day), infants show unique sensitivities to the kinds of auditory and visual stimuli that are species-typical (and thus are likely to be characteristic of parents). The ability to quickly recognize their parents is important for survival in that it insures that infants will attempt to maintain contact and proximity with those individuals who are most likely to provide for their care.

As an example, infants are highly receptive to facial cues, and may recognize their mother's face, as early as 2 days of age (Field, Cohen, Garcia, & Greenberg, 1984). Although it was once believed that this process suggested an innate face recognition mechanism, it is

now thought of as a privileged learning process in which there is high visual engagement with faces early in life (Johnson, Dziurawiec, Ellis, & Morton, 1991). This process fosters the development of relevant neural structures. In the same way, infants appear to show a privileged learning process in identifying their mother's voice. Indeed, the human fetus shows an ability to recognize the mother's voice. Kisilosevsky et al. (2003) exposed human fetuses to a tape recording of the voice of their own mother or the voice of a female stranger reading the same passage. The fetuses' heart rate was found to increase in response to the voice of their own mother but decrease in response to the voice of a female stranger (differential responses that are consistent with reactions to familiar versus unfamiliar stimuli). At birth, this early preparation is demonstrated by the fact that neonates show a preference for their own mother's voice (DeCasper & Fifer, 1987; Ward & Cooper, 1999). Finally, infants quickly come to recognize their mother's smell—an odor that is associated with breast milk (Bartoshuk & Beauchamp, 1994; Schaal, 1988). This sensitivity allows infants to easily locate the mother's breast.

*Activation of Distress Signals.* Unlike precocial animals, the human infant is unable to move away from the mother in the first few months of life. It is not until the infant becomes mobile (during the third trimester of the 1st year of life) that distress calls are shown in response to separation or the presence of a stranger. Even though the care of the young shows many different patterns across cultures, the age at which distress calls emerge is quite regular (Konner, 1972). In the same way, the distress call system is also deactivated at a later age. Among nonhumans, such calls are deactivated in response to increasing levels of testosterone in pubescence (Herman & Panksepp, 1981). Changing levels of testosterone among human adolescents may possibly contribute to declines in their dependency on parents at this time (Steinberg & Silverberg, 1986).

**How Are Parents Prepared for the Protective Care Domain?** Preparation for the protective care domain occurs at different levels. This includes both general preparation and specific preparation at particular time periods.

*Generalized Preparation for Protective Care.* Because parents are prepared for caregiving relationships with a

number of children, their attraction to this domain is broadly based, including attraction to the young (in particular, infants) as a whole. It is important for parents to be attracted to the stimulus features that characterize the young if they are to become invested in their care.

One of the most general stimulus cues to immaturity is appearance. Humans have been found to show a very general attraction to the facial configuration that characterizes immaturity, as in the very general attraction to baby-faces (Zebrowitz, 1997). In addition, the human cry has the capability of eliciting very general attention from others (Ostwald, 1963). Some sex differences are present, however, in the ways in which men versus women respond to the distress calls of the young. Nonparental males typically respond with heart rate deceleration in response to such signals, whereas nonparental females are more likely to respond with heart rate acceleration (Lin, 1999; Power, Hildebrandt, & Fitzgerald, 1982). These differences may be adaptive in that heart rate increases are more consistent with preparation for action (e.g., provision of care), whereas heart rate decreases are more consistent with vigilance (e.g., monitoring the environment for the source of the infant's distress).

Adults share the tendency to interact with the young using prosodic features that are distinctive to this domain. The properties of this style of speech has been referred to as "infant-directed speech" (Fernald et al., 1989), which is a speech style observed very generally across language groups (Kitamura, Thanavisuth, Burnham, & Luksaneeyanawin, 2002). Infant-directed speech (IDS) has been found to be a uniquely effective means of providing comfort to the distressed infant (Papousek & Papousek, 1995). IDS may serve the goals of socialization at younger ages and language acquisition at later ages (Kitamura et al., 2002).

*Prenatal and Perinatal Preparation for Parental Care.* Preparation for parental care needs to be considered separately for females and males. Biological preparation of females for the mothering experience begins prenatally (among both human and nonhuman mammals). During (and immediately following) pregnancy, there are hormonal changes that prepare the mother for parturition and lactation among both humans and other mammals (e.g., oxytocin, prolactin). In addition, there are hormonal changes that lead to increases in the prospective mother's interest in the young and the provision of care. In this chapter, we are primarily con-

cerned with hormonal influences on the mother's social responses to the young.

Among human mothers, there are increases in the levels of cortisol, estradiol, and prolactin across the course of pregnancy (Bridges, 1996; Coe, 1990; Storey, Walsh, Quinton, & Wynne-Edwards, 2000). Of these hormones, circulating levels of cortisol during pregnancy appear to be most clearly related to subsequent maternal behavior (Storey et al., 2000). Elevated cortisol levels predict higher levels of approach behaviors in response to infants (e.g., patting, cuddling, or kissing the baby; talking, singing, or cooing to the baby; Fleming, 1990). In addition, those women who show higher levels of cortisol are more likely to recognize and be attracted to the odor of their own newborn infant (Fleming, Steiner, & Corter, 1997). Among human mothers, other hormonal changes appear to be more associated with the physiological processes of pregnancy rather than with maternal responses (Storey et al., 2000).

Storey, Walsh, Quinton, and Wynne-Edwards (2000) found that men and women showed equivalent levels of stage-specific changes in hormonal levels; for example, both show higher levels of prolactin and cortisol late in the pregnancy. Men who showed higher levels of reactivity to infant stimuli were found to show the highest levels of prolactin increase. In addition, new fathers with higher prolactin levels were more alert and more positive in response to infant cries than were those with lower prolactin levels (Fleming et al., 2002). Similar benefits (in parental care) were found in both of these studies as a result of declines in males' testosterone (and associated aggressive tendencies) across the pregnancy of their partner. These findings are interpreted as showing that prospective fathers' hormonal changes before and at the time of their child's birth facilitate their demonstration of parental care. At a more general level, married men with children have lower testosterone levels during the day than do unmarried men or married men without children (Gray, Kahlenberg, Barrett, Lipson, & Ellison, 2002).

Shared parental care of the young is typically greater in species that are also monogamous (Yogman, 1990), and shared parental care is maintained by continued contact with mates. Suggesting the effects of this experience on gene expression, males' experience in providing care for the young may also lead to changes at the level of the brain: The medial preoptic area (an area that is important for maternal behavior) becomes similar to that of females (Gubernick, Sengelaug, & Kurz, 1993).

*Recognition of the Infant.* After birth, it is important that mothers quickly come to recognize their offspring. In doing so, they show privileged learning. For example, human mothers very quickly learn to identify the sound of their own infant's cry (Green & Gustafson, 1983; Wiesenfeld, Malatesta, & De Loach, 1981). Fathers also show some level of privileged learning in the recognition of their infant cries; however, their accuracy is considerably less than that of mothers. In addition, parents' autonomic responses are different in response to the cries of their own versus unrelated infants (Wiesenfeld et al., 1981).

Oxytocin may also play a role in the easy recognition of one's own offspring (among both humans and nonhumans). Oxytocin has been found to facilitate social recognition processes in general; for example, elevations in oxytocin increase the ability of rodents to recognize a conspecific only seen in a brief encounter (Popik & van Ree, 1991), with influences appearing to be at the level of the hippocampus and the amygdala (Ferguson, Aldag, & Insel, 2001; van Wimersma, Greidanus, & Maigret, 1996). Findings are consistent with the general observation that the brain processes social stimuli differently than nonsocial stimuli (Young, 2002).

### **Coregulation of the Protective Care System.**

Regulation of the protective care domain involves key time-limited tasks to be accomplished, as well as the socialization of the young for later life experiences. Indeed, attachment relationships, which develop as a result of the infant's need for care and protection, are often not included in discussions of the topic of socialization. Such relationships are included here on the basis that the ways in which the tasks of this domain are carried out will differentially affect the ability of the young to manage stress, as well as their ability to provide parental care themselves, at later times. Therefore, in discussing coregulation processes, we are simultaneously concerned with proximal and distal tasks.

*Safety Maintenance.* Early protective care involves a dyadic system maintained by the parent (typically the mother) and the child in this relationship. Caregiving relationships, if they are to be adaptive, require the coordinated activity of the neurohormonal systems as well as the behavioral responses of both individuals. As a caveat, it should be noted that the activation of hormones in response to stressful experiences need not act as a continuing regulator of protective care systems. Ultimately such response systems come to operate efficiently with

minimal cues. This short cut occurs as a function of the involvement of the amygdala. The initial activation of stress hormones in response to separation has an effect on the amygdala, which plays an important role in memory consolidation, as described by McGaugh (2002): "The basolateral region of the amygdala plays a crucial role in making significant experiences memorable" (p. 456).

The operation of protective care is best observed in response to separation or presence of threat and reunion. When separated from their mothers, nonhuman infants (typically based on observations of rats and nonhuman primates) show hormonal changes consistent with physiological stress responses (e.g., Hofer, 1996; Keverne, Nevison, & Martel, 1997; Laudenslager, Boccia, Berger, & Gennaro-Ruggles, 1995). Their responses include increases in the levels of corticosterones that are produced, combined with declines in their production of beta-endorphins. In response to these changes, their level of distress calls increases. Such calls are well-known triggers to maternal recovery and caregiving responses, as mediated by hormonal responses (e.g., increases in production of oxytocin).

Although such research informs us about processes in nonhuman species, questions may be raised about equivalent processes among humans. It is useful then to consider the supportive evidence (albeit nonexperimental) that may be observed in relationships between mothers and infants. Infants have been found to show cortisol increases in response to 30 minutes of separation from their mother (Gunnar, Larson, Hertsgaard, Harris, & Brodersen, 1992). Spangler and Grossman (1993), assessing infant response to the Strange Situation (with more limited separation times), did not find a general pattern of cortisol increase; instead such increases were limited to infants who were insecurely attached. They did, however, find increases (across attachment groups) in heart rate—another indicator of distress.

Among both humans and nonhumans, reunion is associated with increased affiliative activity. Among humans, this includes the infant's positive greeting and clinging. However, cortisol responses to reunion depend on attachment style. If the attachment relationship is insecure, cortisol levels continue to be high following reunion (Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Spangler & Grossman, 1993).

*Regulatory Systems.* The protective care relationship serves both directly and indirectly to foster stress regulation among the young: It serves to both buffer against stress and ultimately facilitate self-regulatory skills. In-

fants show direct benefits as a result of direct touching contact with their mothers. For example, preterm infants in neonatal intensive care units have been found to demonstrate significant increases in the presence of circulating beta-endorphins in response to skin-to-skin contact with their mothers (Mooncey, Giannakouloupoulos, Glover, Acolet, & Modi, 1997). In addition, preterm infants have been found to show a variety of benefits (e.g., decreases in cortisol levels or weight gain) in response to massage (Field, 1998; Kuhn & Schanberg, 1998).

The protective care relationship also serves to facilitate the acquisition of self-regulation skills. Evidence with respect to the benefits of protective care comes from both human and nonhuman research. The research program of Meaney and his colleagues (e.g., Francis, Caldji, Champagne, Plotsky, & Meaney, 1999; Meaney, Aitken, Bodnoff, Iny, & Tatarewicz, 1985) has demonstrated the long-term regulatory advantages of high levels of early maternal care: Pups who received extra licking and grooming in response to distress demonstrated an enhanced ability to cope with later stress. Specifically, they more quickly habituated to novelty. In addition, the experience of high maternal care predicted the willingness of offspring to move out to explore the environment without fear. As is true with humans, early provision of reliable protection acts to foster later capabilities for autonomy. In the same way, human infants are unable to self-regulate either their behavior or emotional states in the first few months of life and use the mother as an external organizer of their biobehavioral regulation (e.g., Spangler, Schieche, Ilg, & Maier, 1994).

*Preparation of the Young to Become Parents.* Finally, the protective care relationship provides a learning experience that produces effects when the young grow up to become parents themselves. Again, we turn to nonhuman research to identify some of the mediating mechanisms that may operate here. Francis, Diorio, Liu, and Meaney (1999) conducted a program of research exploring the cross-generational effects of early maternal care. A comparison was made between a strain of rats in which mothers engaged in high levels of maternal care (e.g., licking and grooming) versus one that engaged in low levels of care. To separate out the effects of genetic influences from experiential ones, the rat pups were cross-fostered by a different strain of rat (i.e., rats from a high lick/groom strain were reared by mothers from a low lick/groom strain, and vice versa). Rat pups were then tracked to observe the parental care they provided to their

own young. The parental care provided by the second generation reflected the care they had received from their foster mother (the experience route) rather than the care that was provided by their biological mother to other pups (the genetic route). This suggests the importance of early care as a precursor to effective parenting at a later age.

Among humans, the attachment literature has provided abundant evidence for the cross-generational transmission of attachment styles. A high degree of convergence has been found between the attachment styles of mothers (as reflected by responses to the Adult Attachment Interview) and the attachment styles of their own infants (Benoit & Parker, 1994; Ward & Carlson, 1995).

**Summary.** More than is true for any other social domain, parents and the young are strongly prepared at a biological level for the tasks of protective care. The tight programming of this domain can be understood by the centrality of its role in the early survival of the young. Among humans, mothers and fathers are both prepared prior to the birth of offspring for parental care. At a general level, they show interest in infant stimuli. More specifically, hormonal changes during pregnancy increase the probability that they will provide appropriate care of the young. The young, in turn, are designed to easily come to recognize their parents and to signal them in response to distress (with separation being a prototypical elicitor of distress). The hormonal responses and signaling systems of mothers and infants are closely coordinated to optimize both retrieval and relief from distress. In addition, protective care in infancy also acts to socialize the child for later experiences: It serves to influence the ability of the young to regulate their own responses to stress and to prepare them for the provision of protective care when they themselves become parents.

### ***Coalitional Group Domain***

The young are also prepared for adaptive functioning within coalitional groups. This process involves biological design as well as selective inputs from parents and peers.

**What Are the Tasks of the Coalitional Group Domain?** The central tasks of the coalitional group domain are (a) the mutual acquisition and sharing of resources within in-groups and (b) mutual defense against external sources of threat (including out-groups). Although this sounds like a coordinated system, there is good evidence in support of the independence of in-group favoritism, provision of group-based benefits, and out-

group derogation/aggression (Brewer, 1999b). Therefore, it is useful to consider the biological preparation for these processes separately. Indeed, the developmental course of relevant processes appears to be different for the two aspects of this domain.

For the protective care domain, we focused exclusively on the relationship between parents and the young. For the socialization of the coalitional group domain, we focus on the socialization processes both by parents and by peers. Although some of the same processes may follow in both cases, there may also be differences.

**How Are the Young Prepared for the Coalitional Group Domain?** There is an emerging body of work that suggests the time course for (a) recognition of and investment in maintaining in-group similarities and adherence to group rules and (b) for the identification of the features of out-groups and the generation of negative responses to those groups.

*Preparation for the In-Group.* Imitation or mimicry of the actions of others appears to occur automatically in both humans (Chartrand & Bargh, 1999) and group-living nonhumans (Macdonald, 1983). One of the central functions of social groups is mutual defense through the ability of groups to intimidate potential predators (through their appearance as a large cohesive entity as opposed to an aggregation of individuals who can be more safely attacked). Among humans, mindless mimicry occurs soon after birth. At the most basic level, a neural basis has recently been found for the capacity of primates to share their experiences (Gallese, Ferrari, Kohler, & Forgas, 2002). "Mirror neurons" have been found in which equivalent neural firings occur when an individual carries out an action and when he or she observes that same action being executed by another individual. These neural processes may underlie the operation of imitation—a process that is manifested on the 1st day of life (Meltzoff & Moore, 1999). Late in infancy, categorization processes lead to a perceptual use of group entities: Children begin to show both that they respond to groups of objects and that they expect groups to move together, which is a core feature of social coalitions (Sugarman, 1983).

By 2 years of age, children became receptive to the rules of group life—the "proper" ways of executing eating, dressing, cleanliness, politeness, and other conventional routines (e.g., Dunn & Munn, 1985; Emde, Biringen, Clyman, & Oppenheim, 1991; Smetana, Kochanska, & Chuang, 2000). This is also the point that

children show self-aware emotions (e.g., shame, guilt). The possibility now exists for self-regulation to occur in response to violation of group norms.

There are indications that children's increasing awareness of and concern with family conventions is accompanied by a positive valuation of broader in-groups, for example, their own racial group (other ways of defining "us"). During these early years, children show a strong in-group attachment/favoritism (Aboud, 2003; Cameron, Alvarez, Ruble, & Fuligni, 2001) but do not show a negative out-group bias. As noted earlier (Brewer, 1999b), in-group favoritism appears to represent a different process than out-group hostility/derogation. Aboud determined that in-group attachment is particularly apparent during early childhood. Indeed, it has been argued that there is a stronger evolutionary preparation for in-group cohesiveness than for out-group hostility (Hirschfeld, 2001). This may follow from the fact that in-group coalitions were highly adaptive at all ages in our distant evolutionary past, whereas out-group hostility only became adaptive when children moved further away from the family and needed to be aware of potential dangers from neighboring groups.

*Preparation for the Out-Group.* A full understanding of out-groups does not appear until middle childhood. It is not until children are at least 5 years of age that they first begin to show an association between in-group favoritism and negative bias to out-groups (Aboud, 2003). As observed by Hirschfeld (1996), younger children may know a group label (e.g., a racial label) but do not easily categorize others or respond to others perceptually on the basis of that label. By middle childhood, they demonstrate out-group hostility and active segregation processes based on the arbitrary ways in which children are grouped. As noted by Hirschfeld (1996): "Children do not find races because they are there to be found. They find races because they are following an impulse to categorize the sorts of things there are in the social world" (p. 345). Supporting this notion, children at this age show group biases (favoring their own group over an out-group) when they are arbitrarily distinguished (e.g., by color of shirts worn; Bigler, Spears Brown, & Markell, 2001). Children from minority groups have been identified as at particularly high risk for bullying (Prothrow-Stith & Quaday, 1996).

By middle childhood, there is increasing maturation of the frontal cortex (Stauder, Molenaar, & Van der Molen, 1999), which facilitates the child's ability to integrate information. This change is temporally associ-

ated with more complex use of social categories, along with increases in social comparison processes (Rholes, Newman, & Ruble, 1990). Children now respond differently to the implications of different groups. For example, thoughts of death lead to increasing in-group bias (Florian & Mikulincer, 1998), which is a response consistent with the protection offered by their own group.

**How Are Humans Generally Prepared for the Coalitional Group Domain?** A central prerequisite for the functioning of the coalitional domain is the recognition of social similarities and differences. However, there does not appear to be any biological design for the specific kinds of the classical coalitional group categorizations (e.g., racial or ethnic groupings). Instead, these are groupings that are arbitrary and are not acquired until there is a readiness to do so (at the point that the child becomes involved in group life beyond the family and needs to be sensitive to groupings that have significance for that particular group at that particular time).

Although infants show a very early ability to categorize others based on sex (or age), as measured by the habituation paradigm, they show no equivalent ability to categorize others by such visually distinctive but arbitrary features as color (Fagan & Singer, 1979; Leinbach & Fagot, 1993). Kurzban, Cosmides, and Tooby (2003) found through the use of a memory confusion paradigm (confusing two exemplars from the same social category in memory) that humans are quite rigid in their categorization of others by sex but are much more flexible in their categorization of others by race. It has been persuasively argued that humans are designed by their evolutionary history to make categorizations by sex (and age), which has shared significance across time and setting; however, their categorization of others by other groupings is arbitrary. The arbitrary nature of group categorization is reasonable in light of the ecology that characterized human associations in the distant evolutionary past. Because of mobility constraints, humans typically came in contact with other groups who could not easily be distinguished or categorized on the basis of appearance. Instead, they had to make use of and become sensitive to subtle markers that distinguished a group that might pose an immediate threat to their own group's resources. Thus, it is likely that (as is still true universally) the coalitional group made use of deliberately created markers (variations in appearance) or variations in ways of communicating. As the simplest contemporary example, think of the colors worn and hand signals used by gang members to promote recognition.

Humans are also hormonally sensitive to the relative resource advantage (win-loss) of their own group versus a competing group. Among males in particular, the experience of winning (or watching "their" team win) leads to elevation of testosterone, whereas the experience of losing (or watching their own team lose) leads to declines in testosterone (Dabbs, 2000).

### **Coregulation of the Coalitional Group Domain.**

At the point the young demonstrate an awareness of their own "first" group (the family), they are receptive to socialization processes regarding the defining characteristics and routines of that group. Dunn and her colleagues (e.g., Dunn & Brown, 1991; Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991; Dunn & Munn, 1985) studied mothers as those most likely to be involved in socialization of the rules of social life in the United Kingdom and the United States. In other cultures, it is often the case that peers serve as the primary socializers of group rules (Harris, 1995).

Although the content of the rules is taught by others, the acquisition of those rules does not appear to occur as a result of reinforcement; instead, the rules are easily internalized without the influence of external consequences. Between the ages of 2 and 4 years, children have been observed to display ritualistic and repetitive behavior (Evans et al., 1997). Their focus on the proper display of conventional routines has an almost obsessive quality to it (Emde et al., 1991). Children of younger or older ages do not display the same ritualistic style in the enactment of everyday activities such as eating, going to bed, or getting dressed. Thus, there appears to be a window of opportunity in which mothers (or others who act to socialize the child with respect to group norms) are able to easily and effortlessly exert behavior control over the young.

During this time period, children come to believe that there is a certain way that "we" (the family) do things and there is resistance to efforts to change established routines. This may be thought of as the first indication of sensitivity to the in-group and the ways in which that group is defined by how members act and what they say and what their routines are. What is seen is the combination of a positive valuation of the family's way of doing things and a concern with violation of those rules (which, at a broader level, implies the possibility of group disapproval or exclusion).

Although mothers rarely punish children for their failures in carrying out accepted routines, children appear ashamed or guilty when they don't "get it right." At

older ages, these self-aware emotions have been found to have autonomic consequences, which may influence the nature of the child's response to rule violations. Shame is associated with immediate increases in activation of the sympathetic nervous system, consistent with energy-mobilization and perceived threat (e.g., increases in heart rate and blood pressure, Harrauld & Tomaka, 2002), followed by a rapid transition to parasympathetic activity, consistent with energy conservation and withdrawal (Schoore, 1998). Gilbert and McGuire (1998) have suggested that the parasympathetic-demobilization response (associated with shame in humans) is part of an ancient, basic defense response that signals the individual to "stop."

The strong motivation to comply with group rules may have its origins in the fear of exclusion, which is one of the most intense fears present at later ages (Baumeister & Tice, 1990; Caporael & Brewer, 1991). The group provides an extremely important source of safety and loss of group support provides a threat to safety. Supporting this notion, depletions in the opioid system (which leads to declines in feelings of safety) motivate approach to the group (Panksepp, Sivi, & Normansell, 1985). This feature of groups may provide the primary basis for in-group preference and cohesion. It might be speculated that as the child's dependence on the mother for safety declines, the dependence on the coalitional group for safety emerges.

By middle childhood, when children are able to categorize others into arbitrary groups (as defined by others at that time), they are then subject to the possibility of responding negatively (jointly with members of their own group) to those out-groups. At this age, there is a high level of stereotyping and prejudice against racial/ethnic out-groups (Bigler, 1999). As noted by Bigler, the shift from more virulent forms of racial bias to more subtle forms of bias in society as a whole has not been reflected in a comparable softening of responses shown by children. In addition, no significant relationship has been found between the biases of parents and those of their children; for example, parents who show little bias often have children who hold strong racial stereotypes (Aboud & Doyle, 1996). Without encouragement from adults, children show aggression to arbitrarily created out-groups when those groups offer competition for scarce resources (Sherif, Harvey, White, Hood, & Sherif, 1954).

**Summary.** Biological preparation for coalitional group processes (including both the preparation for the

socialization of the conventional rules that act to maintain similarity with one's own group and a devaluing of and hostility toward those in other groups) occurs in a set of steps. Sensitivity to the conventional rules of group life, along with in-group preference, emerges at an age when children become subject to self-aware emotions, such as shame, an emotion that may be triggered by violation of group rules or standards and that has powerful physiological effects (parasympathetic demobilizing responses). Although parents (as well as peers) are models and advocates of conventional rules, such rules are likely to be acquired through spontaneous internalization. Intergroup hostility, on the other hand, appears to be under the control of peer, rather than parental influence.

### ***The Hierarchical Power Domain***

The hierarchical power domain is centrally concerned with the establishment and management of interpersonal relationships that are unequal in the resource holding potential (RHP) of interactants. The basic notion of RHP includes not only the relative dominance or formidability of two individuals but also their relative access to desired objects or events (Parker & Rubenstein, 1981). Unlike protective care or coalitional relationships, processes in this domain are unstable and may involve frequent renegotiation of relationships (whereas protective care or coalitional relationships tend to be relatively stable once a bond is established to an individual or group).

Humans (as is true for other species) are motivated to acquire or maintain their RHP. Some level of dominance and access to resources is necessary for survival. The motivation for dominance is more salient for males than females (because the relative power of males has greater implications for successful mating). However, females are also motivated to maintain a favorable RHP in that higher access to resources provides benefits not only for themselves but also for their young.

**What Are the Tasks of the Hierarchical Power Domain?** As is true for other domains, there are both proximal and distal tasks to be accomplished in the hierarchical power domain. At a proximal level, the successful regulation of this domain acts to keep the child safe from harm (and thus simultaneously serves the reproductive interests of parents). In accomplishing this task, the child is prepared for wariness and submission to power cues from others. At a distal level, power-based

relationships in childhood help to prepare the young for the successful negotiation of power-based relationships at later ages. The accomplishment of this task requires preparation for (a) the appropriate use of dominant responses (affording the opportunity for acquiring/maintaining resources) and (b) the upper-limit control over dominant responses (i.e., a shut-off mechanism that prevents lethal harm to kin). As suggested by Kelley and Thibaut (1978), interdependent relationships, even when they involve unequal resources or power, typically involve benefit to both parties.

Parents, siblings, and unrelated adults or children may all act to socialize hierarchical power relationships. The negotiation of power relationships among the young themselves represents an omnipresent activity across species, in particular among young males.

**How Are the Young Prepared for the Hierarchical Power Domain?** The preparation of the young for power-based relationships is shared for some features but sexually dimorphic for others. All children need to be prepared to respond to the warning signals of adults to avoid harm. Even infants show an early preparation for power messages contained in the speaker's vocal properties. Infants are sensitive (and reactive) to the vocal prohibitions of adults. Fernald (1993) has demonstrated the universality with which young infants respond with behavioral inhibition to vocal prohibition signals (vocalizations that involve short, loud, and staccato prosody). This infant response pattern is shown whether adult messages are voiced by their mothers or voiced by unrelated women speaking a different language.

Across many species, there is also a biologically prepared sensitivity to cues to physical power or formidability. Infants, across species, show greater fear in response to unfamiliar adult males than to unfamiliar adult females (Cheney & Seyfarth, 1985; Skarin, 1977). As pointed out by Cheney and Seyfarth, sensitivity to unfamiliar males (among nonhumans) precedes sensitivity to predators, suggesting the high importance of this response. In addition, there is a high level of continuity in response to power signals across ages (Keating & Bai, 1986).

As well as the general preparation for power-based relationships, there is also sexually dimorphic preparation of the young for this domain. First of all, there appears to be some level of prenatal preparation for the power domain among males as a function of the intrauterine hormonal environment. The presence of ele-

vated levels of androgens (male sex hormones) late during gestation or shortly after birth acts to predict later sex differences that are relevant for this domain (Breedlove, 1992; Mazur & Booth, 1996). Although questions have been raised about this process among humans (see Ruble & Martin, 1998), there are indications that, across species, these early hormonal differences organize the architecture of the brain in ways that are manifested in behavioral patterns at later ages. When females are exposed prenatally to androgens (either through the introduction of exogenous androgens or as a result of naturally occurring hormonal anomalies), they show subsequent social responses that are closer to those usually shown by males, including rough and tumble play. Among nonhuman primates, there are also differences in the nature of their social signals in response to threat. Nonhuman primate females are more likely to produce vocalizations that act to recruit attention (and help) from kin. Males (beginning as juveniles), although they are at much greater risk, are less likely to engage in vocal signaling behavior (Bernstein & Ehardt, 1985).

Across the course of postnatal development, sex differences also emerge in the presence of testosterone, a difference that becomes most striking at puberty. At this age, the increasing levels of testosterone among males allows for more serious forms of power assertion, including aggression. There are also some indications that the changing hormonal environment of the young at pubescence may lead to an altered relationship with adults in a position of power. A number of investigators (e.g., Inoff-Germain et al., 1988; Moffitt, 1993; Susman et al., 1987; Udry & Talbert, 1988) have found that that antisocial behavior in the young (e.g., resistance to authority) rises with increases in testosterone, even when the visible signs to the individual's stage of puberty are statistically controlled.

### **Coregulation of the Hierarchical Power Domain.**

The coregulation of the hierarchical power domain serves multiple purposes. These include the maintenance of child safety and regulation of rough and tumble play.

*Use of the Power Domain in Maintaining Child Safety.* The regulation of the hierarchical power domain involves the accomplishment of tasks that serve proximal goals as well as the accomplishment of tasks that serve to prepare the child for later power engagements. As one of the proximal tasks, the safety needs of the young are met by parental regulation at a distance when infants become mobile. The vocal signals of both human and non-

human primates have both informational and motivational properties (Marler, Evans, & Hauser, 1992). As noted earlier, Fernald (1993) has demonstrated that mothers produce a distinctive prohibition vocal signal to preverbal infants as a means of stopping some ongoing action. Such signals are often used by mothers to prohibit touching an object that may pose a hazard to the child, and they have the advantage in that they stop the infant's behavior before the child is old enough to understand speech. This signaling system carries the advantages of effective inhibition of dangerous actions and the preparation of the child for associated prohibitional speech ("No!"). In short, it allows human parents to bootstrap off of a biologically prepared sensitivity to facilitate their tutional role. Thus, the accomplishment of a proximal task may also extend to the parent's later use of communications that serve in a socializing role.

*Regulation of Rough-and-Tumble Play.* A distal task of the hierarchical power domain involves the preparation of the young for power engagements at older ages. Juvenile play (in particular, rough-and-tumble play) serves to safely prepare the young for later more serious types of hierarchical power encounters. This play style, much more common among boys than girls, begins in early childhood. Although social play does not constitute aggression, it does prepare the young for later relationships that carry the potential for aggression. The nature of rough-and-tumble play is typically managed (by children themselves) to be 50/50 in wins and losses (Pellis, 2002). In peer relationships, this balance is fairly easily attained.

Adaptive timing features are shown in the deactivation of the playful power struggles of the young. The "clock" for manifestations of rough-and-tumble play is set in such a way as to maintain the utility of this power-relevant social response pattern: Rough-and-tumble play follows a well-defined course during its development across species. The activation pattern represents an inverted U function in which this play style increases and then declines late in middle childhood (Panksepp, 1993). These declines are associated with increases in the presence of testosterone. At this point, young males would be more likely to inflict serious physical harm in the course of such play bouts (thus decreasing their utility). It appears that increases in testosterone at the onset of pubescence mediate the declines in playful types of power struggles. Before this age, rough-and-tumble play involves a dopamine-based reward system in which participants (in particular, males) experience this activity

as positive (Panksepp, 1993). In contrast, serious (rather than playful) aggression between the young may be regulated by testosterone (Sanchez-Martin et al., 2000).

Among humans, fathers (as well as juveniles) show an involvement in social play with the young. At one level, social play provides preparation for novel events, an important aspect of socialization (Bekoff & Allen, 2002). More relevant to the current discussion, fathers are differentially involved in play activity (rough-and-tumble play) that may serve to prepare the young for relationships that involve power asymmetry (Jacklin, DiPietro, & Maccoby, 1984). In doing so, they provide experience with different distributions of power. For example, at one time, the father may win disproportionately; at other times, he can shift the balance of power in the play relationship in such a way that the young win disproportionately (Bekoff & Allen, 2002). These experiences train the child for ways of negotiating power-based relationships at later ages: They provide experience with winning and losing, including the submissive or dominance behavior associated with both roles. They also provide experience in escalating the challenge posed to a more dominant individual as a means of testing to see whether they can increase their hierarchical position. Fathers provide realistic (but safe) consequences when a juvenile's play responses become too intense. In this way, the young also learn upper-limit control over fighting with those of their own coalitional group. For example, nonhuman primate fathers make use of play bites that are limited in intensity (Bekoff & Allen, 2002), which is an upper-limit control that is learned by the young. Power contests are used to establish hierarchical position (rather than destruction of another person), and therefore modulation of aggression is adaptive.

As an indication of the significance of fathers for their children's socialization in this domain, Flinn, Quinlan, Decker, Turner, and England (1996) found hormonal effects that followed from father absence. In particular, the endocrine responses of sons (more than daughters) were sensitive to the presence or absence of the father. Sons whose fathers were absent, although showing low cortisol levels during infancy, demonstrated a combination of high cortisol and low testosterone levels in adolescence. This combination is consistent with a subordinate role in power-based relationships with peers.

The long-term occupation of a subordinate role carries high costs; thus, the presence of preparation for the

young to optimize their power position is critical. For example, males experiencing social defeat (as opposed to nonsocial stress) show hypercortisolism—strong increases in the activation of the hypothalamic-pituitary-adrenal (HPA) axis (Abbott et al., 2003). As noted earlier, social defeat or subordination also leads to increases in noradrenaline, a change viewed as a “de-escalating response pattern.” In contrast, those individuals who achieve higher levels of power show higher levels of serotonin relative to others (i.e., a hormonal advantage). Although most of the evidence for this hormonal correlate of power has come from nonhuman primate research (e.g., Raleigh, McGuire, Bramner, Olkkacj, & Yuwiler, 1991), similar patterns have also been found with humans (e.g., Madsen, 1986).

**Summary.** The experiences of the young in the hierarchical power domain serve the child's immediate needs (e.g., responsiveness to parents in safety regulation at a distance) and set the stage for later relationships. Their experiences are orchestrated by an integrated system of social signals and hormonal patterns. Preparation for the power domain reveals both uniformities and variations between males and females. Beginning in infancy, both males and females are responsive to the power signals of adults. However, the prenatal hormonal environment of males selectively influences their preparation for physically competitive encounters (e.g., rough-and-tumble play). Rough-and-tumble play at younger ages is hormonally regulated in ways that are consistent with positive play and provides safe experience in power negotiation. In contrast, serious involvements in power contests (more common by puberty) are regulated by testosterone. The engagement of fathers in social play with the young also provides an early training role for the effective management of future relationships involving power asymmetry.

### *The Mutuality/Reciprocity Domain*

As the last social domain to be considered, humans (along with other primates) are prepared by biological processes for interactions based on mutuality or reciprocity. Such relationships are based on the mutual provision of benefits between functional equals. Kin selection theory (Hamilton, 1964) offers an easy account of the reasons why an individual benefits by the provision of aid to kin: The provision of benefits to kin simultaneously serves to benefit a person's own reproductive success. Less easily explained is the provision of

benefits to nonkin. However, when the relationship between individuals is based on the possibility of reciprocal benefits, such relationships can be seen as adaptive (Cosmides & Tooby, 1992). Reciprocity in social relationships has been described as the hallmark of primate behavior, although some forms of reciprocity have occasionally been observed in lower species (Wilkinson, 1988). Among primates, reciprocity extends past simple tit-for-tat short-term exchanges, and is reflected in an elaborate cost-benefit accounting that transcends specific behavioral currencies or contexts (Silk, 1992).

Friendships (an important example of mutual/reciprocal relationships) are distinct from other kinds of peer interactions (Newcomb & Bagwell, 1995). Most notably, friendships are characterized by high levels of reciprocity and intimacy (although intimacy is more commonly linked with female than male friendships). In addition, the benefits that follow from peer associations are greater for friends than nonfriends (Newcomb & Bagwell, 1995).

**What Are the Tasks of the Mutuality/Reciprocity Domain?** The proximal tasks of the mutuality/reciprocity (MR) domain include (a) the provision of mutual benefits with unrelated others by sharing and reciprocating tangible and/or social-emotional benefits and (b) the collaboration of two individuals to accomplish a goal that neither one can reach alone (e.g., coordinated activity in reaching a goal or defending against an opponent). The long-term tasks of the MR domain include preparation of the young by parents for mutual/reciprocal relationships with their peers.

**How Are the Young Prepared for the Mutuality/Reciprocity Domain?** In early infancy, infants show pleasure in response to contingency; for example, they smile when an object moves in response to their actions (e.g., Watson & Ramey, 1987). Later during the 1st year, they react to contingently responding objects as though they are human. For example, Johnson and her colleagues (Johnson, Dziurawiec, Ellis, & Morton, 1991) found that, by 1 year of age, infants react to an object (even when it is a nondescript blob) as having intentions after it has been observed responding contingently to another person (e.g., making contingent sounds or flashing a light in response to the speech of another person).

*Joint Attention as the Basis for Coordination.* By 1 year of age, children show the ability to share attention and to solicit the joint attention of others (Bakeman &

Adamson, 1984). This process involves the infant's active coordination of his or her interest in some object or event with the ongoing attentional engagement and intentions of another person. This new capability involves what may be thought of as coordination or matching of motives. At this point, the young can coordinate their activities with others with a new level of planning and purpose. This capability can be understood as important in the negotiation of reciprocal or shared activities.

*Theory of Mind.* By age 4, children have moved one step further in the MR domain by showing that they now understand that others act on the basis of their beliefs, even when those beliefs are false, that is,—they have acquired a theory of mind. This capacity allows the child to understand the thoughts and desires of others in establishing mutually beneficial interactions. Secondary representational capacity (e.g., pretense, means-end reasoning), thought to reflect an early stage in the development of theory of mind, has been observed among the great apes, suggesting some limited level of continuity across species (Suddendorf & Whiten, 2001).

**What is the General Preparation for the Mutuality/Reciprocity Domain?** The regulation of the MR domain appears to involve basic computational and neural mechanisms for which there is an evolutionary design. Trevarthen, Kokkinski, and Flamenghi (1999) have suggested that humans are born ready to reciprocate interactions with others. Indeed, Forman and Kochanska (2001) have observed a correlation between young children's willingness to imitate their parent in a teaching context and to comply in a control context, and they suggest that both reflect a responsiveness or receptive stance toward parental socialization. Unlike automatic mimicry or imitation in the coalitional domain, "imitation" in the MR domain appears to involve intentional response matching or turn-taking and may be better thought of as "emulation" (a distinction in concepts that has been proposed by Want and Harris, 2002).

At a higher level, humans (and other primates) appear to have a "cheater detection" mechanism that provides a sensitivity to violation of implicit social contracts (e.g., providing benefits to another but not receiving benefits in return; Cosmides & Tooby, 1992). When other individuals fail to reciprocate benefits, they are subject to penalties in the withholding of future benefits by the individual who has been "cheated." Over a program of research, Cosmides and Tooby have demonstrated the

greatly enhanced ability of individuals to solve complex logical problems (the Wason task) when they are framed as social contracts.

**Coregulation of the Mutuality/Reciprocity Domain.** The ability of young children to engage in successful MR relationships is facilitated by their early interactions with parents (in particular, mothers).

*Early Parental Socialization in MR Relationships.* Before infants engage in peer interactions, they may be thought of as having a practice period in which their skills in joint regulation processes develop and are honed. Although children may be thought of as experience-expectant for MR interactions, a “guided apprenticeship” with parents, involving jointly coordinated interactions, may be needed before this domain is fully operational. However, this finding may be limited to societies in which mothers (rather than peers) play a predominant role in the early play activities of the young. Thus, there are variations across cultures in the extensiveness of the early role of parents as opposed to peers in the socialization process.

Suggestive support for the experience-expectant nature of MR interactions comes from research conducted in the still face paradigm. The exchange of eye contact and smiles is an important part of the early relationship between mothers and infants, and is associated with positive affect. For example, a high level of contingent responsiveness has been shown by mothers (by their facial expressions) to the facial expression of their infants during nursing (Leveille, Cossette, Blanchette, & Gaudreau, 2001). If the mother violates the infants’ expectations by displaying an immobile face, children show heart rate increases, a decrease in vagal tone, and negative affect (Weinberg & Tronick, 1996). The level of distress shown by infants in this setting indicates the significance of mutual interactional engagement with the mother.

Another early manifestation of parental guidance in MR processes is seen in the vocal communication between mothers and infants. At around 3 or 4 months of age, infants are ready for coordinated vocal dialogues with parents that for the first time involve turn-taking (e.g., Papousek & Papousek, 1995), through a dialogue in which parents take the lead. Consistent with the affective consequences of mutuality/reciprocity in relationships, vocal dialogues between infants and mothers are regularly associated with positive affect. The importance of the infant’s stage of cortical development for such exchanges is suggested by the deficits shown by

premature infants in establishing such dialogues (e.g., Lester, Hoffman, & Brazelton, 1985).

The later initiation by mothers of ritualized MR games (e.g., peekaboo) also serves to further prepare the infant for reciprocal, coordinated activity (Parrott & Gleitman, 1989). Thus, children who were observed to engage in high levels of mutuality in play (play initiations and compliance to initiations) were found to be more socially competent with peers, which was a relationship found to be mediated by increases in children’s emotional knowledge (Lindsey, 1998; Lindsey, Mize, & Pettit, 1997). In short, mutuality in interactions with parents provides an opportunity for guided practice in mutual/reciprocal interactions with peers.

*Coregulation with Friends.* The basic processes that operate to regulate the MR domain are in place when children first form social ties with other children (processes that are shared with nonhuman primates). Some of the mechanisms are fully operational early on, whereas others come online with children’s increased cognitive ability. At the most basic level, the interactive system and physiological regulatory systems of friends (beginning when children are only toddlers) appear to be coordinated. Among toddlers, this concordance appears in their baseline heart rate and cortisol levels as well as their play behaviors (Goldstein, Field, & Healy, 1989). This suggests that young children become synchronized with each other not only in their attention and actions but also at a physiological level.

As one outcome of successful MR relationships with peers, the child is buffered against stressful experiences, both at a direct and an indirect level. At the most direct level, friends serve to buffer the child against bullying by other children (Schwartz, Dodge, Pettit, & Bates, 2000; Smith, Shu, & Madsen, 2001). By the alliance with a friend, children are able to accomplish something that they could not do on their own. More indirectly, the presence of a friend serves to buffer against stress: Children show reduced levels of stress (as reflected in cortisol levels) when a preferred friend is present (Field et al., 1992). In addition, children’s level of norepinephrine in response to painful medical experiences has been found to be buffered by their level of perceived support from friends (Hockenberry-Eaton, Kemp, & DiTorio, 1994).

A long-term benefit of early involvement in MR ties with peers is the increased ability to engage in affiliative activity of many kinds (e.g., Lindsey, 2002; Vaughn, Colvin, Azria, Caya, & Krzysik, 2001). Early ties may provide an internship in which there is an opportunity to

more fully develop both the regulation of mutual benefits and the more complete understanding of the minds and feelings of others. For example, young children who have a stable and mutual friendship were shown to outperform, on a theory of mind task, children who lacked such a relationship (Peterson & Siegal, 2002). Finally, MR relationships also serve to facilitate positive emotional states, as mediated by both the opioid system and the dopamine system, which are involved in social reward (Depue, Luciana, Arbisi, Collins, & Leon, 1994; McClelland, Patel, Stier, & Brown, 1987; Panksepp, 1993; Vanderschuren, Nisick, & Van Ree, 1997).

**Summary.** The MR domain serves to accomplish mutually beneficial relationships between unrelated individuals who have a peer relationship. Such relationships facilitate the shared provision of social-emotional benefits (e.g., generation of positive affect or reduction in stress), joint collaboration in shared defense (e.g., against bullying), or task accomplishment. In addition, humans (and other primates) have demonstrated the capacity to keep track of the provision of reciprocal benefits with specific others, thus facilitating the likelihood that an equitable, mutually beneficial relationship will be maintained. The capacity for higher-level MR functions (complex coordination or mutual understanding) follows as children develop cognitively. Early in infancy, children may be thought of as expecting the experience of mutuality/and reciprocity. Mothers respond by facilitating the infant's affectively positive engagement with reciprocal and mutual interaction (e.g., coordinated communication activities or games).

### Biological Preparation for Different Environments

Some researchers have been concerned with the extent to which children come to demonstrate an adaptive fit with the experienced environment. From a biological standpoint, this is thought of as "facultative polymorphism": The young are designed to respond in adaptive ways to variations in the world to which they are born. For example, Belsky, Steinberg, and Draper (1991) proposed that early social experiences provide the young with information that is diagnostic with respect to the kinds of environments they will face later in their lives. In a facultative fashion, the young may then "select" response strategies best suited to those probable environments. Thus, mothers who are low in sensitivity and high in rejection are more likely to have insecurely at-

tached children (e.g., Ainsworth, Blehar, Waters, & Wall 1978). At the same time, the response strategies characterized by insecurely attached children may be optimal for maintaining contact with a particular type of mother (Cassidy, 1994; Simpson, 1999). At a more general level, such children may develop an opportunistic rather than a stable pattern of close relationships. In mating relationships, this plays out in the form of short-term mating strategies. For example, avoidantly attached adults tend to become involved in unstable short-term sexual relationships that include low parental investment (Brennan & Shaver, 1995; Simpson, 1999). Mating occurs early and in a way that maximizes the number of progeny.

In addition, there are other more direct cues early in life that are diagnostic with respect to future life experiences. For example, a high level of early stress (e.g., parental divorce or marital conflict) or lack of resources may signal a harsh future (Belsky et al., 1991). Such experiences have been found to be associated with faster rates of sexual maturation—a pattern that might influence mating and parental investment strategies in ways that maximize the number of progeny early in life. These formulations are not without their critics (Macoby, 1991). In addition, there are indications that pubertal timing as a result of early experience follows more from the benefits associated with positive-harmonious family relationships rather than the costs associated with negative-coercive family relationships (Ellis, McFayden-Ketchum, Dodge, Pettit, & Bates, 1999): Girls who experienced a more positive early history (e.g., greater paternal investment or more mother-daughter affection) showed later pubertal onset.

### Integration and Segue

In this section, we have considered the ways in which biological processes prepare both the child and the parent for the domains of social life. We have observed that the brain is experience-expectant. As such, there is a prepared sensitivity to social experiences as well as privileged learning in acquiring the social knowledge that is essential to accomplishing the basic tasks of social life.

In reviewing these processes, we have suggested that there are meaningful distinctions in both the tasks and the mechanisms that regulate interactions in different social domains. However, the domains cannot be seen as entirely distinctive in that some tasks are accomplished by one domain at one stage of development (e.g., safety provided by parents in infancy) and by another domain

at later stage (e.g., safety provided by coalitional groups at later ages). However, there are meaningful distinctions in the time course, the mechanisms, and the hormonal and emotional processes that serve to regulate the different domains.

We have given considerable attention to the role of hormones in the preparation of the young to function adaptively in different domains. Such processes may be thought of as key mediators in the preparation of the young and their caregivers for the socialization experience.

We have also suggested that evolutionary history (the mechanisms that have evolved to solve recurrent problems in human history) provides some of the basic design features of socialization. We have also pointed out that evolutionary history prepares individuals for the recurrent variations (as well as the regularities) in their experiences. For example, there have been variations in the resources available to parents and in the characteristics of the young. As a result, there are variable strategies available for optimizing the reproductive success of parents and the young in different ecologies.

Socialization is accomplished most effectively when parents are able to read the changing states of their children, as well as the changing motives and capabilities of children across the course of development. In the framework offered here, this process may also be thought of as involving the parent's ability to shift domains in appropriate ways. So, for example, if an infant is distressed, effective parenting involves parental responsiveness to the child's state and the ability to activate responses consistent with the protective care domain. In contrast, if a parent responds to a distressed child with efforts to engage him or her in a reciprocal game (a domain mismatch), parenting is more likely to be unsuccessful—the child will not be calmed and the parent will not succeed in efforts to engage the child.

In short, biology creates a platform on which sociocultural influences are built. Acceptable variations in socialization processes are afforded by virtue of the fact that the evolutionary history of humans has provided alternative designs for the different kinds of environments they have faced.

## SOCIOCULTURAL APPROACHES

We move now from a discussion of the biological mechanisms that operate during socialization to a different level of analysis—a consideration of the impact of the so-

cial context and of social experiences on development. In so doing, we keep in mind the biological foundation described in the preceding pages of this chapter. The bulk of empirical knowledge about socialization processes and mechanisms, however, comes from decades of research conducted in a different framework. This perspective acknowledged the existence of biological pressures and predispositions but focused on the actions and attitudes of agents of socialization and the impact of these actions and attitudes on children's behavior, cognitions, and emotions. We provide an overview of the research using that framework. What is added in the present discussion, however, is an attempt to see how the findings from a direction that has historically largely characterized the study of socialization can be considered in the domain framework proposed in the previous section. Such a discussion will reveal large gaps in knowledge that need to be filled. At the same time, it may help to organize and to make sense of the existing data.

In this section we consider how agents of socialization operate to produce individuals who fit into their cultural milieu. The focus is on human research. In these points of focus, different kinds of linkages can be drawn with the biological platform discussed in the last section. In cases where there is a high degree of similarity in processes across sociocultural contexts, the linkages are clearer; for example, the central features of the parental care domain show a high level of continuity across cultures, species, and presumably across human history. In other cases, the linkages are less obvious. As humans have accommodated to circumstances that would have been less central in their evolutionary past, socialization processes have arisen culturally to manage contemporary needs. For example, processes relevant to the socialization of independence would have been less relevant in highly interdependent hunter-gatherer societies. Nonetheless, biology places some level of constraints on socialization: Socialization practices that focused too much or too early on autonomy, without sufficient concern for interdependence, would be likely to meet with resistance. Similarly, those who ignored the biologically based need for some form of separation from the group and attempted to inhibit autonomous action would also be likely to meet with resistance.

Much of the focus in this section, as in the previous section, will be on parents as the primary agents of socialization who prepare children for their social roles. The focus on parents is because, as discussed earlier,

children and parents comprise a biosocial system that is set up to favor parents as having a heavy investment in child rearing and children as being equipped very early on to respond to parental cues, including such events as recognition of the face, voice, and smell of their primary caregiver. A fundamental need of children is for security and protection, and parents are in a unique position to satisfy this need. Indeed, the need for protection forms a basis for the development of a strong relationship between parent and child and, as will be shown, the quality of relationship between child and agent of socialization is of major significance in ensuring the success of socialization practices. Moreover, the parent-child relationship is fixed and immutable, unable to be altered or terminated except under the most unusual circumstance. In addition to being constrained by legal and kinship definitions, this relationship, because of the long period of dependency of child on parent, also demands long histories of interaction and facilitates the development of routinized patterns of interaction that foster accommodation to family values and expectations (Collins, Gleason, & Sesma, 1997). As well, parents are usually the local representatives of the social mores and therefore society formally assigns them the task of socialization. In this way, society and biology work together to designate the family setting as the primary context in which children are prepared to function in the larger social milieu. From a practical perspective, the prolonged period of dependency and close contact between the parent-child dyad also motivates parents to instill appropriate and desirable behavior in children with whom they have to share a comfortable daily existence. And, finally, close and frequent contact between parent and child affords opportunities for parents to monitor their children and to come to understand and anticipate their beliefs and actions (conditions that are essential for successful socialization).

We begin this section with a discussion of the basic dimensions of interrelatedness and autonomy in the socialization process—traditional concerns of socialization theory. These map well on to the socialization domains already discussed because they involve both different forms of interaction with others and separation from others. It is the latter that is necessitated by the inequality that is inherent in the hierarchical power domain—an inequality that does not exist in the other domains. We then move on to a discussion of different socialization practices and strategies that are employed in the implementation of the different domains of social

life. Finally, we discuss the role of cultural context as an important qualifier of the effects of different socialization practices.

### Dimensions of Socialization

Contemporary models of personality and social development frequently converge on two critical aspects of human functioning: (1) the ability to develop and maintain close interpersonal relationships and (2) the growth of self-definition or autonomy (e.g., Blatt, 1995; Deci & Ryan, 1991; Grotevant & Cooper, 1986). This echoes the continuing theme of shared regulatory processes and self-regulatory processes in the last section. Thus, in the context of relatedness to others, infants, children, and adolescents acquire the ability to function as separate and independent individuals who make their own decisions and guide their own behavior. These two processes of interpersonal relatedness and self-definition develop synergistically so that, as one unfolds, changes in the other are enhanced. In attachment, for example, as infants develop a feeling of security with their caregivers they become more ready to explore their environment and their own mental states. This exploration promotes a more detailed sense of self, which promotes the ability to relate to others (Blatt, 1995). Those individuals who are optimally developed maintain relationships without losing their autonomous view of self—striving to achieve individuality without sacrificing links to others. Those who emphasize interdependence with others and sacrifice autonomy are alleged to develop a dependent personality style, whereas those who emphasize self at the expense of relationships are alleged to develop a self-critical personality style (Blatt, 1998). In addition, the two processes assume differential importance in different contexts (Brewer, 1999a).

The concepts of interdependence or interrelatedness and autonomy appear consistently in treatments of socialization practices as researchers have tried to understand how children learn to fit in with the social group but become in some sense independent of or differently dependent on that group. Thus, there is a continuing interest in maintenance of the protective care, coalitional group, hierarchical power, and MR domains—but in changing ways across the course of development and shifting settings.

Socialization involves continued close ties to others, but decreasing power imbalances. The caveat to be signaled here is that the notion of independence from the

group is a culturally bound one and that much thinking and research about interrelatedness and autonomy has been conducted in a middle-class and Western European cultural context. The extent to which existing notions about interpersonal relatedness and self-definition and their interactions are universal is an open question that we address later in this section. To anticipate, however, current conceptions seem to be that these are universal aspects of human development and functioning, albeit with different expressions as a function of the ecological niche in which individuals currently find themselves.

### *Interdependence/Interrelatedness*

Already discussed is the importance of the caregiver-child dyadic relationship in the parental care domain: Attachment is a major foundation of social development, promoting safety, comfort in response to distress, emotional self-regulation, and trust in others. Attachment is not the only form of relationship that children develop with socializing agents (Belsky, 1999; Goldberg, Grusec, & Jenkins, 1999; Thompson, 1999). For example, in addition to providing protection to their children in the face of threat and stress, parents can demonstrate warmth and verbal and physical affection in their interactions with them. They can spontaneously hug and praise their offspring, frequently without any obvious eliciting action on the part of the offspring. Warmth has played an important role in early conceptions of socialization and identification (e.g., Sears, Maccoby, & Levin, 1957) and operates in a different way from protection in facilitating the socialization process; for example, making it pleasurable for children to reproduce the actions of nurturant and rewarding agents of socialization. Warmth, however, is governed by a different system from that which operates in the attachment domain (MacDonald, 1992; Goldberg et al., 1999) and provides a different mechanism for assumption of social roles. For example, the provision of protection and responsiveness to the child's distress makes a unique contribution to the prediction of children's negative affect and empathy and prosocial behavior when the effects of warmth are controlled for, whereas warmth does not when the effects of responsiveness to distress are controlled for. Moreover, warmth makes a unique contribution to the prediction of children's regulation of positive affect when the effects of responsiveness to distress are controlled for, whereas responsiveness to distress does not when the effects of warmth are controlled for (Davidov & Grusec, in press).

Protection and warmth expose children to socialization attempts by keeping them near socialization agents and attentive to their actions. But protection may be of particular significance in the socialization of emotion regulation because of the focus on negative affect and distress. Warmth may play a more prominent role in shared actions and shared identity that is part of the coalitional domain. Thus, being a valued and accepted member of the group (as conveyed through social inclusion processes) may motivate conformity to the standards of that group both to confirm a feeling of belongingness and to avoid alienation and separation as well as anxiety about threat from outside.

### *Autonomy and Control*

The basis of successful socialization is the creation of a positive relationship with parents or other agents of socialization that fosters a willingness or desire to be receptive to their directives. Central here is the notion of willingness, with its implication that behavior is self-directed or autonomous. Children are responsive because of positive aspects of the relationship they have with socialization agents. A considerable part of socialization, however, involves control and the imposition of standards of conduct, and it is here that the hierarchical power domain comes into play. Indeed, control has historically been the major focus of attention for socialization researchers. Often, but not always, the desires of the child and the parent are somewhat or distinctly at odds, and one goal of socialization for parents is to make the child's desires more concordant with their own. This has to be done, however, in a way that encourages the child's feelings of autonomously directed action. Parents have the advantage in this particular situation because they control more resources (although children do have many resources in the relationship involving their ability to provide gratification to the parent; see Kuczynski, 2003; Rheingold, 1969). The challenge is to achieve concordance between adult and child desires, or at least some degree of concordance, in a way that minimizes antagonism and maximizes willing compliance and a feeling on the part of the child that behavior is self-directed or autonomously chosen. Indeed, the existence of conflict and its resolution is frequently considered to be an essential ingredient in the development of autonomy and self-regulation (Maccoby & Martin, 1983; Yau & Smetana, 1996) given that it sharpens the distinction between self and other and helps in the achievement of self-direction.

Events in the hierarchical power domain are complicated by the fact that, as described earlier, relationships change in a far more complex way than in the other domains. Although parental care, coalitional, and MR domain relationships all change with children's expanding competencies and interests, relationships in the hierarchical power domain are particularly likely to change as children become less willing to accept control in areas that they now come to see as personal and where they consider intervention by authority figures to be less acceptable (Smetana, 1988, 1997). In the hierarchical power domain, there is constant negotiation and compromise as socializers and objects of their socialization try to find a middle ground between what the two are willing to tolerate (although the extent to which this occurs may be culturally determined; e.g., Trommsdorff & Kornadt, 2003). Driving this particular aspect of development is the latter's changing notion of autonomy and the former's adjustment as to which actions can be tolerated or negotiated (Goodnow, 1994). Always the focus is on autonomy and self-regulation and the child's acceptance of standards of action and conduct as self-regulated and self-imposed. Without such acceptance, socialization is deemed to be unsuccessful, arousing anger, reactance, and hostility (M. Hoffman, 1970). Indeed, support for the emphasis placed by socialization theorists on autonomy and self-regulation emerges from findings by biological researchers who, as noted earlier, have found that the long-term occupation of a subordinate role has high costs with its accompanying detrimental levels of cardiovascular strain and activation of the HPA system (Abbott et al., 2003). Thus, there is a strong biological basis for the traditional position that successful socialization requires an approach that minimizes feelings of subordination and force. And obviously, in this unstable system, there are developmental differences in what is perceived to be subordination. Indeed, there may be sex differences as well, with boys more likely to resist authority as their testosterone levels increase and they become more aggressive (Panksepp, 1993).

**Varieties of Control.** Control is a complex variable, which can, for example, be used in either an autonomy-supportive or an autonomy-destructive way. This feature of its use has led to considerable confusion in analyses of socialization, as researchers and theoreticians have focused on either the harmful or beneficial consequences of a clearly multifaceted construct. Those who view control as positive, for example, emphasize

clarification and consistency of limits in child rearing (Baumrind, 1971; Baumrind & Thompson, 2002). Those who see it as detrimental to the child's development regard it as coercive and synonymous with the use of force to gain compliance, an approach that undermines willing and autonomous action on the part of the recipient (e.g., Deci & Ryan, 1991). The meaning of the term needs further clarification. The most recent way in which this has occurred is through a distinction between psychological and behavioral control (Barber, 1996, 2002; Steinberg, 1990; Steinberg, Dornbusch, & Brown, 1992).

*Psychological versus Behavioral Control.* A historical description of approaches to control is helpful in understanding the confusion surrounding its meaning. In early analyses of socialization, control carried a substantially negative connotation. Levy (1943), for example, argued that parents whose own emotional needs had been unmet in childhood developed attitudes toward their own children that reflected these unmet needs. These attitudes manifested themselves either in overprotection and intrusiveness in their child-rearing practices or in the behavioral opposite of rejection. Schaefer (1965), in his treatment of control or, more specifically, the dimension of psychological control versus psychological autonomy, treated it as involving intrusiveness, parental direction, and control through guilt. For Baumrind (1971), control was an important feature of both authoritarian and authoritative parenting, but the nature of the control was not distinguished. Disaggregation of authoritarian and authoritative parenting into three parts—acceptance, behavioral control, and psychological control—has helped to make sense of when control is positive and when it is negative in its consequences (e.g., Steinberg, Elmen, & Mounts, 1989).

*Behavioral control*, the positive aspect of control, refers to the rules, regulations, and restrictions that parents impose on their children as well as their knowledge or awareness of their children's activities that is obtained in an active way through inquiry and observation. It focuses on control over daily actions, and includes parental monitoring of the whereabouts of their children and of the people with whom they associate. *Psychological control*, in contrast, refers to control that undermines the child's autonomous development. It includes parental intrusiveness, guilt induction, and love withdrawal. Psychologically controlling parents are not responsive to the psychological needs and emotions of their children; their actions imply derogation of the

child and they interfere with the child's establishment of a sense of identity (Barber, 1996, 2002). Psychological control seems more relevant to the emotional climate in which parenting is conducted.

High levels of psychological control predict both externalizing problems and internalizing problems (e.g., anxiety, depression, and loneliness) and difficulties with academic achievement, low self-esteem, low self-reliance, and self-derogation. In contrast, low levels of behavioral control have been linked with externalizing problems, including drug use, truancy, and antisocial behavior (Barber & Harmon, 2002). Moreover, the evidence seems to indicate that, in accord with a bidirectional analysis, problematic children and adolescents, to some extent, elicit these parenting behaviors but that parental behaviors also promote problem behaviors in children (e.g., Dodge & Pettit, 2003; Laird, Pettit, Bates, & Dodge, 2003). Although the consequences of psychological and behavioral control are opposite in their valence, it appears that the two forms of control are not simply opposite ends of the same continuum: Behavioral control culminates in increased social responsibility and impulse control, whereas psychological control has its outcome in the development of negative self-processes. The motivation behind parental use of psychological control is not the enhancement of social responsibility in children but the domination and manipulation of emotional and psychological boundaries between parent and child in a way that works to satisfy the needs of the parent. In this sense, it has more to do with the nature of the parent-child relationship than it does with the imposition of demands for socially acceptable behavior. Finally, low psychological control and psychological autonomy are not synonymous: Although a parent may not be psychologically controlling, a parent may not engage in the kind of supportive behavior that facilitates autonomy either (Barber, Bean, & Erickson, 2002).

*Psychological Control Elaborated.* Although the distinction between behavioral and psychological control marks a significant step forward in understanding of socialization processes, the story does not end here, leaving room for still further distinctions. Note, for example, psychological control includes a variety of socialization practices that may have somewhat different impacts on children's social, emotional, and cognitive development. Specifically, psychological control can manifest itself in several different ways—through the suppression of independence of thinking, through

the production of guilt, or in an overprotectiveness of the child. Each of these features of psychological control may have different outcomes that remain to be elucidated (Morris et al., 2002). Consider, for example, suppression of independence of thinking, or what has been labeled by some as “intrusive control” (e.g., Grolnick, 2003; Pomerantz & Eaton, 2001). Adults who are intrusively controlling are overbearing and inhibiting in their interventions with children, allowing them little choice in their actions. They do not, however, engage in emotional manipulation. Intrusively controlling agents of socialization value compliance, pressure children to engage in specified outcomes, and do not engage in discussion and verbal give-and-take. In spite of the fact that they inhibit a child's autonomy and feelings of choice, their intrusiveness can be an indication of caring. Moreover, under certain conditions, intrusive control can be predictive of positive child outcomes (Pomerantz & Eaton, 2001).

*Autonomy Support versus Intrusive Control.* Intrusive control appears to overlap with the autonomy-threatening style of intervention described by Deci, Ryan, and their colleagues (e.g., Deci & Ryan, 1991; Grolnick, Deci, & Ryan, 1997) in their discussions of self-determination theory. According to self-determination theory, children require structure or the clear setting out of rules and expectations. Structure can be imposed, however, in either an autonomy-supportive or controlling way. Even in high-risk, dangerous environments where parents impose more rules and restrictions (a practice that does not work so well in low-risk environments at least with respect to the development of children's social competence), those who do it in a democratic way and provide explanations have children who are more competent (A. Baldwin, Baldwin, & Cole, 1990). Nor does autonomy support suggest lack of parental involvement. High involvement and high autonomy support together foster the most positive outcomes academically and socioemotionally. High involvement with low autonomy support, however, stifles development, whereas low involvement deprives children of resources and assistance (Grolnick, 2003). Further refinement in an understanding of intrusive control also requires attention to the specific areas in which control is exerted. For example, adolescents who rate parents as restrictive in areas deemed by the adolescents to be personal issues, as opposed to moral or social conventional, rate their parents as higher in psychological control than do those who see those same issues as legitimately subject to parental authority (Smetana & Daddis, 2002).

A significant feature of autonomy support is the provision of choice (Grolnick, 2003). Some caution is in order, however, with the observation that too much choice can be overly challenging. Here, the evidence comes from studies that show adults have difficulty managing large amounts of choice (Dhar, 1997; Shafir, Simonson, & Tversky, 1993; Shafir & Tversky, 1992). When faced with a large number of alternative possibilities, they find the experience enjoyable but feel frustrated and dissatisfied with the alternatives they have chosen (Iyengar & Lepper, 2000). It does not stretch the imagination to suggest that similar outcomes may exist for children. There comes a point when making choices is so demanding that individuals may defer to the more expert opinion of others, including agents of socialization.

*Guilt.* Possibly more harmful than intrusive control is parental production of guilt. Some time ago, M. Hoffman (1970) suggested that parental withdrawal of love was a practice that promoted “neurotic” guilt. Children who were recipients of love withdrawal felt guilt from awareness of unacceptable impulses rather than from harm done to others. In a similar vein, Grolnick et al. (1997) allude to introjected regulation, a form of internalization of social standards that have been “taken in” by the child but are maintained in their original form. Thus, the regulation that results from this form of internalization is internally, rather than externally, imposed and is not integrated with the self and thereby becomes a source of tension and inner conflict. As an example, introjected regulation is apparent in individuals who pressure themselves to do well on a test rather than to perform well because it is important to be academically proficient or because achievement is an integrated or cohesive part of their self-concept. Withdrawal of love seems to be particularly implicated in the production of neurotic guilt and may also reflect emotional manipulation that threatens feelings of being respected and included as an important member of the social group (Eccles, 2002): In this way, it moves into or takes advantage of events in the coalitional group domain, involving the desire to be an integral and valued member of the group.

*Monitoring and Knowledge about Children and Their Activities.* Monitoring is a feature of behavioral control that has received considerable attention from socialization theorists as an approach to parenting. It is conceptualized as close surveillance in the form of parents’ requests for information about their children’s activities (Laird, Pettit, Mize, Brown, & Lindsey, 1994), shared ac-

tivities with children (Waizenhoffer, Buchanan, & Jackson-Newsom, 2004), and conversations with teachers, peers, and other parents (Crouter, Helms-Erikson, Updegraff, & McHale, 1999). For young children monitoring involves direct supervision by parents themselves or by others, whereas for older children and adolescents more distal forms of monitoring, such as parent-initiated conversation and imposition of rules, are the norm. Many investigators have found significant relations between parental monitoring and positive child outcomes (see Crouter & Head, 2002, for a review), presumably in part at least because monitoring or knowledge of their children’s activities enables parents to ensure that their children are not exposed to influences that would have a detrimental effect on their socialization. (Again, the linkage is bidirectional, with high levels of delinquent behavior predicting decreases in parental knowledge, in addition to low levels of parental knowledge predicting increases in delinquent behavior; e.g., Laird et al., 2003). An extension of the concept of monitoring comes with the notion of “collective socialization” (Brody et al., 2001) that alludes to neighborhood monitoring and refers to feelings of trust and cohesiveness in neighbors that promote agreement about what is acceptable behavior. Brody et al. found that collective socialization, or the willingness of adults to monitor and supervise the behavior of both their own children and that of other members of the community, combined with positive parenting, was associated with a reduction in children’s associations with deviant peers, particularly as neighborhoods became more disadvantaged. They hypothesize that collective socialization reduces the negative impact of deviant peers by decreasing the amount of antisocial behavior in the community, by determining appropriate standards of conduct, and by providing more opportunities for supervision of children.

Although monitoring, as noted earlier, is seen as attention to and tracking of a child’s activities and the setting of limits, Stattin and Kerr (2000) point out that it has been frequently operationalized simply as knowledge of the child’s activities and whereabouts. They suggest that knowledge can come from one of three sources: (1) parents’ solicitation of information, (2) parents’ control over their children’s activities, and (3) disclosure by children. Thus, they argue that it is premature to suggest that tracking and limit-setting account for positive links between monitoring and prosocial outcomes when monitoring is measured as knowledge. Indeed, in a study of Swedish adolescents and their families, Stattin and Kerr (2000) found that disclosure was the most important source of parents’ knowledge

about their children's activities and friends, with the clear implication that children who engage in antisocial behavior probably hide their activities from their parents and that this, at least in part, accounts for the correlation between knowledge and outcomes. Kerr and Stattin (2000) report that low levels of child disclosure were highly predictive of adolescent maladjustment, whereas solicitation of information and control were not.

Kerr and Stattin (2000) and Stattin and Kerr (2000) operationalized parental solicitation and control as parents asking adolescents about their activities and friends and setting limits on their behavior. When monitoring was defined as parents participating in activities with adolescents and questioning knowledgeable adults about their children, Waizenhoffer, Buchanan, and Jackson-Newsom (2004) found that parental monitoring was, contrary to the Swedish results, predictive of their knowledge. Waizenhoffer et al.'s report of mixed results with respect to links between sources of information and adolescent maladjustment underlines the complexity of the issue and suggests that, among other things, monitoring that is too controlling may indeed have a negative impact. In accord with this interpretation, Kerr and Stattin (2000) found that adolescents who reported feeling overly controlled by their parents also reported higher levels of both external (e.g., delinquency or school problems) and internal (e.g., depression or low self-esteem) maladjustment. One conclusion is that surveillance and questioning—done in an autonomy-supportive manner—helps parents head off problems and respond to warning signs. But an additional contributor to the knowledge required for such responding involves the fostering of an atmosphere of warmth and trust—a relationship that makes children and adolescents more likely to disclose information about their activities. Not to be overlooked, children who have few school problems and are low in delinquency are no doubt more willing to disclose.

### **Summary**

Children need to feel interrelated with, as well as separate and autonomous from, others. Interrelatedness and autonomy take place in the context of the domains of socialization we describe in this chapter, with autonomy as a feature of human behavior that has implications for successful handling of events in the hierarchical power domain. Control is the operative concern in the power domain, as the nature of relative power changes over the course of development. Positive relationships foster socialization. But control is also a part of socialization and

for it to be used effectively it must not threaten children's feelings of autonomy. Researchers have distinguished among different forms of control, with some more effective than others at achieving positive socialization outcomes.

### **Socialization Practices**

To this point, we have discussed the manner in which parents influence behavior through their relationship with the child and through the particular way in which they exercise control. Relationships and the manner in which control is exercised have to do with the context in which caregivers socialize children. Ultimately, they convey the generalized motives of socializing agents rather than their motives with respect to a child's specific actions. But socialization also involves specific content as well as goals or outcomes that parents hope to achieve (Darling & Steinberg, 1993). Included in the content are not only discipline practices, such as punishment or various types of reasoning, but also a whole range of other practices. Some of these practices are deliberate and intentional interventions on the part of socializers, designed to achieve desired goals, and others are less intentional and deliberate. Thus, children are deliberately exposed to models deemed worthy of emulation, but at other times they are exposed to the unintended influences of others. Such unintended influences may either be consistent with or counter to the intended goals of socialization. For example, parents (or agents of socialization) may model prosocial actions in their daily lives. Conversely, children may also be inadvertently exposed to less worthy actions modeled by agents of socialization themselves, deviant members of society, or the media. The use of strongly power assertive discipline techniques is another example of a practice that can be deliberate or unintentional as when it sends the message that force and coercion are good ways to achieve wanted outcomes.

The domain approach that forms the core of the present analysis of socialization processes suggests that different types of socialization practices will be appropriate in different social domains, so we organize a discussion of these practices by their relevance to the four domains of protective care, coalitional group, hierarchical power, and mutuality/reciprocity. As noted earlier, such organization may help to make sense of disparate bodies of research as well as clarifying where there are missing gaps in information and underemphases in the focus of empirical investigations of socialization practices. We also

remind the reader that, as noted earlier, these strategies are differentially effective as a function of a whole series of variables including child characteristics (e.g., age, sex, or temperament). These are interactions that are revisited in the concluding section of the chapter.

***Socialization Practices in the Protective Care Domain: Sensitive and Responsive Caregiving***

In the protective care domain, parental sensitivity is the major parenting practice that promotes positive outcomes for children, with these outcomes including mastery, emotion regulation, and interpersonal closeness (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969; Sroufe, 1988). Caregivers are positioned along a series of continua involving their sensitivity to the needs of their children, their acceptance or rejection of those needs, the extent to which they cooperate with or are intrusive in their interactions with their offspring, and the degree to which they are accessible (Ainsworth et al., 1978). Those who are sensitively responsive, accepting, and accessible best prepare their offspring to effectively self-regulate negative affect associated with distress. They enable the young to trust their caregivers (and others with whom they form strong attachment relationships) to fulfill their needs for physical and emotional protection and make reasonable demands for compliance to social standards of behavior (Bretherton, Golby, & Cho, 1997). Thus, the human species has evolved to be willingly compliant, given that such compliance markedly increases the chances of individual survival (Stayton, Hogan, & Ainsworth, 1971). Securely attached individuals are also able to explore their physical and psychological worlds because they have a protective base to which they can return. In this way, their developing sense of competence is fostered by the belief that they are supported, and by adjustments they learn to cope with the stress of impending threats of danger. Rejecting and interfering, or rejecting and neglecting, caregivers promote feelings of insecurity, lack of trust, anger, and feelings of helplessness. As a result, they promote lack of willing compliance (Stayton et al., 1971).

***Socialization Practices in the Coalitional Group Domain: Cultural Practices, Routines, Rituals, Joint Play, and Observational Learning***

The coalitional domain is marked by children's interest in abiding by rules and conventions, doing things in a ritualized way, and conforming to avoid implicit exclusion from the group. This moves us into a discussion of cul-

tural practices and routines, or everyday ways of acting that simply happen, such as assignment of roles and activities to boys and girls, sleeping arrangements, routine work around the house, how people dress, divisions of parenting between mothers and fathers, and distinctions between what is allowed to occur in public and what must be done only in private (Goodnow, 1997). No rationale or explanation is provided for these actions, and they develop a momentum of their own that mitigates against reflection or questioning. They are to be distinguished from special moments that have been the principal focus of socialization theorists for understanding the way in which rules and standards of behavior are most likely to be made explicit (Bugental & Goodnow, 1998). Rituals (e.g., holiday celebrations) also belong in the category of activities that need no explanation but nevertheless impart considerable information about what is proper and expected. They are different from routines by virtue of their symbolism, endurance, associated affect, and meaning that extend across generations (Fiese et al., 2002).

Routines and rituals play their part in socialization by supporting feelings of group belongingness. Families, for example, develop a group identity through their routines and rituals and these events foster a sense of participation in and feeling of group membership (Moore & Myerhoff, 1977). In this way, they foster the transmission of values from one generation to another and strengthen intergenerational relationships that are important for successful transmission. We use the word *transmission* deliberately in this context, struck by the fact that children's input into routine and ritual may be less than it is in other socialization contexts. Routine and ritual denote an unchanging set of conditions where discussions about usefulness or appropriateness are not even contemplated. Indeed, once such discussion ensues, acceptance may well break down.

Other socialization practices can be assigned to the coalitional group domain. One of these is joint play (to be distinguished from rough-and-tumble play associated with the hierarchical power domain). Parents who engage in enjoyable activities with their children, in addition to providing them with the experience of harmonious and rewarding relationships, are also structuring their children's time. Time spent in joint play at age 3 years predicts improvement in conduct problems at age 4, independent of the initial level of those problems (Gardner, Ward, Burton, & Wilson, 2003). In adolescence, joint play transforms itself into time spent together in mutual activities and continues to be an

important feature of parent-child functioning that is linked with reduced conflict with fathers although not with mothers for whom time in joint activity and conflict are not correlated. For fathers and sons, there is some suggestion that it is the time spent together that in part accounts for reduction in conflict, in addition to the obvious observation that high conflict makes fathers and adolescents less likely to share activities (Dubas & Gerris, 2002). Although joint play might seem to have some of the features of mutual reciprocity, the evidence suggests that reciprocity is not a major component of joint play in well-functioning families and that parents of children who do not have conduct problems tend to initiate and organize play in contrast to parents of children with conduct problems who are more likely to sit back and let their children take the lead (Gardner, 1994).

Another way in which parents socialize their children that is of relevance to the coalitional group domain is through management of their experiences of and exposure to desirable influences. Parents select children's schools and their after-school activities, and they determine the neighborhoods in which their children live. They monitor their activities and arrange formal and informal play contacts. Through their own social networks, they provide the opportunity for social contacts for their children (Parke et al., 2002). They also cocoon their children or protect them from undesirable events and people (e.g., restricting exposure to certain forms of media or to particular peers) as well as prearm them by warning them of temptation or providing them with ways of avoiding temptation (e.g., P. Miller & Sperry, 1988; Thornton, Chatters, Taylor, & Allen, 1990; Watson-Gegeo, 1992).

Finally, observational learning shares with cultural practices, routines, rituals, joint play, and management a lack of linkage to special moments, a lack of reaction to a child's specific behavior, and, often, a lack of specifically intended transmission of information or intimation about the desirability of particular actions. It is not immediately obvious to observers why they imitate particular actions, and there may be less occasion or need for discussions about the usefulness or appropriateness of modeled actions. Indeed, it is striking how receptive young children become to "proper" ways of acting or conventional routines, many of which are acquired through observation (e.g., Dunn & Munn, 1985; Emde et al., 1991).

Observational learning occurs in different circumstances that may well affect its potency in the socialization process. In some cases, for example, it happens in a

setting where instruction is intended as opposed to others where it is not. Rogoff, Pardies, Arauz, Correa-Chavez, and Angelillo (2003) talk about third-party observation that involves keen attention and listening in or eavesdropping in anticipation of engaging in a similar activity at a future time. Although less studied than other forms of teaching, "intent participation" is a particularly powerful form of learning, especially in cultural communities where children have easy access to everyday activities of adults and other children and where they can engage in collaborative actions with other members of the group. H. L. Rheingold's (1982) observations about the early appearance of helping provide a good example of intent participation in American families. She noted that children between 18 and 30 months of age eagerly helped adults engaged in household work, appearing to enjoy themselves and to understand that they were contributing to the management of the household as opposed to playing. Intent participation stands in sharp contrast to the form of tuition in which teachers deliver knowledge (either in the classroom or in the home) and provide incentives for the successful acquisition of that knowledge. In keeping with the horizontal nature of the process, intent participation fosters complementarity of roles and cooperation. Moreover, the intrinsic merit of the activity is self-evident so that, once again, the need for internalization of values and guidelines for behavior is minimized.

### *Socialization Practices in the Hierarchical Power Domain: Reward and Punishment*

Discipline and reward are the parenting practices that have been the primary focus of socialization researchers over many years. Historically, they have been addressed by their ability to facilitate internalization—the taking over by children of societal attitudes and values as their own (Grusec & Goodnow, 1994). Both have a strong element of control, although it may be easier for children to attribute prosocial behavior to their autonomously self-chosen actions after reasoning than after punishment or power assertion (Lepper, 1983).

In addition to disciplining undesirable actions, parents reward desirable ones. Although rewards detract from an inference of freely chosen action and, therefore, internalization, socialization agents still use them (e.g., Warton & Goodnow, 1995) and they play a major part in some socialization theories. Already discussed in the introductory section of this chapter is the important work of Patterson and his colleagues (Dishion, Andrews, & Crosby, 1995; Patterson, 1980), who have

demonstrated how coercive cycles of interaction develop in problem families through inadvertent use of negative reinforcement and how this sets the stage for the exposure of children to positive reinforcement for antisocial action from deviant peer groups. Socialization researchers have distinguished between reinforcement of actions and attributions of good behavior to children's prosocial dispositions, with the latter being a more effective form of reinforcement (Grusec & Redler, 1980; Kuczynski, 1984).

**The Case of Corporal Punishment.** Power assertive strategies of discipline include verbal criticism, social isolation, and corporal punishment. Given space limitations we briefly discuss corporal punishment only, in part because of the considerable debate that exists with respect to its potentially harmful consequences to children. In spite of the controversy, it remains an acceptable intervention for many parents, at least in the United States where most parents report that they have spanked their young children (Straus & Gelles, 1988). This level of usage is in sharp contrast to many countries (specifically, Austria, Croatia, Cyprus, Denmark, Finland, Germany, Israel, Italy, Latvia, Norway, and Sweden) in which corporal punishment has been outlawed. It is also in contrast to Canada, a country where only 48% of mothers of children aged 0 to 17 years reported that they had used it in mild form (smacking, slapping, pinching) in the past year as opposed to 97% of parents responding to the same question in the United States (Oldershaw, 2002; Straus & Gelles, 1988). Although 14 years separates these two reports—the first Canadian and the second American—the relative figures seem unlikely to have changed substantially and point to considerable philosophical differences between two countries in close geographical proximity and seemingly with many shared values. Holden (2002) notes that in the United States legislation banning corporal punishment is highly unlikely to succeed given the importance placed in American history on corporal punishment as an important part of child rearing and beliefs about the privacy of the family and personal freedoms that mitigate against societal and governmental intervention at this level. In Canada, where history and attitudes about personal freedom are somewhat different, the Supreme Court, in January, 2004, upheld a provision of the Criminal Code that allowed teachers, parents, and guardians to use reasonable force to correct children in their charge. It did, however, set guidelines for reasonable force, quoting experts as saying it should not be used

against children younger than two or against teenagers and should never involve use of an object, such as a belt or ruler, and never include a slap or blow to the head.

Opponents of corporal punishment see it as a predictor of later antisocial behavior (e.g., Strassburg, Dodge, Pettit, & Bates, 1994) and as a potential way station to physical abuse (e.g., Straus, 1994). Supporters (e.g., Baumrind, Larzelere, & Cowan, 2002; Baumrind & Thompson, 2002) regard occasional mild corporal punishment (spanking of a child's extremities with an open hand) that is used only between toddlerhood and puberty and occurs in an authoritative context as a helpful tool in parental efforts to socialize their children and one that young children are willing to accept as a reasonable and fair practice on the part of their parents (Siegal & Barclay, 1985). Certainly, at very young ages, children are unable to understand the rationale or justification for corporal punishment and, in such instances, it may serve only as a source of fear or stress. Supporting this notion, Bugental, Martorell and Barraza (2003) found that children who were the recipients of corporal punishment below the age of 1 year were more likely than other children to show high reactivity (production of cortisol) to stress-inducing events (separation from the mother) at older ages. Similarly, high levels of harsh physical punishment are predictive of children's externalizing problems even when previous levels of problem behavior are held constant (e.g., Nix, Pinderhughes, Dodge, Bates, & Pettit, 1999).

Evidence for the argument that corporal punishment can easily shade into physical abuse is seen to come from the observation that the two are correlated (Gershoff, 2002). Moreover, statistics with respect to rates of child homicide support a hypothesis that there are links between favorable attitudes toward corporal punishment and extreme physical abuse: In Sweden, in 1996, three children between the ages of 0 and 4 years were the victims of homicide. In Canada, in 1997, 24 children of that same age were killed. In the United States, in 1998, the comparable homicide figure was 723 (WHO, 2002). Even controlling for differences in population the per capita rate is markedly discrepant among the three countries. These sorts of correlations do not imply causality, and it is plausible that positive attitudes to and the use of corporal punishment and child abuse have different antecedents (Baumrind et al., 2002). Indeed, Jaffee et al. (2004) have found that shared genetic influences account for a very large portion of the correlation between children's antisocial behavior and corporal punishment, whereas child maltreatment does not

appear to be genetically mediated. Thus, they argue that corporal punishment and child maltreatment have distinct origins, with the latter lying in the family environment and characteristics of the abuser and the former in characteristics of the child. This does not mean of course that corporal punishment does not contribute to increases in children's antisocial behavior, as well as being elicited by their antisocial behavior.

Holden (2002) suggests that appropriate analyses of the impact of corporal punishment need to consider children's physiological and affective reactions to the intervention and their cognitive appraisals of its meaning. Thus, punishment that arouses fear, anger, or pain in the child is likely to reduce the child's willing compliance and to increase the child's avoidance of the parent, thereby reducing opportunities for socialization or the building of a positive relationship. Alternatively, if punishment is seen as well-intentioned, or as an accepted and expected part of the cultural context in which it occurs, then it may be viewed in a less negative way by the child. Ultimately, the issue may be reduced at least in part to one of impulsivity versus instrumentality in parental use of corporal punishment as well as the meaning its use has for the child.

There is still much to learn about the long-term effects of corporal punishment and the factors (means of implementation, responses of children) that serve to moderate its effects. It is typically associated with negative outcomes for the child, but the associated pathway and the qualifying variables for this relationship are unclear. Corporal punishment in some contexts may be less detrimental in its impact than other forms of punishment such as derogation and humiliation. Socialization researchers have argued for some time that power assertive discipline techniques, including physical punishment, will be effective only if they are moderate and mild in usage, combined with reasoning, and used in the context of a warm and loving relationship (e.g., Hoffman, 1983). Under all circumstances, corporal punishment, even when mild, does convey the message that the use of force is a justifiable way in which to solve conflicts, and this is a criticism that does not seem to have been adequately answered by its proponents and a message that most adults probably do not wish to send.

### *Socialization in the Mutuality/Reciprocity Domain*

Caregivers who are responsive to the reasonable demands of their children have children who, in turn, are responsive to their demands (Parpal & Maccoby, 1985). This mutually responsive orientation facilitates chil-

dren's willing compliance with caregiver requests, as opposed to situational or forced compliance based on externally imposed threat of punishment or hope of reward. Moreover, it is seen as a precursor to the development of conscience or early internalization (Kochanska & Aksan, 1995). Indeed, Kochanska and Murray (2000) report that parent-child relationships characterized by mutual compliance, harmony, and positivity during the toddler and preschool years predict children's conscience at early school age (guilt after deviation, resistance to temptation in the absence of surveillance, reluctance to violate rules, and maternal reports of moral and prosocial behavior), even after controlling for the developmental continuity of conscience.

Unlike rewards and punishment that function in the hierarchical domain, with parents imposing demands on their children, parent responsiveness moves the socialization process into the MR domain. As well as setting the stage for future willing compliance, it is also one aspect of the guided apprenticeship involving jointly coordinated interactions that is necessary for the MR domain to be fully operative with others. Although parents (as kin with shared interests with the child) will be willing to produce benefits for their related children, other unrelated individuals will be much less likely to do so. When parents create experiences that foster reciprocal relationships (in which there are two-way benefits), the child can be expected to learn the pragmatic rules of exchange that govern much of social life. Such experiences also create a means of negotiating the relationship between parents and children when the young decline in dependence and increase in power—as the relationship becomes more symmetrical. As suggested, there is empirical evidence to support the notion that mutual reciprocity continues to play a significant role in socialization through middle childhood. Labeled as synchrony and referring to interactions that are reciprocal, responsive, interconnected, and engaged, mutual reciprocity is predictive both of low levels of harsh parenting and low levels of antisocial behavior (Criss, Shaw, & Ingoldsby, 2003). In synchronous relationships children engage in mutual exchange with their parents. More than this, they also impart greater amounts of information to their parents (an important feature of effective socialization as noted earlier) and have the opportunity to practice positive social skills (Criss et al., 2003).

### *Summary*

Different social domains require different socialization strategies to achieve the tasks associated with that do-

main. According to this analysis, parents who use the “wrong” strategy for a particular domain will not be successful in their socialization goals. Children cannot learn the pragmatic rules of exchange that govern much of social life by being punished, nor can they learn to accept rules of behavior through sensitive and accepting parenting. What works when a child is ill is not the same as what works when a child is well, given that different social domains are activated. There are clear interactions between social domain and socialization strategy.

### **Socialization and the Cultural Context**

One of the most powerful moderators of the impact of experience on children’s development is the cultural context in which the experience occurs. We turn now to a discussion of its role in socialization. Context gives meaning to a socialization activity; thus, the same action may have a different outcome in a different cultural context because it has a different meaning in each of those contexts. Investigation of culture also increases understanding of mechanisms of socialization and features of human behavior by demonstrating the role of goals and practices that are influenced by the cultural context, as well as identifying those goals and practices that cut across cultures. Context helps address questions, such as why it is that authoritarian parenting leads to negative outcomes in one culture and not in another, or whether autonomy and separation are universal features of psychological functioning independent of the context in which they are exhibited.

A frequently employed distinction in cultural research is that between individualism and collectivism. The distinction has both its advocates and its critics as we note in the following discussion. We use it, however, because it parallels so closely the dimensions of relatedness and autonomy that have been a prominent part of the discussion of socialization presented in this chapter.

#### ***Individualism versus Collectivism as Organizers of Culture***

Differences between national cultures have been highlighted through the use of dichotomies, such as individualist-collectivist (Hofstede, 1983), agentic-communal (Kashima et al., 1995), and independent-interdependent (Markus & Kitayama, 1991), all of which emphasize the distinct way that each values the self versus others. Thus, cultures are broadly characterized as focusing on different aspects of the two social-

ization dimensions of interrelatedness and autonomy. Some (generally North American and Western European) focus on separation and autonomy of the individual, with the self seen as a distinct entity having unique internal attributes. These individualist cultures emphasize competition, self-actualization, dominance, and open expression of emotion. In contrast, collectivist cultures, more characteristic of most of the rest of the world, highlight interrelatedness and connectedness with the group, social harmony, and the organization of behavior around relationships with others. Cooperation, empathy, accommodation with the needs of others, subtle expressions of emotion, and, sometimes, deference to the authority of others are central in descriptions of collectivist approaches to psychological functioning.

Individualistic and collectivistic orientations arose as a result of adaptation to different environmental conditions and restraints, with specific economic and environmental conditions favoring different developmental pathways (e.g., Berry, 1976). Thus, the interdependent route is linked to small communities and a subsistence economy, where cooperation and interpersonal harmony are necessary features for survival. In contrast, the independent pathway is an adaptive response to large, anonymous, urban centers and a commercial economy, or modes of production that do not require group support. In the small and interdependent community, ideas tend to be transmitted from one generation to the next in a vertical fashion, and so they maximize continuity and facilitate respect for authority. In the more independent context, ideas are negotiated horizontally in generations and subject to influence from outside sources. As a result, there may be less continuity and respect for the traditional ways of doing things (Greenfield, Keller, Fuligni, & Maynard, 2003).

Pure examples of individualism and collectivism are not easy to find in a world that is changing speedily and where technological developments break down cultural distinctions. The dichotomy has been the object of considerable criticism, much of it a result of the tendency of researchers to treat individualism-collectivism as an individual difference variable rather than as a feature of differences between nations as the original proponents of the distinction (e.g., Hofstede, 1983) intended. Individualism and collectivism are orientations that are found in all societies and individuals (Brewer, 1999a; Brewer & Gardner, 1996; Killen & Wainryb, 2000; J. Miller, 2002; Oyserman, Coon, & Kemmelmeier, 2002). Turiel (2002), who maintains that a desire for autonomy from the group is universal rather than just a feature of

individualistic cultures, argues that individuals can respond to ideological belief systems in ways that show active acceptance as well as tacit disapproval or rejection. As an example, the Druze in Israel are a hierarchically organized society in which there are differences between men and women in their rights and individual autonomy. Druze women frequently support the rights of men to exercise their power, but they see it as unjust and they see their own endorsement of male rights simply as a way to avoid severe social sanctions (Wainryb & Turiel, 1994). In a similar vein, Helwig, Arnold, Tan, and Boyd (2003) report that Chinese children express concepts of rights, individual autonomy, and democratic norms in their social reasoning as well as use them to critically evaluate existing social practices. Further criticisms emerge in observations that the concepts appear to change as they move across major cultural areas, with collectivism in Asian societies different from that in African or Latin American societies, and individualism in the United States different from that in Europe (Harkness, Super, & van Tijen, 2000).

In spite of these concerns, Oyserman et al. concluded in a meta-analysis that there is good evidence to support the speculation that so-called individualist- and collectivist-focused societies differ in organization, with the latter promoting in-group harmony and group obligation and the former making personal uniqueness salient and requiring separation from others. Oyserman et al. hasten to add that this does not mean that societies uniformly enforce these mandates on all members. But they suggest the dichotomy does signal that some features of human functioning believed to be universal may not be so. For example, not all individuals make sense of the self through high self-esteem or positive self-views to the extent that European Americans do, nor do all individuals have attributional and cognitive styles that lead them to ignore contextual influences on human behavior as much as do European Americans. People, as a function of the cultural context in which they find themselves, are likely to be different in what they consider to be rewarding outcomes and may treat in-group as opposed to out-group members differently. Ultimately, well-being is linked to a considerable degree to the attainment of culturally valued outcomes.

Some have suggested that, given that elements of autonomy and interrelatedness occur in all cultures, a better way of conceptualizing the impact of different goals in so-called collectivist and individualist societies may be to focus on the relative balance of each. This is a point made by Rothbaum, Pott, Azuma, Miyake, and

Weisz (2000) in their analysis of close relationships in Japan and the United States, with the analysis shifting from a focus on the importance and strength of relationships to one that concentrates on the meaning and dynamics of relationships. Their argument is that individuation, which characterizes American thinking, and accommodation, which characterizes Japanese thinking, influences the nature of relationships in those cultures rather than individuation diluting relationships. Specifically, the need for affiliation with others involves either a pull toward adaptation of the self to fit the needs of others—the path of symbiotic harmony, or a tug between the desire for proximity and closeness and that for separation and exploration—the path of generative tension. Examples are provided from a variety of domains. In the protective care domain, Japanese infants derive security from the mother's indulgence of their needs and American infants from the use of the mother as a secure base from which to explore the world, a distinction reflected in greater body contact by Japanese mothers and greater eye contact by American mothers (e.g., Barratt, Negayama, & Minami, 1993). In the hierarchical domain, American parents show respect for noncompliance but exercise more direct control. Japanese parents avoid confrontations and often back down when children resist their requests. As well, they are more likely to use guilt and anxiety induction, shaming, and modeling (Lebra, 2000). American parents threaten to ground their disobedient children inside the home, whereas Japanese parents threaten to banish them outside the home (Johnson, 1993). In the MR domain, American adolescents increasingly seek intimacy with peers in sharp contrast to Japanese adolescents who view the parent-child relationship as enduring and mutually supportive across the life span (Lebra, 2000). Indeed, in Japan there are, in contrast to North America, no laws concerning legal and economic independence from parents (Hsu, 1983). In essence, relationships are central in both cultures, but they take a different form as a function of differential emphasis on individuation and accommodation. The Japanese model is only one contrasting possibility, but it offers a means of expanding conceptualizations of how the nature of relationships is affected by cultural goals.

The usefulness of the collectivist-individualist comparison is reflected in the frequency with which it is employed in many studies (a number of which are discussed later) as a source of hypotheses for cultural differences in the socialization of social, emotional, and cognitive development. Moreover, as noted earlier, it maps well

onto the basic socialization mechanisms that appear in the social domain analysis presented in this paper. Given these observations, we treat different attitudes toward interdependence and independence as useful organizing and explanatory devices in the following discussion. Ultimately, we conclude that interrelatedness and autonomy/control are important in all cultures, but the way in which they manifest themselves differs as a function of the values and goals that exist in a particular cultural setting (e.g., Greenfield et al., 2003; Rothbaum, Pott, et al., 2000; Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000). Thus, one challenge for investigators is to see how interrelatedness and autonomy are differentially expressed as a function of goals and belief systems that characterize a particular cultural group.

In the following discussion, we first describe how parental goals are affected by different cultural contexts and how those goals are manifested in different socialization practices. We ask what context reveals about mechanisms of socialization in different social domains and discuss developmental pathways and the expansion of meaning of interrelatedness and autonomy that cultural comparisons provide.

#### ***What Context Reveals about the Mechanisms of Socialization***

In socialization situations, values are transmitted not only in the form of statements about valued behavior ("Family is important," "Learn to think for yourself") but also in modes of intervention. Power assertion, for example, sends the message that obedience is a desirable and important outcome, whereas reasoning indicates that willing acceptance of a particular position is an important social goal. Negotiation and compromise indicate that maintenance of positive relationships should be an aim in social interactions and that what constitutes acceptable behavior can be stretched as a function of discussion and conciliation. The way in which socialization is carried out, as well as the specific content that is conveyed, reflects general values inherent in the culture.

We begin with a general discussion of the impact of culture on goals and socialization practices and then consider, in greater detail, socialization practices in two domains that have received the most attention from cultural researchers—protective care and hierarchical power.

**The Impact of Culture on Goals.** The collectivist focus on interdependence and group harmony is reflected in different emphases from the individualist focus on autonomy on what are important goals or out-

comes for the child. Familial obligation and the duty of children in the maintenance of the household, for example, marks a prime difference between collectivist and individualist orientations. Although family obligations are valued less by adolescents than by their parents regardless of culture (Phinney, Ong, & Madden, 2000) there is greater endorsement of these obligations by collectivist youth than by individualist youth. Thus, Asian American and Mexican American adolescents are more likely than their European American peers to believe they should assist parents and siblings throughout the life span and be willing to make sacrifices for the family (Fuligni, Tseng, & Lam, 1999). In a parallel way, prosocial behavior or a concern with the needs of others is more duty-based and seen as an important achievement of justice among Hindus, whereas concern for the needs and welfare of others involves an element of choice and personal decision in Anglo-Western contexts (J. Miller & Bersoff, 1992). Greenfield et al. (2003) contrast concepts of intelligence as a function of cultural orientation: Individualists value scientific intelligence because it emphasizes the person in relation to the world of objects. The collectivist contrast is valuation of social intelligence and the development of a child who can contribute to the well-being and cohesiveness of the group rather than one who stands out as different and better. Attention is on shared perspectives rather than different perspectives, one possible reason for why collectivists do less well on theory of mind tasks (Vinden, 1999). Finally, with respect to autonomy, American parents value independence, assertiveness, and self-expression, whereas Chinese parents place the emphasis on obedience, reliability, proper behavior, social obligation, and group achievement (Chao, 1995).

#### **The Impact of Goals on Socialization Practices.**

The attainment of different goals is achieved by the use of different practices. Japanese American families discuss group activities and shared experiences at the dinner table and Caucasian American families focus on children's activities and individual experiences during dining encounters (Martini, 1996). Similarly, American and Israeli comparisons reveal a concern with the individual's daily experience among the former and the telling of stories that include multiple members of the group among the latter (Blum-Kulka, 1997). American children are encouraged to discuss their own feelings and those of others as a way of increasing their understanding of emotion and ability to regulate it, whereas, in Chinese families, attunement to the feelings of others

but restraint in the expression of one's own feelings is encouraged as a key to group harmony (Chao, 1995). Chinese children are expected to read or infer the thoughts and feelings of others without being told (Wang & Leichtman, 2000). Chinese parents are also more likely to remind children of their past transgressions, using story-telling, for example, as a way to teach social norms and behavioral standards and to engender a sense of shame over bad behavior: In contrast, American parents avoid stories of transgression so as not to damage their children's self-esteem (P. Miller, Fung, & Mintz, 1996; P. Miller, Wiley, Fung, & Liang, 1997). European American parents are more likely to engage in authoritative parenting, emphasizing the growth of separation and autonomy in a supportive and responsive relationship; Asian American, Latino, and African Americans are more likely to engage in authoritarian parenting with its greater emphasis on obedience and conformity (Steinberg, Mounts, Lamborn, & Dornbusch, 1991). Learning in cultures that foster interdependence involves keen observation, attentiveness, and focused listening (Greenfield et al., 2003; Rogoff et al., 2003) as opposed to direct tuition and formal schooling. Even in school classrooms, however, children in interdependent cultures are more likely than teachers to take responsibility for classroom management and to solve problems together than those in independent cultures (Rogoff et al., 2003).

Maternal behavior in the protective care domain offers a detailed example of how different cultural values are mirrored in the ways that parents handle the tasks of socialization. For example, Keller et al. (2004) have identified two styles of parenting of very young infants: (1) distal with an emphasis on object stimulation and face-to-face exchange (mutual eye contact and frequent use of language) and (2) proximal with an emphasis on body contact and body stimulation. The former, found in individualist settings (German and Greek), links infants to the nonpersonal world of objects and informs them of their ability to influence the world. The latter, characteristic of collectivist settings (Cameroon Nso, Costa Rican, and, partially, Indian Gujarati Rajput), is associated with social cohesion, feelings of belongingness, and the experience of the body as an agent situated in the environment. In an analysis of how sensitivity in mother-infant interactions manifests itself in different cultural settings, Rothbaum, Weiss, et al. (2000) focused on the contrasting emphasis in Japanese and American cultures on independence and interdepend-

ence and how it reveals itself in the way mothers respond to distress and bids for attention in their infants. They suggest that, for example, sensitivity is expressed to American infants in distal forms of contact and encouragement of expression of negative emotion as opposed to its expression to Japanese infants through prolonged skin-to-skin contact and discouraging of emotion expression. Sensitivity occurs in response to children's signals in the American context and in anticipation of children's signals or needs in the Japanese context; sensitivity fosters exploration and autonomy in the former and emotional closeness in the latter. Secure attachment promotes social competence, but competence differs in the two cultures—exploration, autonomy, willingness to express emotion, and a positive self-concept as opposed to dependence, emotional restraint, self-effacement, and indirect expression of feelings. In this cultural approach the universals of attachment—pursuit of proximity and protection and distress at separation—remain unchanged but some of the basic tenets, including the meaning of sensitivity, competence, and the function of the caregiver as a secure base for exploration, assume more culture-specific forms. With this sort of cultural analysis, the understanding of what it means to be securely attached is perceived in more diverse and context-relevant ways. Different goals in different cultures channel caregiving practices, so that close body contact, immediate or anticipatory reactions to infant distress signals, and disapproval of mother-child separation feature in a variety of collectivistic cultural contexts as a way of fostering early close relationships, in contrast to practices more familiar to researchers in individualist cultures (Greenfield et al., 2003).

Turning to practices in the hierarchical power domain, we note that many studies have found Asians to be more restrictive in their parenting (Chao, 2002) and numbers of others have failed to find the usual relations between authoritative and authoritarian parenting and children's cognitive and social outcomes in different cultural groups. For example, the association between authoritative parenting and academic achievement is stronger for European American than for Asian and African American adolescents (Darling & Steinberg, 1993). Authoritarianism is positively related to externalizing problems for European Americans but unrelated for Mexican Americans (Lindahl & Malik, 1999), and authoritarian parenting has positive effects on adolescents' school performance among the Chinese in

Hong Kong (Leung, Lau, & Lam, 1998). Supervision and consistency of discipline are negatively related to delinquency among European Americans but unrelated among Mexican Americans (C. Smith & Krohn, 1995), and corporal punishment is associated with externalizing problems in European American but not African American children (Deater-Deckard, Dodge, Bates, & Pettit, 1996).

A number of factors can plausibly account for the differential impact of authoritarian parenting. First, socialization styles convey values, and values differ in different social contexts. In collectivist contexts, deference to authority would be supported by authoritarian approaches to child socialization to the extent that such deference fosters family coherence and harmony. Second, authoritarian parenting appears to have different meaning in different contexts. Chao (1994, 2001, 2002) notes that authoritarian parenting in China can involve the concept of *guan* or training that emphasizes the importance of hard work, self-discipline, and obedience. When it has this meaning it may well have a more positive outcome, particularly in the area of academic achievement.

The adverse impact of strict and controlling parenting in Western European cultures may stem to a considerable extent from its association with a variety of negative cognitions and emotions experienced by authoritarian parents in interaction with their children. These include rejection and lack of warmth (Baumrind, 1967), negative attributions for children's actions (Dix, Ruble, & Zambarano, 1989), low feelings of control in interactions with difficult children (Bugental, Brown, & Reiss, 1996), and inability to take the perspective of the child (Dekovic, Gerris, & Janssens, 1991). In contrast, control has been found to be unrelated to these negative emotions and cognitions in collectivist cultures (Rudy & Grusec, 2001, in press) and even to have positive associations with warmth and acceptance (Rohner & Pettengill, 1985; Stewart et al., 1998; Trommsdorff & Iwawaki, 1989). Authoritarian parenting in Western European contexts frequently may be pursued to establish authority over children who are felt and thought about in relatively negative terms. In other cultural groups, however, authoritarianism may often be pursued in children's interests. Indeed, it may be the negative cognitions and emotions that ultimately produce the kinds of outcomes that have been attributed to authoritarian parenting across all cultural contexts. In this sense, control is not the issue so much as rejection, hos-

tility and derogation (resulting from negative attributions), and lack of ability and/or willingness to take the perspective of the child. Accordingly, levels of emotional expression but not parent control and directiveness are related to children's social acceptance (Isley, O'Neil, & Parke, 1996), and warmth and involvement are better predictors of academic achievement and socioemotional outcomes among Korean American, Mexican American, and Anglo European adolescents than is control (Kim & Rohner, 2002; Knight, Virdin, & Roosa, 1994). As well, when coercive discipline is operationalized as observed rejection, criticism, and failure to say good-bye or to greet children in a day care setting it is a predictor of conduct problems even among African American children (Kilgore, Snyder, & Lentz, 2000). Similarly, when parental control is defined for Asians not as *guan*, but as domineering or overprotective behavior, it has negative effects (Herz & Gullone, 1999; Stewart et al., 1998) just as it does in a Western European context. Barber and Harmon (2002) also suggest that psychological control has negative correlates in a variety of cultural contexts. These findings all point to the fact that relationships and parenting style are central in socialization and that they moderate the meaning of control for the developing child.

### *Linkages to Developmental Pathways*

The last question to be addressed in this section has to do with differences among cultures in developmental pathways. If the ideal developmental outcome involves a balance between interrelatedness and autonomy (Blatt, 1998), what might one expect with respect to greater emphasis on the one rather than the other in different cultural contexts? Does the emphasis on autonomy and separation in the West serve the needs of the culture but impede optimal development? The general question has been most frequently addressed with respect to the collectivist model with its weight on interdependence and group harmony. Rothbaum, Pott, et al. (2000) suggest that adaptation to group needs over self-assertion may lead to internalizing problems, although Lewis (2000) notes that the suicide rate is lower in Japan than in the United States and that Japanese high school students report fewer feelings of stress, anxiety, and depression. Lebra (2000) describes the difficulty Japanese children have in breaking away from their mothers and the fact that marital relationships are sometimes strained because exclusive intimacy is not legitimized and, as a result, husbands and wives become distanced. The reliance

on shame that characterizes some collectivist cultures may be problematic given that it gives rise to more intense levels of physiological arousal than does guilt (Scherer & Wallbott, 1994) and that it is less likely to lead to reparative behaviors than is guilt (Tangney, Wagner, Hill-Barlow, Marschall, & Gramzow, 1997). Alternatively, the psychological well-being of Chinese American adolescents in the United States does not appear to be harmed by the fact that they have more family obligations than their European American counterparts (Fuligni, Yip, & Tseng, 2002).

**Autonomy.** Considerable attention has been paid to the issue of autonomy and whether or how interdependence and group harmony undermine it. An extension of this question has to do with whether autonomy is indeed the universal human need suggested by self-determination (Deci & Ryan, 1991) and other theorists (e.g., Killen & Wainryb, 2000). One stance is that the values of autonomy are opposed to those of group cohesion and that autonomy is not important across all cultures. Another suggestion is that yielding to controlling pressure is more satisfying in some cultures than is making decisions in the absence of any external influences (e.g., Iyengar & Lepper, 2000; J. Miller, 1997). In accord with this viewpoint, the adoption of choices made by trusted others has been found to enhance intrinsic motivation for Asian Americans but not for European Americans (Iyengar & Lepper, 2000). Some (e.g., Chirkov & Ryan, 2003; Ryan & Deci, 2000), however, argue that decisions made in conformity with the guidance of others is not an accurate rendering of the concept of autonomy and that autonomy is experienced when individuals perceive their actions to be willingly enacted and when they themselves fully endorse these actions. The autonomous individual is not defined as individualistic or independent (both of which are indicators of low relatedness) nor does the autonomous individual act in independent, detached, or selfish ways. The opposite of autonomy is not dependence or lack of physical separation (Kagitcibasi, 1996) but, rather, heteronomy in which choices are seen as controlled by those who do not share one's own values or interests. In accord with this distinction, Chirkov and Ryan (2003) found that autonomy and well-being were correlated in both individualist and collectivist countries (South Korea, Turkey, Russia, and the United States). They also found that values involving vertical or status-

oriented issues were more difficult for people to internalize, possibly because vertical issues frequently require individuals to give up their own freedom of choice as well as restricting the set of people with whom intimacy and connectedness can be established.

The focus on autonomy as willing enactment and endorsement of a position has been labeled "reflective autonomy" (Koestner & Losier, 1996; Koestner et al., 1999) and distinguished from "reactive autonomy," with individuals who are high in reflective autonomy more willing to follow expert advice and those high in reactive autonomy more likely to reject the influence of others even when such action is counterproductive. We note the parallel distinction between willing and situational compliance (Maccoby & Martin, 1983) and the fact that willing or receptive compliance promotes a positive and cooperative stance in relation to agents of socialization that may fit better with collectivist than individualist goals. Indeed, one is reminded of the fact that Asian parents in general will often give in to their children's demands rather than encourage conflict and confrontation (Chao, 2002), either as a way of avoiding confrontation or because they see young children as not responsible for their actions. This is a practice that may not work well when the goal is separation and individuation, but may work well with a goal that actions be seen as freely chosen.

**Conflict.** Conflict is a significant contributor to the development of individuation and separation. An important question has to do with the role and extent of conflict in collectivist contexts. Although parent-adolescent conflict may be more discouraged in collectivist settings it does exist and is widespread (Schlegel & Barry, 1991). Thus, even under conditions in which interdependence and family harmony are stressed, there is expressed disagreement between the generations, an indication of growing autonomy. In a study of Chinese (Hong Kong) adolescents Yau and Smetana (1996), for example, report the existence of conflictual interactions, albeit fewer than in American families. Despite the particularly great emphasis on respect for parental authority in Chinese families, Yau and Smetana report that Chinese adolescents reasoned about conflicts as issues of exercising or maintaining personal jurisdiction, similar to the way in which American adolescents express their growing need for individuation and autonomy. These appeals to personal jurisdiction may reflect

the fact that parental respect and filial piety seem to have more of the characteristics of family harmony and love and affection than they do of strict obedience (Sung, 1995). Smetana and Yau did find some differences in the content of conflicts, with more disagreement over academic matters and the behavior of parents themselves (e.g., their smoking or their relationship with other family members), with each of these reflecting the greater Chinese emphasis on academic achievement and family functioning. Yau and Smetana conclude that similarities between adolescents in Hong Kong and American adolescents reflect the universal developmental task of separation or de-individuation from parents, with conflict one way of achieving this de-individuation. However, the way in which conflict is expressed, and the extent to which it occurs, is obviously directed by the cultural context in which it occurs.

What do we conclude about the links between relatedness, autonomy, and developmental pathways? An important observation is that interrelatedness and autonomy appear to be important features of all cultures. Analyses of their manifestations in a variety of contexts suggest differences in emphasis and differences in form but an underlying and common concern with feeling related to others and feeling some degree of control over one's own actions. There may be tradeoffs in the ways in which these motives are expressed. Close family ties provide the benefit of a high sense of safety but at the cost of reductions in the individual's ability to achieve personal goals. Rothbaum and Trommsdorff (in press) talk about tradeoffs between forms of relatedness, contrasting trust and assurance. They argue that trust, or faith in the intentions of others that allows people to seek spontaneous relationships with new partners, is associated with autonomy, self-esteem, and self-actualization. However, assurance, or commitment to and guarantee of loyalties and reciprocity from members of a tightly knit group, promotes group cohesion and family security. Thus, culture may be characterized as preference for different social domains or different points of balance but with no one centrality more adaptive than another.

### **Summary**

Culture provides an example of an interactional model of socialization, pointing to the importance of meaning in understanding mechanisms of socialization. The study of socialization in different cultural contexts re-

veals how cultures affect goals and, thereby, socialization practices. For example, research suggests that when authoritarian parenting harms children it is because of its association with lack of warmth and respect for the child. Thus, authoritarian parenting, guided by goals of the culture, has a different meaning in those cultures. Cultures have been distinguished by a differential balance of the two basic dimensions of socialization: interrelatedness and autonomy. Nevertheless, interdependence or interconnectedness appears to be important in all cultures, as does autonomy—a willing enactment of a position.

### **OUTCOMES OF THE YOUNG AS A RESULT OF THEIR LIFE HISTORY**

To this point, we have considered the sociocultural processes that operate in socialization as built on a biological platform that is common to all members of the species. We now move to consider individual variation in biological characteristics and how they combine with sociocultural experiences in determining the outcomes of the young. Researchers have proposed different models of contingent causality in conceptualizing the ways in which child characteristics and life history combine to influence the child's ultimate outcomes. As a beginning to our discussion, we briefly review some of these models. The models differ in their starting points. Some investigators begin with a consideration of children's reactivity to novelty and change in their environment as a function of genetic variables (e.g., sex or temperament differences). Others begin by considering the impact of a variety of child characteristics (e.g., learning disorders or negative emotionality) on their receptivity to socialization per se. Still others begin with a focus on the shared (and unshared) characteristics of children that lead them to be able to adapt to changing ecologies. Despite variations in their starting points, there is a high level of overlap in these models.

We then move on to consider the route through which children's long-term outcomes are determined as a function of these interactions. Specifically, we are concerned with the life outcomes of the young as a function of the mediating role of (a) children's acquired ways of cognitively representing their social worlds, (b) hormones in the responses shown to their experiences, and

(c) gene expression in the continuous reorganization of the brain in response to experience.

### **Child Characteristics as Sources of Influence on and Reactivity to the Environment**

Children's early environment necessarily includes both change and stability. The child is increasingly confronted with novel or surprising events that potentially serve as sources of stress. At the same time, children differ in the extent to which and the ways in which they respond to such normative experiences.

#### ***Genetic Variations in Children's Reactivity to Stress-Inducing Events***

Variations in children's reactivity to the environment have often been found to be due to genetic differences in children. Researchers initially focused on the extent to which children are selectively vulnerable to negative experiences; for example, boys have generally been found to be more reactive to environmental stress than are girls. They show faster rise times and higher levels of physiological arousal to commonly occurring sources of stress (Maccoby, 1988). On a more ongoing basis, boys are more negatively affected than are girls by single parenthood (Hetherington, 1993), poverty (Elder & Rockwell, 1979), and divorce (Needle, Su, Doherty, 1990).

There has also been a continuing line of research focused on children's temperament as an influence on their reactivity to potential stress (e.g., Gunnar, Porter, Wolfe, Rigatuso, & Larson, 1995; Kochanska, 1993; Ramsay & Lewis, 2003; Schmidt, Fox, Rubin, & Steinberg, 1997). Among the ways in which children differ on the basis of temperament, child fearfulness or inhibition has been most strongly associated with vulnerability to potentially stress-inducing events (Goldsmith & Lemery, 2000; Kagan, 2001). An initial focus on temperament differences that led to differential vulnerability to stress was extended to include temperament differences (e.g., positive emotionality) that led to differential resilience in the face of stress or adversity (Wills, Sandy, Yaeger, & Shinar, 2001).

In considering these genetically influenced differences in children, researchers have focused more recently on the interaction between genes and the child's socializing environment in determining their long-term outcomes (Collins et al., 2000). For example, temperamentally fearful children whose mothers use harsh discipline are more likely to exhibit lower levels of con-

science than are those who are low in fearfulness or than do those who are high in fearfulness and have gentle parents (Kochanska, 1997). In addition, fearful boys exposed either to harsh or overinvolved parenting show elevated levels of depression (Colder, Lochman, & Wells, 1997). At the same time, young children who are fearful or display discomfort in strange situations show a greater level of conscience development to the extent their mothers use a gentle disciplinary style. In addition, fearful children may manifest unique regulatory benefits (habituation to repeated stress) when they experience more responsive parenting (Schwartz & Bugental, 2004).

Supporting the notion that temperament and experience interact in a way that allows clear causal inference, Suomi (1997) has demonstrated that rhesus macaques that show a highly fearful temperament, when cross-fostered by average mothers, showed deficits in their exploratory behavior and in their responses to stressful events. In contrast, temperamentally fearful animals that were cross-fostered by very nurturant mothers showed high levels of exploratory behavior and ability to cope with stress.

In the same way, those children who demonstrate irritability (or negative emotionality) early in life, show different outcomes based on the responses shown by their parents. For example, Crockenberg (1987) observed that infant irritability, when combined with angry and punitive mothering, predicted child anger and noncompliance at 2 years of age; no such relationship was found for nonirritable infants. At the same time, children who show early negative emotionality are more likely to show benefits when they experience positive parenting. For example, Blair (2002) found that infants who showed high negative emotionality demonstrated greater cognitive and social benefits (fewer externalizing problems at later ages) than did other children when their parents participated in an early intervention program that afforded enriched rearing experiences.

#### ***Children's Responsiveness to Socialization or Tuition***

Consistent differences have been found between children in their receptivity or responsiveness to socialization (Belsky, in press). Both at home and school, children differ in the extent to which they are positively responsive or unresponsive to social influence and/or tutorial efforts. In some cases, child unresponsiveness is due to learning disorders such as attention deficit disorder (ADD) or attention-deficit hyperactivity disorder

(ADHD). In other cases, it may involve child characteristics that have sometimes been summarized as involving a "difficult" temperament (Bates, 1980). Finally, some researchers have been concerned with children's physiological response patterns as predictive of their receptivity to socialization.

Ordinarily, children's reduced responsiveness to socialization is maladaptive, and thus might be thought of as having been weeded out by natural selection. In contemporary, stable environments, a child's unresponsiveness to socialization typically poses a potential problem to parents (or teachers). However, Belsky and his colleagues (Belsky, *in press*; Belsky, Hsieh, & Crnic, 1998) suggest that there are advantages for such unresponsiveness under some circumstances. In unpredictable environments, such children may be less constrained by a socialization history that is not well-suited to the changing demands. For example, it has been suggested (Jensen et al., 1997) that children with ADHD might have fared well in harsh, unstable environments more characteristic of our evolutionary past. These authors suggested that such children show an exceptional readiness to explore their environment (high levels of motor activity) and rapidly changing responses (impulsivity) in reaction to it. During harsh times, they may have had an "edge" in avoiding danger and taking advantage of unstable benefits.

Attention has also been given to variations in children's emotional and physiological reactions as indicators of their receptivity to socialization. For example, Kochanska (1993) has suggested that children are more receptive to socialization to the extent that they are emotionally reactive to punishment and that they engage in effective self-regulation. In infancy, physiological reactivity (e.g., heart rate or cortisol elevations) of children in response to stress acts as a predictor of later responsiveness to socialization (Gunnar et al., 1995; Kagan & Snidman, 1991). Children who show this type of reaction to aversive stimuli may be thought of as showing adaptive neurobehavioral organization (Gunnar et al., 1995).

### *Context Sensitivity of Children*

It has also been proposed that children are quite generally sensitive to context (Boyce & Ellis, *in press*), with genotypic variations in this sensitivity. Boyce and Ellis conceptualized context-dependent effects as conditional adaptations that have evolved as a basis for calibrating the child's response patterns to match their environment

in an adaptive way: Children are seen as designed by their evolutionary history to show a facultative responsiveness to the environment in which they are born. If the environment is harsh, such context sensitivity may lead to increased vigilance for potential threat. If, however, the environment offers positive support, such context sensitivity may lead to increased receptivity to positive aspects of the social environment. In either case, children's context-sensitivity can be expected to increase their reproductive success (in the particular ecology that confronts them). High levels of context sensitivity may set the child in quite different directions on a phenotypic basis. This sensitivity allows children to be able to adapt to the environment they come to experience.

In addition, early experience with stress (or adversity) may also heighten the context-sensitivity of the child. Children who experience early medical problems (and thus experience the stress associated with the neonatal intensive care unit or stress-inducing medical treatments) represent one such example. Research focused on response to early stress or adversity has documented the very different life outcomes such children may experience based on their parenting history. Although early stress may yield negative life outcomes when parents fail to buffer children against the effects of such experiences (the "risk" pathway), early stress may also yield exceptionally positive life outcomes when parents provide a high level of support (an outcome that may be described as "thriving," e.g., Bugental, 2003).

Infant prematurity represents a case in point, in that it is accompanied by the greater likelihood of early stress, combined with limited self-regulation abilities. Although children who were born prematurely are hyper-reactive to environmental stimuli, they often down-regulate their responses in ways that lead to hypo-reactivity (suggested to serve as protective responses against overstimulation; Tronick, Scanlon, & Scanlon, 1990). Mothers often respond to these reactions with excess stimulation efforts, which foster further problems (Brachfield, Goldberg, & Sloman, 1980); in contrast, when mothers show a response style that is better synchronized to infant needs, such children have more positive self-regulatory and interactional outcomes (Feldman, Weller, Sirota, & Eidelman, 2002).

The parenting history of context-sensitive children may ultimately influence their health outcomes. For example, Bugental and Beaulieu (2004) observed that children who were born at medical risk (as assessed by their

premature status or elevated Apgar scores) demonstrated either exceptionally positive or negative health outcomes as toddlers as a function of their parenting history. Those born at medical risk (in comparison with low-risk children) demonstrated exceptionally positive health outcomes if their mothers participated in a cognitively based home visitation intervention (which, in turn, fostered reductions in maternal depression). Medically at-risk children whose mothers were in control conditions were more likely to show negative health outcomes. In support of the observation that early stress, under appropriate conditions, can have a beneficial effect on health, young adults whose history included early medical complications have been found to show exceptionally high levels of health (as well as habituation to repeated stress) when they had been the recipients of supportive parenting (Bugental, Beaulieu, Cayan, et al., 2004). In contrast, young adults with a history of early medical complications showed exceptionally low levels of health (and poor ability to habituate to repeated stress) when they had been the recipients of harsh parenting. No equivalent effects were found for young adults who had not experienced medical risk early in life. Such findings are consistent with Boyce and Ellis's (2000) proposal that parental support and protection serve as key moderators of the extent to which context-sensitive children experience negative or positive outcomes.

### **What Is the Route by Which Children's Experiences Lead to Different Outcomes?**

Children's outcomes as a result of early experiences can be mediated by different means. Consideration is given here to both cognitive and biological routes.

#### ***The Mediating Role of the Child's Cognitive Representations of the Social World***

One route through which children may come to have different life outcomes involves their acquisition of different ways of representing the social world as a function of their early socialization experiences. In family relationships, children's experiences with their own parents form a central influence on their cognitive representations of the caregiving relationship (Grusec, Hastings, & Mammone, 1994). For example, girls who have experienced maltreatment early in life come to have a low perception of their social power in relationship with others (Bugental & Shennum, 2002). Such representations are

predictive of the propensity to become abusive in their relationships with their own children (Bugental & Happaney, 2004). In the same way, socialization history leads some children to acquire a "victim schema," which is predictive of their being more likely to be victimized by other children (Perry, Hodges, & Egan, 2001). Even broader links are found between children's representations of family, peer, and self; negative representations are predictive of dysfunctional social behavior and low peer status (Rudolph, Hammen, & Burge, 1995).

Relationships with significant others early in life serve as the basis for cognitive representations of relational information. M. Baldwin (1992) proposed that individuals, as a result of their relational history, form cognitive structures that include a script for the interaction pattern, a schema for the role of the other person in the relationship, and a schema for the role of self in the relationship. Such relational schemas come to influence the individual's expectations and experiences in subsequent relationships.

#### ***The Mediating Role of Hormones***

Developmental neuroscience has provided insights into another route through which socialization may influence children's outcomes. In doing so, the field has focused on regulation of stress in early relationships, including parent-child relationships. In the socialization literature, increasing attention has been given to a key stress regulation system—the HPA axis. Across ages (and species), the HPA axis is activated in response to events that might pose a threat; for an infant, this could include as little as an unfamiliar toy or as much as a frightening parent.

Although an activated HPA axis facilitates the effective management of short-term stress, such is not the case if the HPA axis is repeatedly activated without recovery. In this case, there is destructive wear and tear on the system, a process that McEwen (2000) refers to as "allostatic load." As an end product of this process, the individual became decreasingly able to cope with future stress. Over long time periods, the child's dysregulated HPA axis (as indicated either by cortisol hyper-reactivity, hypo-reactivity, or deviant basal levels), following from unrelieved stress early in life, may produce long-term changes in the capacity of the system to respond to stress, and in the effective functioning of other parts of the central nervous system that are affected by the HPA axis.

When the young child is exposed to very high levels of unbuffered stress, the normatively well-functioning

HPA axis is overactivated. As a result, this regulatory system becomes more limited in its ability to manage new sources of stress, and other linked regulatory systems (e.g., the growth system, the immune system) do not function optimally. Ultimately, the continuous activation of the HPA axis (and associated changes in the functioning of other aspects of the central nervous system) may lead to deficits not only in brain development but also in the social-emotional and cognitive functioning of the child and the health and growth of the child (e.g., Bremner & Narayan, 1998).

The immediate effects of an unsupportive environment on children's stress regulation abilities have been demonstrated in a number of different ways. For example, maternal depression has often found to be associated with children's stress regulation problems. Depressed mothers, as well as mothers subject to panic disorder, are less responsive to infant distress than are nondepressed mothers and thus are less likely to buffer the young against stressful experiences (e.g., Donovan, Leavitt, & Walsh, 1998; Warren et al., 2003). Not surprisingly, children of such mothers are dysregulated in their production of cortisol (e.g., Bugental et al., 2003; Dawson & Ashman, 2000; Essex, Klein, Cho, & Kalin, 2002; Field, 1994; Newport, Stowe, & Nemeroff, 2002). In the same way, stress-inducing experiences later on during the life of the child produce problems if those children fail to receive supportive parenting. For example, the loss of a parent, when combined with a hostile or rejecting family environment, predicts long-term dysregulation of the HPA axis (e.g., Luecken, 1998).

McEwen (2001) has suggested that stress (in particular, early stress) may have positive as well as negative long-term outcomes. There may be circumstances under which high levels of stress lead to enhanced functioning of the system—enhanced allostatic efficiency may occur. If stress occurs repeatedly but is regularly followed with recovery, the HPA axis may become more efficient in the management of future stress. In short, we see the adaptive possibilities for the socializing system to foster resilience (and even exceptionally positive outcomes) in response to early stress. Such accommodations may operate when the parent serves in a buffering role.

What is the route by which parental support serves to foster the positive outcomes of infants who experience early stress? Some of the best evidence comes from experimental work with nonhuman animals. Meaney and his colleagues (e.g., Meaney et al., 1985) found that rat pups that were exposed to repeated stress (handling by humans) showed later benefits in their brain develop-

ment, along with their ability to cope with future sources of stress. As described earlier, these benefits were mediated by the response of rat mothers to their distressed pups (Francis et al., 1999). When the pups were returned to the litter, their mothers engaged in vigorous licking and grooming, a response that served to calm the pups and led to changes in the development of the corticotropin-releasing factor (CRF). This developmental change led to changes in the expression of behavioral, endocrine, and autonomic responses to stress (through the activation of forebrain noradrenergic systems), which led to an increased ability to manage stress, and subsequent increases in their health as adults (as a result of their reduced vulnerability to the effects of stress-induced illness). This research provides a concrete example of more general processes that are operating in the area of stress and parental support. Thus, Francis, Champagne, Liu, and Meaney (1999) propose:

the relationship between early life events and health in adulthood is mediated by parental influences on the development of neural systems that underlie the expression of behavioral and endocrine responses to stress. (p. 64)

Gunnar and her colleagues (Gunnar et al., 2003), in a review of the literature, concluded that mother-infant interactions have effects on the neuroendocrine stress activity of humans as well as nonhumans. For example, maltreatment or unresponsiveness early in life influences stress hormone activity. In addition, children who manifest reactive temperament patterns show increased stress responses as the quality of parental care declines.

### *The Mediating Role of Gene Expression*

Molecular biology provides insights into the “activation mechanisms” by which the effects of the caregiving environment are accomplished. Thus, there has been an emerging focus on gene expression—the ways in which the environment influences the activation of genes (Brown, 1999). This line of inquiry has led to the general study of differential gene expression in response to environmental variables. Specific to our topic, researchers have become increasingly concerned with the ways in which experiences (including socialization experiences) influence gene expression and resultant variations in brain development (e.g., Bruer & Greenough, 2001). For example, stress may lead to changes in the production of hormones, which serve as messengers to relevant brain cells and the subsequent expression (activation) of genes. Although genes are typically located at

inactive sites in brain cells, those genes that have most recently been activated are repositioned to locations in the nucleus in which they are easily accessed in response to recurring environmental triggers (Lamond & Earnshaw, 1998).

This altered process of gene expression lies at the heart of the benefits of maternal buffering of pup distress observed by Meaney and his colleagues (2000). It has been suggested that there are two distinct CRF systems—one of which is adaptive and one of which is maladaptive (Schulkin, Gold, & McEwen, 1998). The first system leads to restraint of CRF receptor gene expression in the paraventricular nucleus of the hypothalamus, which then serves to “turn off” the HPA axis when the source of threat has passed. The second system fosters CRF gene expression in the central nucleus of the amygdala, and the resultant perpetuation of chronic elevations in fear and anxiety. Maternal licking and grooming of rat pups leads to restraint of CRF receptor gene expression in the hypothalamus, with the net effect that the HPA axis is more easily turned off. In contrast, the young who are exposed to unbuffered stress are more likely to experience the continuing costs associated with the involvement of the amygdala.

The extent to which processes that follow early stress are reversible is unclear. In addition, it is unclear whether efforts to counteract the effects of early stress produce effects at the level of structural changes or functional changes in the brain. Francis, Diorio, Plotzky, and Meaney (2002) concluded that an enriched environment served to reverse the hormonal and fear responses that resulted from earlier stress but did not alter gluco-corticoid receptor gene expression. Others have argued that altered life experiences may indeed act back to influence gene expression in ways that reverse the effects of earlier stress (e.g., McEwen, 2001). These questions will undoubtedly stimulate considerable research in the coming years.

In summary, behavioral neuroscientists have increasingly asked about the role of molecular biology in the developing child. From this perspective, the human genome does not automatically create a working brain; instead, hormonal processes are influenced by the environment and subsequently act to foster brain development (via the activation of gene expression), which ultimately promotes the child’s social development (e.g., Brown, 1999; Schulkin, Gold, & McEwen, 1998). The promise of this field for human development (and socialization) is suggested by Brown (1999):

In child development, gene expression responds to love; security; effective role models; stimulating language and cognitive environments; a positive family environment including support, discipline, values and positive directions; and appropriate management of stress and anxiety. (p. 40)

## INTEGRATION

In reviewing the current status of the field of socialization, we have presented an integrated account that spans many aspects of developmental psychology as well as incorporating insights from other disciplines. Countering increasing specialization in the field of psychology, there has been a recent movement toward integration in and across fields. The life outcomes of the developing child have come to be viewed as situated in both the biological and social-cultural networks of the family. As one example, Dodge and Pettit (2003) provided a synthesis of studies looking at the impact of biological predispositions, sociocultural context, parenting, peers, and mental processes on chronic conduct problems in adolescence. Similarly, Repetti, Taylor, and Seeman (2002) offered a model that links risky parenting with mental and physical health disorders, showing linkages between harsh family experiences, deficits in emotional control, emotional expression and social competence, disturbances in physiologic and endocrine system regulation, and health-threatening behavior. Relevant processes begin even before birth and cross-influence each other both in adaptive and maladaptive ways to influence the mental health, social competencies, physical health, and productivity of the young.

In describing the bridges across coordinated biological systems, evolutionary psychology has suggested basic design features; developmental neuroscience has suggested potential mediators operating at the level of the central nervous system; and behavior genetics has suggested the ways in which the brain is receptive to changes in structure and function as a result of the experiences of the child. Thus, biological systems represent recursive processes that involve continuous corrections of the child’s capacities in light of changing environments. Although there are biological constraints on such flexibility, there is also considerable openness to modification. Within this flexibility arises the possibility for the benefits (or costs) that may be experienced by children as result of their socialization history. This counters an early (and limited) view of biological forces as

dictating fixed outcomes for the young as a function of individual or shared genetic endowment. As developmentalists have come to realize the fallacy of the notion of nature and nurture as competing forces, they have simultaneously come to appreciate the mutual facilitation that occurs between environment and the brain.

Just as developmentalists have come to understand the biosocial processes as recursive and integrated, they have changed in their conceptualization of the social-cultural factors that influence the outcomes of the young. In particular, there has been movement away from the view of effective socialization as involving a fixed design that has general applicability. One of the earliest questionings of this approach followed from consideration of the variations between children in temperament—and thus the socialization methods likely to be effective. Subsequently, there was a questioning of the effectiveness of different patterns of socialization across cultures. It became apparent that there were many variations possible in socialization practices and styles that lead children to live healthy, happy, productive lives in their cultural framework. Finally, increasing consideration has been given to the role of social context (or domain) in determining the differing processes that operate in socialization. In different contexts and settings (acting in the service of different goals or tasks), socialization appears to operate according to different algorithms. Such algorithms have biological, motivational, behavioral, and cognitive components that work together to facilitate the accomplishment of the relevant socialization goals or tasks.

The models used to represent socialization are shifting in ways that reflect the changing processes thought to operate. Unidirectional models (and exclusive reliance on self-report) can be expected to be replaced with bidirectional models that make use of an expanded range of dependent (and mediating) variables. In addition, the increased focus on context can be expected to lead researchers to make greater use of moderator models in which socialization outcomes are measured differentially as a function of contextual variables. In doing so, conditional models can be used to represent the circumstances under which different types of socialization processes may operate or under which different biological “switching mechanisms” may occur.

Along with changes in the ways of conceptualizing socialization, there have been corresponding changes in the variables of interest. In one direction, there has been an increasing interest in physiological processes. Many

labs concerned with socialization are exploring changes that occur in neurotransmitters and hormones and the functioning of the sympathetic-adrenal-medullary system. Concern even extends to the level of the brain and its development. New technology (e.g., functional magnetic resonance imaging) and new findings in other fields (e.g., research in molecular biology that has implications for gene expression) can be expected to expand horizons still further.

In another direction, socialization researchers now incorporate knowledge drawn from anthropology and cultural psychology to consider the differing processes and outcomes of socialization in different settings. Such explorations increase understanding not only of the diversity of experiences that foster healthy outcomes for the young but also the ways in which there is continuity across cultures in the socialization of the young. At the same time, consideration is given to the possibility that there are unhealthy societies (e.g., societies that foster extreme discrepancies in the opportunities for the young or that foster continuing stress without recovery) that limit the life experiences of the young.

Finally, the ways in which investigators in the field of socialization operate is changing. With the increasing complexity of knowledge and methodology comes the need for greater collaborative efforts across labs and across disciplines. Behavioral neuroscientists now work either to incorporate the concepts drawn from socialization theory or to collaborate with socialization researchers to bridge understanding of processes that occur across species or that differ in important ways across species. In those projects concerned with human socialization, researchers have capitalized on the opportunities for determining the outcomes of “natural experiments.” Researcher teams (as notable illustrations, Rutter and his colleagues, e.g., Rutter & O’Connor, 2004; and Gunnar and her colleagues, e.g., Gunnar, Morison, Chisholm, & Schuder, 2001) have tracked (and continue to track) the changes in life outcomes that follow from the socialization history introduced into the lives of adopted children. In conceptualizing the outcomes of children who experience adversity early in life, there are also changing expectations. The circumstances that foster later risk have expanded to consider not only the circumstances that allow resilience but also the circumstances that foster advantage or thriving.

In these changes are hopeful outlooks for social policy. As developmentalists come to understand the ways the life course of the young changes as a result of their

socialization history, doors open for ways to foster the opportunities that are available for them. National funding agencies concerned with facilitating physical and mental health have created opportunities for researchers across many disciplines to come together to consider how shared knowledge can encourage new collaborations, allow new hypotheses, and resolve puzzles that plague researchers who may acquire new insights regarding resolutions available from other fields. Finally, it becomes the obligation of such collaborative teams to inform policymakers of the possibility and feasibility of sustainable socializing environments that can be expected to optimize the life outcomes of the young.

<b>REFERENCES</b>	491

Socialization is a process in which an individual's standards, skills, motives, attitudes, and behaviors change to conform to those regarded as desirable and appropriate for his or her present and future role in any particular society. Many agents and agencies play a role in the socialization process, including family, peers, schools, and the media. Moreover, it is recognized that these various agents function together rather than independently. Families have been recognized as an early pervasive and highly influential context for socialization. Children are

dependent on families for nurturance and support from an early age, which accounts, in part, for their prominence as a socialization agent.

In this chapter, we have several goals. Our primary goal is to expand our framework for conceptualizing the family's role in socialization. This takes several forms, including treating the family as a social system in which parent-child, marital, and sibling subsystems, among others, are recognized. The diversity of family forms has increased in the past several decades and a second

---

Preparation of this chapter was facilitated by National Science Foundation grants BNS 8919391 & SBR 9308941 and

---

NICHD grant HD 32391 to Parke. Finally, thanks to Faye Harmer for her preparation of the manuscript.

goal is to explore the implications of various family configurations for the socialization process. Third, cultural and ethnic variations in family traditions, beliefs, and practices are increasingly being recognized, and a further aim of this chapter is to explore how ethnic diversity informs our understanding of family socialization. Fourth, our goal is to locate family socialization in an ecological context to appreciate how family environments shape and constrain their socialization practices. We demonstrate the value of a life-course perspective on socialization that recognizes the importance of both developmental changes in adult lives and the historical circumstances under which socialization unfolds. Finally, we recognize that families are increasingly diverse in their organization, form, and lifestyle. Some issues are beyond the scope of the chapter including the recent work on gay and lesbian families and research on adopted children (see Brodzinsky & Pinderhughes, 2002; C. Patterson, 2002, for reviews).

### **THEORETICAL APPROACHES TO SOCIALIZATION IN THE FAMILY: HISTORICAL AND CONTEMPORARY PERSPECTIVES**

In this section, we examine historical and contemporary theoretical perspectives on the role of socialization in the family.

#### **Historical Perspectives on Family Socialization Theory**

To appreciate these goals, an overview of historical changes in socialization theory is necessary. The history of this field over the past century can be traced to two theoretical perspectives: behaviorism and psychoanalysis (Maccoby, 1992). In the 1920s, Watson offered a learning theory approach to socialization, which was based on conditioning as an explanatory mechanism. This legacy continued under Skinner and followers in the behavior modification movement who applied these principles to children's behavior (Bijou & Baer, 1961).

The other legacy was Freudian psychoanalysis. Perhaps no other view has had so wide an influence—even if often unrecognized and unacknowledged—as Freudian theory. Freud's stage theory with its emphasis on the importance of early experience as a determinant

of later social and personality was a major force in socialization research for nearly half a century. Although it was difficult to test as originally formulated, the theory provided the outlines for the major socialization products, such as aggression, dependency, moral development, and sex typing, as well as the major sets of formative experiences in the family, especially the mother-child relationship.

In the 1930s, the fusion of Hullian learning theory with psychoanalysis provided the opportunity to empirically evaluate the propositions of psychoanalytic theory by translating them into drive-reduction language. This led to several renowned studies by Whiting and Child (1953) and Sears, Maccoby, and Levin (1957). As Maccoby (1992) noted, "These large scale efforts to merge psychoanalytic and behavior theory and then to predict children's personality attributes from parental socialization methods, were largely unsuccessful" (p. 1009).

The 1960s and 1970s marked the advent of further developments in socialization theory. First, social learning theory (Bandura, 1977; Bandura & Walters, 1963) emerged as an alternative to the Hullian-Freudian legacy (see Grusec, 1992). The distinguishing feature was the emphasis on imitation or observational learning, which emphasized the central role of cognition in social learning and reduced dependence on external reinforcement for the acquisition of new behaviors. In terms of method, social learning theory relied on the experimental analog approach in contrast to the retrospective interview of Sears and colleagues. Moreover, in a break with the Freudian tradition, social learning theorists placed greater emphasis on the plasticity and modifiability of the organism at different points in development and downplayed the psychoanalytically based concept of early experience as a constraining condition on later development. At the same time, the role of social contingencies in shaping parent-child interaction was receiving increased attention (Gewirtz, 1969). Studies of parent-infant interaction (e.g., Stern, 1977) and interactions of parents and children, especially aggressive and/or deviant children, were flourishing (G. Patterson, 1981).

As approaches to socialization, these theories were limited in several ways. First, they were largely nondevelopmental, and it was generally assumed that the principles applied equally to children at all ages. This is surprising in view of the increased interest in the role of cognition in social learning theory (Bandura, 1977).

Second, the role of affect was given a comparatively minor role. Third, genetic factors and biological constraints were given relatively short shrift. Fourth, the agents of socialization were still narrowly defined as primarily mothers. In the late 1960s, John Bowlby's fusion of psychoanalysis and ethology into his theory of attachment and loss foreshadowed changes that materialized in the 1970s and beyond. Concepts of biological preparedness for social interaction combined with emphasis on the importance of early close relationships served to anticipate modern concepts of biological constraints (Schaffer, 1971) and revive early notions of the importance of early experience and critical periods. Finally, Bowlby's focus on the dyad as the unit of analysis led to the recognition of the importance of *relationships* for development.

In the late 1970s to the present, a variety of changes have taken place in our theoretical approaches to socialization that have corrected some of the shortcomings of these earlier analysis and extended our frameworks into new domains as well.

### Contemporary Perspectives on Family Socialization Theory

Several themes are evident in current theoretical approaches to socialization. First, systems theory (Sameroff, 1994; Thelen & Smith, 1994) has transformed the study of socialization from a parent-child focus to an emphasis on the family as a social system (Parke, 2004a). To understand fully the nature of family relationships, it is necessary to recognize the interdependence among the roles and functions of all family members. For example, as men's roles in families shift, changes in women's roles in families must also be monitored.

Second, family members—mothers, fathers, and children—influence each other both directly and indirectly (Minuchin, 2002; Parke, Power, & Gottman, 1979). Examples of fathers' indirect impact include various ways in which fathers modify and mediate mother-child relationships. In turn, women affect their children indirectly through their husbands by modifying both the quantity and the quality of father-child interaction. Children may indirectly influence the husband-wife relationship by altering the behavior of either parent that changes the interaction between spouses.

Third, different units of analysis are necessary to understand families. Although the individual—child,

mother, and father—remains a useful level of analysis, recognition of relationships among family members as units of analysis is necessary. The marital relationship, the mother-child relationship, and the father-child relationship require separate analysis (Parke et al., 2001). Finally, the family as a unit that is independent of the individual or dyads in the family requires recognition (Cook, 2001; Sigel & Parke, 1987).

A fourth shift is from unidirectional to transactional models of relationships among family members. There have been various phases in the conceptual thinking in this domain. First, scholars traditionally were guided by unilateral models of parent-child relations (Kuczynski, 2003) in which the direction of causality was unidirectional, from parent to child. The child's role was relatively passive, the focus was on individuals rather than relationships, and power relations were relatively static. In addition, the mother rather than either the father or other family members was the major focus of both theoretical and empirical work.

In the 1960s with Bell's (1968) classic reformulation, the field began to recognize the bidirectional nature of parent-child relationships. This shift occurred in a climate of reevaluation of infant competence; instead of the passive creatures of earlier times, infants and children were viewed as more competent and active in their own development. A bilateral model has emerged as the dominant paradigm in the parent-child relationship domain (Kuczynski, 2003) in which the direction of causality is bidirectional, equal agency on the part of parent and child is recognized, and power relations are characterized as "interdependent asymmetry."

At the same time, views of the pathways through which parents can influence their children expanded. Historically, socialization models directed attention toward the nature of the parent-child relationship and the types of child-rearing practices that parents employ. Research on infant-parent attachment and on parenting styles exemplifies this tradition. More recently, views of parenting have expanded to include parents as active managers of the child's social environment outside the family. In this role, a parent actively regulates the child's access to physical and social resources outside the family (Parke, Killian, et al., 2003) and serves as regulator of opportunities for social contact with extrafamilial social partners. Although peer influence increases as children develop, parents continue to play an important regulatory role as gatekeepers and monitors

of children's social contacts, even in adolescence (Mounts, 2000). However, recent thinking has recognized that in the managerial domain, as in other parts of the parent-child relationship, both children and parents play active roles in decisions about children's social opportunities (Kerr & Stattin, 2000).

Fifth, under the influence of Bronfenbrenner's ecological theory (1989), recognition is being given to the embeddedness of families in other social systems as well as the cultures in which they exist (Parke & Kellam, 1994). These include a range of extrafamilial influences, such as extended families, and informal community ties such as friends and neighbors, work sites, and social, educational, and medical institutions (Repetti, 1994).

Sixth, the importance of considering family relationships from a developmental perspective is now recognized. Although developmental changes in infant and child capacities continue to represent the most commonly investigated aspect of development, other aspects of development are viewed as important too. Under the influence of life-course and life-span perspectives (Elder, 1998; Parke, 1988), examination of developmental changes in adults is gaining recognition because parents continue to change and develop during adult years. For example, age at the onset of parenthood has implications for how females and males manage their parental roles. This involves an exploration of the tasks faced by adults such as self-identity, education, and career, and an examination of the relation between these tasks and parenting.

Developmental analysis need not be restricted to the individual level—either child or parent. Relationships (e.g., the marital, the mother-child, or the father-child relationship) may follow separate and partially independent developmental courses over childhood (Parke, 1988). In turn, the mutual impact of different sets of relationships on each other will vary as a function of the nature of the developmental trajectory. Families change their structure (e.g., through the addition of a new child or the loss of a member through death or divorce), norms, rules, and strategies over time. Tracking the family unit itself over development is an important and neglected task (Cook, 2001).

A major shift over the past 2 decades is the challenge to the universality of our socialization theories. This challenge takes several forms. First, as cross-cultural work in development accumulated, it became evident that generalizations from a single culture (e.g., American) may not be valid in other cultural

contexts (Rogoff, 2003). Second, social class differences in socialization challenged the generality of findings even in one cultural or national context (Gauvain, 2001; Hoff, Laursen, & Tardif, 2002). Currently, there is an increased awareness of the importance of both recognizing *and* studying variations in families and family socialization strategies in both other cultures (Rogoff, 2003) and across ethnic groups in our own culture (Parke, 2004b). It is important not only to examine the diversity of familial organization, goals, and strategies *across* ethnic groups but it is equally critical to explore variations *within* different ethnic groups (Garcia Coll & Magnuson, 1999; Parke, 2004b). Although there are many similarities across and within groups, appreciation of the variations is of central concern.

Another assumption that guides current theorizing involves the recognition of the impact of secular shifts on families. In recent years, there have been a variety of social changes in American society that have had a profound impact on families including the decline in fertility and family size, changes in the timing of the onset of parenthood, increased participation of women in the workforce, rise in the rates of divorce, and the subsequent increase in the number of single-parent families as well as remarried step families (Elder, 1998; Hetherington & Kelly, 2001). The ways in which these societal changes impact relationships between parents and children merit examination.

A related theme involves the recognition of the importance of the historical time period in which the family interaction is embedded. Historical time periods provide the social conditions for individual and family transitions: Examples include the 1960s (the Vietnam War era), the 1930s (the Great Depression), or the 1980s (Farm Belt Depression; Conger & Elder, 1994; Elder & Conger, 2000). Across these periods, family interaction may be quite different due to the unique conditions of the era. The distinctions among different developmental trajectories, as well as social change and historical period effects, are important because these different forms of change do not always harmonize (Modell & Elder, 2002). For example, a family event such as the birth of a child may have profound effects on a man who has just begun a career in contrast to the effects on one who has advanced to a stable occupational position. Moreover, individual and family developmental trajectories are embedded in both the social conditions and the values of the histor-

ical time in which they exist. The role of parents, as is the case with any social role, is responsive to such fluctuations.

To understand the nature of parent-child relationships in families, a multilevel and dynamic approach is required. Multiple levels of analysis are necessary to capture the individual, dyadic, and family unit aspects of operation in the family itself, and to reflect the embeddedness of families in a variety of extrafamilial social systems. The dynamic quality reflects the multiple developmental trajectories that warrant consideration in understanding the nature of families.

The central processes that are involved in accounting for *both* the choice of and regulation of socialization strategies and the effects of socialization on the developing child have undergone a major revision (see Bugental & Grusec, Chapter 7, this *Handbook*, this volume). The renewed interest in the biological bases of behavior has clearly altered our views of socialization. This interest takes several forms including the role of genetics across development, which has produced not only a more sophisticated understanding of the potential role genetics can play in the onset of certain behaviors but also in the unfolding of behavior across development. Moreover, the reformulation of genetic questions has led to studies of the effects of nonshared family environment on children's development (O'Connor, 2003). Finally, this work has suggested that individual differences between children—some of which are genetically based—play a central role in eliciting and shaping parent's socialization strategies (recognition that the child is an active contributor to his or her own socialization). A second focus is found in studies of hormones and behavior, especially during infancy and adolescence (Corter & Fleming, 2002). Third, the increased use of psychophysiological assessments with families represents a further instance of how biological processes are changing socialization studies (Eisenberg, 2000). Fourth, the resurgence of interest in evolutionary approaches to socialization is producing new and provocative hypotheses and research directions (Geary & Bjorklund, 2000).

Affect is increasingly viewed as a central socialization process. The study of affect has assumed a variety of forms, including the development of emotion regulation (Denham, 1998), emotional production, and understanding of the role of emotion in the enactment of the parenting role (Dix, 1991). Cognition is also viewed as central to socialization. Again the role

of cognition comes in many guises, including the child's own cognitive capacities as a determinant of socialization strategies and parents' cognitions, beliefs, values, and goals, concerning their parental role as constraints on their socialization practices (Dix & Branca, 2003). Equally important is the recognition of the importance of the ways in which parents perceive, organize, and understand their children's behaviors and beliefs for appreciating how parent-child relationships are regulated and change (Goodnow, 2002). Underlying much of current research is the recognition that these processes are interdependent, mutually influencing each other. Cognition and affect for example, generally operate together in determining parenting practices (e.g., Dix, 1991; Dix & Branca, 2003).

Just as processes are viewed as interdependent, there is an increasing appreciation of the need for perspectives from a variety of disciplines to understand the family socialization process. No longer restricted to developmental psychology, the field of family socialization is increasingly multidisciplinary. History, anthropology, sociology, demography, pediatrics, psychiatry, and economics are all fields that are playing a role in the study of socialization (Parke, 2004b).

Finally, the methodological rigor of the field has increased in recent years. Instead of sole reliance on cross-sectional and/or correlational studies, greater weight is being given to carefully designed longitudinal studies (Gottfried, Gottfried, & Bathurst, 2002) and experimental studies (Cowan & Cowan, 2002) because these approaches allow more confidence in interpreting direction of effects. Second, more recent studies typically avoid the problems of shared method or reporter variance by reliance on either multiple reporters and/or multiple methods. Third, in view of the challenges from other fields, such as behavior genetics (Harris, 1998; Plomin, 1994), there is increasing recognition of rival explanations of apparent socialization effects. Both shared genetic effects and contextual influences are commonly viewed as alternative perspectives that merit consideration in explaining socialization outcomes. Finally, there is a clear trend to move beyond description by the emergence of theories that specify the mediating variables that can account for the relation between parenting and child outcomes (Parke et al., 2004). Closely related is the recognition of moderating influences, such as social context, ethnicity, or family structure on the operation of socialization processes (Mounts, 2002). Throughout our

review, we focus on work that meets these new standards of scientific rigor whenever possible.

### FAMILY SYSTEMS APPROACH TO SOCIALIZATION

Consistent with a family systems viewpoint, recent research has focused on a variety of subsystems, including parent-child, marital, and sibling-sibling systems. In the next several sections, we focus on each of these subsystems as contexts for socialization. Finally, we examine recent attempts to conceptualize the family as a unit of analysis.

#### The Parent-Child Subsystem: A Tripartite Approach

In this section, we consider the parent-child subsystem and the relation between this parent-child subsystem and children's social adaptation. Although it has been common in traditional paradigms to focus on the impact of the parent-child relationship or parental child-rearing styles, according to the Parke, Burks, Carson, Neville, and Boyum tripartite model (1994), this represents only one pathway (see Figure 8.1).

In this case, the goal of parent-child interaction is not explicitly to modify or enhance children's relationships with extrafamilial social partners. In addition, this scheme posits that parents may influence their children through a second pathway namely as direct instructor, educator, or consultant. In this role, parents may explic-

itly set out to educate their children concerning appropriate norms, rules, and mores of the culture. This second socialization pathway may take a variety of forms. Parents may serve as coaches, teachers, and supervisors as they provide advice, support, and directions about strategies for managing new social situations or negotiating social challenges. In a third role, parents function as managers of their children's social lives and serve as regulators of opportunities for social contacts and cognitive experiences. Researchers have begun to recognize the managerial function of parents and to appreciate the impact of variations in how this managerial function influences child development (Parke, Killian, et al., 2003). By managerial, we refer to the ways in which parents organize and arrange the child's home environment and the opportunities for social contact with playmates and socializing agents outside the family. Although the model has been largely applied to the issue of family peer relationships, it is useful for explaining a wide range of socialization outcomes such as gender roles and aggression (see S. McHale, Crouter, & Whiteman, 2003, for an application to gender roles).

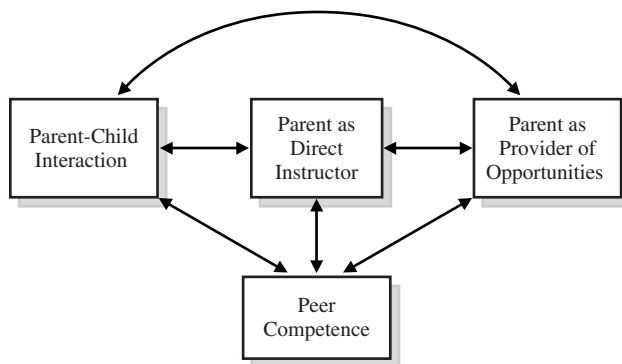

#### Parent-Child Relationships: Interaction and Child-Rearing Styles

In this section, we consider descriptive studies of differences in both the quantity of mother versus father involvement with their children and qualitative differences in styles of interaction. Then, we explore the implications of parent-child interactive style and level of involvement for children's socialization outcomes.

Not all forms of parental involvement are conceptually equivalent. Lamb, Pleck, and Levine (1985) have distinguished various types of parental involvement: interaction, availability, and responsibility (see Lamb, 2004). Each is further defined as follows:

Interaction refers to the parents direct contact with his child through caregiving and shared activities. Availability is a related concept concerning the child's potential availability for interaction, by virtue of being present or accessible to the child whether or not direct interaction is occurring. Responsibility refers to the role the parent takes in ascertaining that the child is taken care of and arranging for resources to be available for the child. (Lamb et al., 1985, p. 125)

Several further distinctions have been offered. Specifically, it is important to distinguish involvement in child-care activities and involvement in play, leisure, or

**Figure 8.1** A tripartite model of family-peer relationships. (Adapted from "Family-Peer Relationships: A Tripartite Model" (pp. 115–145), in *Exploring Family Relationships with Other Social Contexts: Family Research Consortium—Advances in Family Research*, R. D. Parke, V. M. Burks, J. V. Carson, B. Neville, and L. A. Boyum, 1994, In R. D. Parke & S. Kellam (Eds.), (pp. 115–145). Hillsdale, NJ: Erlbaum.

affiliative activities with the child because there are different determinants of these two types of parental involvement. Absolute and relative involvement need to be distinguished because prior work suggests that these indices are independent and may affect both children's and adults' views of role distributions in different ways (Pleck & Masciadrelli, 2004).

### ***Quantitative Assessments of Mother and Father Involvement in Intact Families***

Despite current shifts in cultural attitudes concerning the appropriateness and desirability of shared roles and equal levels of participation in routine caregiving and interaction for mothers and fathers, the shifts toward parity are small but nonetheless real in the majority of intact families. Fathers spend less time with their infants and children than mothers (Pleck & Masciadrelli, 2004) not only in the United States but also in other countries such as Great Britain, Australia, France, Belgium, and Japan (Zuzanek, 2000). Mothers and fathers differ in the amount of time that they spend in actual interaction with their children. Pleck and Masciadrelli (2004) document that fathers' involvement has increased, even if slowly. Compared to the 1970s, proportional engagement (relative to mothers) was about 33%, whereas accessibility was approximately 50%. In contrast, recent estimates for the 1990s suggest that proportional engagement increased to approximately 70%, whereas accessibility was over 70%.

Studies of African American and Hispanic-American families confirm the pattern found for European Americans. Middle-class and lower-class African American and Latino fathers were less involved in caregiving with their infants than mothers (Roopnarine, 2004; Roopnarine, Fouts, Lamb, & Lewis-Elligan, 2005). Comparisons across ethnic groups (African, Hispanic, and European American) revealed few differences in the level of father involvement (Yeung, Sandberg, Davis-Kean, & Hofferth, 2001). These findings are important given past negative characterizations of low-income African American and Hispanic American fathers as uninvolved. The stereotype surrounding fathers of different ethnic backgrounds needs to be discarded as inaccurate and outdated (Roopnarine, 2004). Much of the earlier work was based on single-parent families and failed to recognize differences within cultural groups.

The pattern of contact time between mothers and fathers with their children in infancy continues into middle childhood and adolescence (Collins & Madsen,

2003). In middle childhood (6- to 7-year-olds), Russell and Russell (1987) found that Australian mothers were available to children 54.7 hours/week compared to 34.6 hours/week for fathers. Mothers also spent more time alone with children (22.6 hours/week) than did fathers (2.4 hours/week). However, when both parents and child were together, mothers and fathers initiated interactions with children with equal frequency and children's initiations toward each parent were similar. Adolescents spend less time with their parents than younger children and less time alone with their fathers than their mothers (Larson & Richards, 1994). From infancy through adolescence, mothers and fathers clearly differ in their degree of involvement with their children.

**Qualitative Effects: Stylistic Differences in Mother and Father Interaction.** Fathers participate less than mothers in caregiving but spend a greater percentage of the time available for interaction in play activities than mothers do. In North American families, fathers regardless of ethnicity (European American, African American, or Hispanic American) spent a greater percentage of their time with their infants in play than mothers, although in absolute terms mothers spent more time than fathers in play with their children (Yeung et al., 2001). The quality of play across mothers and fathers differs, too. For young infants, older infants, and toddlers, fathers play more physically arousing games than mothers. In contrast, mothers played more conventional motor games or toy-mediated activities and were more verbal and didactic (Parke, 1996, 2002).

Nor are these effects evident only in infancy. MacDonald and Parke (1984) found that fathers engaged in more physical play with their 3- and 4-year-old children than mothers, whereas mothers engaged in more object-mediated play than fathers. According to a survey (MacDonald & Parke, 1986), fathers' distinctive role as a physical play partner changes with age. Physical play was highest between fathers and 2-year-olds, and between 2 and 10 years of age, there is a decrease in father-child physical play.

Despite the decline in physical play across age, fathers remain more physical in their play than mothers. In an Australian study of parents and their 6- to 7-year-old children (Russell & Russell, 1987), fathers were more involved in physical/outdoor play interactions and fixing things around the house and garden than mothers. In contrast, mothers were more actively involved in caregiving and household tasks, school work, reading,

playing with toys, and helping with arts and crafts. In adolescence, the quality of maternal and paternal involvement continues to differ. Just as in earlier developmental periods, mothers and fathers may complement each other and provide models that reflect the tasks of adolescence—connectedness and separateness. Evidence suggests that fathers may help adolescents develop their own sense of identity and autonomy by being more peer-like and more playful (e.g., joking and teasing), which is likely to promote more equal and egalitarian exchanges. “Fathers, more than mothers conveyed the feeling that they can rely on their adolescents, thus fathers might serve as a ‘facilitating environment’ for adolescent attainment of differentiation from the family and consolidation of independence” (Shulman & Klein, 1993, p. 53). Although the style of fathers’ involvement as a play or recreational partner appears to have reasonable continuity from infancy through adolescence, the meaning and function of this interaction style shifts across development. The positive affect associated with fathers’ play in infancy is not as evident in adolescence, although other goals of this age period may be facilitated by this more playful egalitarian style.

A word of caution is in order because fathers in several other cultures do not show this physical play style. In some cultures that are similar to U.S. culture, such as England and Australia, there are similar parental sex differences in play style. In contrast, findings from several other cultures do not find that physical play is a central part of the father-infant relationship (Roopnarine, 2004). Neither Swedish nor Israeli kibbutz fathers were more likely to play with their children or to engage in different types of play (Hwang, 1987). Similarly, Chinese Malaysian, Indian, and Aka pygmy (Central Africa) mothers and fathers rarely engaged in physical play with their children (Hewlett, 2004; Roopnarine, 2004). Instead, both display affection and engage in plenty of close physical contact. In other cultures, such as Italy, neither mothers nor fathers but, instead, other women in the extended family or in the community were likely to play physically with infants (New & Benigni, 1987).

Why do mothers and fathers play differently? Both biological and environment factors probably play a role. Experience with infants, the amount of time spent with infants, the usual kinds of responsibilities that a parent assumes—all of these factors influence the parents’ style of play. The fact that fathers spend less time with infants and children than mothers may contribute as well. Fathers may use their distinctive arousing style as a way to in-

crease their salience despite more limited time. Biological factors cannot be ignored given that male monkeys show the same rough-and-tumble physical style of play as American human fathers and tend to respond more positively to bids for rough-and-tumble play than females (Parke & Suomi, 1981). “Perhaps [both monkey and human] males may be more susceptible to being aroused into states of positive excitement and unpredictability than females” (Maccoby, 1988, p. 761)—speculation that is consistent with gender differences in risk taking and sensation seeking. In addition, human males, whether boys or men, tend to behave more boisterously and show more positive emotional expression and reactions than females (Maccoby, 1998). Together these threads of the puzzle suggest that predisposing biological differences between males and females may play a role in the play patterns of mothers and fathers. Yet, the cross-cultural data underscore the ways in which cultural and environmental contexts shape play patterns of parents and remind us of the high degree of plasticity of human social behaviors.

**Parent-Child Interaction and Children’s Adaptation.** Two approaches to this issue of the impact of parent-child interaction on children’s socialization outcomes have been utilized in recent research. Some have adopted a typological approach and examined styles or types of child-rearing practices (Baumrind, 1973). Others have adopted a social interaction approach by focusing on the nature of the interchanges between parent and child (G. Patterson, 2002).

*The Typological Approach.* Perhaps the most influential typology has been offered by Baumrind (1973) who distinguished between three types of parental child-rearing typologies. She found that *authoritative* but not *authoritarian* or overly *permissive* behavior by parents led to positive emotional, social, and cognitive development in children. Baumrind has followed her authoritarian, authoritative, and permissive parents and their children from the preschool period through adolescence in a longitudinal study (Baumrind, 1991). She found that authoritative parenting continued to be associated with positive outcomes for adolescents as with younger children and that responsive, firm parent-child relationships were especially important in the development of competence in sons. Moreover, authoritarian child rearing had more negative long-term outcomes for boys than for girls. Sons of authoritarian parents were low in both cognitive and social competence. Their academic and

intellectual performance was poor. In addition, they were unfriendly and lacking in initiative, leadership, and self-confidence in their relations with their peers.

Maccoby and Martin (1983) extended the Baumrind typology based on combinations of the warm/responsive, unresponsive/rejecting dimension and the restrictive/demanding, permissive/undemanding dimension and included a fourth type of parenting style, which is characterized by neglect and lack of involvement. These are *disengaged* parents who are “motivated to do whatever is necessary to minimize the costs in time and effort of interaction with child” (Maccoby & Martin, 1983). Such parents are motivated to keep the child at a distance and focus on their own needs rather than the needs of the child. They are parent centered rather than child centered. With older children, this is associated with the parents’ failure to monitor the child’s activity or to know where the child is, what the child is doing, and who the child’s companions are. In infants, such a lack of parental involvement is associated with disruptions in attachment; in older children, it is associated with impulsivity, aggression, noncompliance, moodiness, and low self-esteem (Baumrind, 1991). Older children also show disruptions in peer relations and in cognitive development, achievement, and school performance (Hetherington & Clingempeel, 1992). It is the combined impact of not having the skills to be able to gain gratification in either social or academic pursuits that frequently leads to delinquency in children with neglecting parents (Reid, Patterson, & Snyder, 2002). Parental involvement plays an important role in the development of both social and cognitive competence in children.

*The Status of the Typological Approach.* A major concern about the focus on parental style is the limited attention to the delineation of the processes that account for the effects of different styles on children’s development. Throughout the history of socialization research, there has been a tension between molar and molecular levels of analysis. Over the past 3 decades, the pendulum has swung back and forth between these levels of analysis. Currently, these two strands of research coexist and are seldom united in a single study. On the molecular side, the work of G. Patterson (2002), and Gottman (1994) can be cited. On the molar side, the search for typological answers to parenting style continues (Baumrind, 1991; Steinberg, Dornbusch, & Brown, 1992). Some exceptions can be noted. For example, Hetherington and Clingempeel (1992) have used both parenting style in combination with sequential analyses of chil-

dren’s levels of compliance to parental control, which is a useful bridging of the two levels of analyses.

In an attempt to resolve this issue, Darling and Steinberg (1993) have argued that parental style and parental practices need to be distinguished. Parenting style is “a constellation of attitudes toward the child that are communicated to the child and create an emotional climate in which parents’ behaviors are expressed” (p. 493). In contrast to style, “parenting practices are behaviors defined by specific content and socialization goals” (p. 492). These authors cite attending school functions and spanking as examples of parenting practices. Style is assumed to be independent of both the content of parenting behavior and the specific socialization content. Critical to their model is the assumption that parenting style has its impact on child outcomes indirectly. First, style transforms the nature of parent-child interaction and thereby moderates the impact of specific practices. Second, they posit that style modifies the child’s openness to parental influence, which, in turn, moderates the association between parenting practices and child outcomes.

A second concern focuses on the issue of direction of effects. It is unclear whether the styles described by Baumrind are, in part, in response to the child’s behavior. Placing the typology work in a transactional framework (Sameroff, 1994) would argue that children with certain temperaments and/or behavioral characteristics would determine the nature of the parental style.

A third concern is the universality of the typological scheme. Recent studies have raised serious questions about the generalizability of these styles across either socioeconomic status (SES) or ethnic/cultural groups. Two issues are involved here. First, does the rate of utilization of different styles vary across groups? Second, are the advantages of positive social outcomes associated with a particular style (e.g., authoritative) similar across groups? The answer to both questions seems to be negative. In lower-SES families, parents are more likely to use an authoritarian as opposed to an authoritative style, but this style is often an adaptation to the ecological conditions, such as increased danger and threat, which may characterize the lives of poor families (Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999). Moreover, studies find that the use of authoritarian strategies under these circumstances may be linked with more positive outcomes for children (Baldwin, Baldwin, & Cole, 1990). A second challenge to the presumed universal advantage of authoritative child-rearing styles comes from cross-ethnic studies.

Accumulating evidence underscores the nonuniversality of these stylistic distinctions and suggests the importance of developing concepts that are based on an indigenous appreciation of the culture in question (R. K. Chao, 1994). In summary, it is evident that contextual and cultural considerations need more attention in typological approaches to child rearing.

**The Parent-Child Interactional Approach.** Research in this tradition is based on the assumption that face-to-face interaction with parents may provide the opportunity to learn, rehearse, and refine social skills that are common to successful social interaction with other social partners. This work has yielded several conclusions. First, the style of the interaction between parent and child is linked to a variety of social outcomes including aggression, achievement, and moral development. To illustrate this approach, studies of children's social competence are considered. Recent studies have found that parents who are responsive, warm, and engaging are more likely to have children who are more socially competent (Grimes, Klein, & Putallaz, 2004). Moreover, high levels of positive synchrony and low levels of nonsynchrony in patterns of mother-child interaction are related to school adjustment rated by teachers, peers, and observers (Harrist, Pettit, Dodge, & Bates, 1994). In contrast, parents who are hostile and controlling have children who experience more difficulty with age-mates in the preschool period (Harrist et al., 1994) and middle childhood.

Evidence suggests that family interaction patterns not only relate to concurrent peer relationships but also predict peer relationships across time. In their study of third grade children, Henggeler, Edwards, Cohen, and Summerville (1992) found that children of fathers who were responsive to their children's requests became more popular over the school year than children of less responsive fathers. Similarly, J. Barth and Parke (1993) found that parents who were better able to sustain their children in play predicted better subsequent adaptation to kindergarten.

Although there is an overlap between mothers and fathers, evidence is emerging that fathers make a unique and independent contribution to their children's social development. Studies (Hart et al., 1998; Isley, O'Neil, & Parke, 1996) have shown that fathers continue to contribute to children's social behavior with peers—after accounting for the mothers' contribution. Although father involvement is quantitatively less than mother involvement, fathers have an important impact on their

offspring's development. Quality rather than quantity of parent-child interaction is the important predictor of cognitive and social development.

Differences in interactive style associated with children's social competence and the emotional displays during parent-child interaction are important. The affective quality of the interactions of popular children and their parents differs from the interactions of rejected children and their parents (Parke, Cassidy, Burks, Carson, & Boyum, 1992). Consistently higher levels of positive affect have been found in both parents and children in popular dyads than in the rejected dyads. Negative parental affect is associated with lower levels of peer acceptance (Isley et al., 1996, 1999): Carson and Parke (1996) found that children of fathers who are likely to respond to their children's negative affect displays with negative affect of their own are less socially skilled (e.g., less altruistic, more avoidant, and more aggressive) than their preschool classmates. The results for the reciprocity of negative affect were evident only for fathers, which suggests that men may play a particularly salient role in children's learning how to manage negative emotions in the contexts of social interactions. Boyum and Parke (1995) confirmed the importance of parental negative affect for children's social development but demonstrated that father anger is a particularly salient predictor of children's social acceptance by peers. Less accepted children were likely to receive angry affect from their fathers during observations of family dinner. This finding underscores the importance of distinguishing among specific affective displays rather than reliance on categories of negative or positive emotions.

Together these findings lead to a revision in traditional thinking about the ways that mothers and fathers influence their children's development. This work suggests that fathers may play a larger role in socialization of children's emotion than earlier theories suggested. And it is through the management of their own emotions and their reactions to their children's emotions that fathers may have their greatest impact on their children's social relationships with peers and friends. In summary, both the nature of parent-child interaction and affective quality of the relationship are important correlates of children's social development.

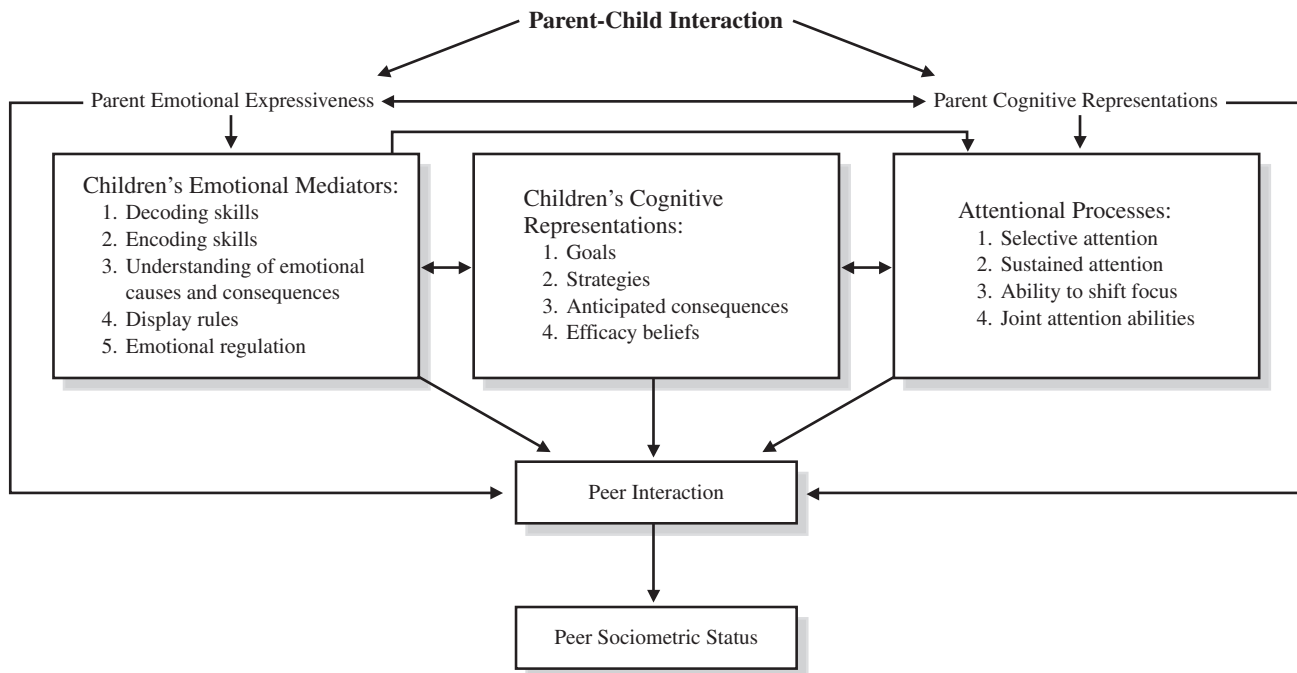

**Beyond Description: Processes Mediating the Relations between Parent-Child Interaction and Children's Social Competence.** A variety of processes have been hypothesized as mediators between parent-

child interaction and peer outcomes. These include emotion-encoding and emotion-decoding skills, emotional regulatory skills, cognitive representations, attributions and beliefs, and problem-solving skills and attention-deployment abilities (Eisenberg, 2000; Ladd, 1992; Parke, McDowell, Kim, & Leidy, 2006; Parke & O'Neil, 1999). These abilities or beliefs are acquired in parent-child interchanges during development and, in turn, guide the nature of children's behavior with their peers. We focus on three sets of processes that seem particularly promising candidates for mediator status: (1) affect-management skills, (2) cognitive representational processes, and (3) attention regulatory processes (see Figure 8.2).

**Affect-Management Skills as a Mediating Mechanism.** Children learn more than specific affective expressions, such as anger or sadness or joy, in the family. They learn a cluster of processes associated with the understanding and regulation of affective displays, which we term *affect-management skills* (Parke, Cassidy, Burks, Carson, & Boyum, 1992). These skills are acquired during the course of parent-child interaction and are available to the child for use in other relationships. Moreover, it is assumed that these skills play a mediating role between family and children's social competence.

One set of skills that is relevant to successful peer interaction and may, in part, be acquired in the context of parent-child play, especially arousing physical play, is the ability to clearly encode emotional signals and to decode others' emotional states. Through physically playful interaction with their parents, especially fathers, children may be learning how to use emotional signals to regulate the social behavior of others. In addition, they may learn to accurately decode the social and emotional signals of other social partners. Several studies have found positive relations between children's ability to encode emotional expressions and children's social competence with peers (Halberstadt, Denham, & Dunsmore, 2001). Successful peer interaction requires not only the ability to recognize and produce emotions but also a social understanding of emotion-related experiences, of the meaning of emotions, of the cause of emotions, and of the responses appropriate to others' emotions. Cassidy, Parke, Butkovsky, and Braungart (1992), in a study of 5- and 6-year-old children, found that a higher level of peer acceptance was associated with greater (a) ability to identify emotions, (b) acknowledgment of experiencing emotion, (c) ability to describe appropriate causes of emotions, and (d) expectations that they and their parents would respond appropriately to the display of emotions. Family emotional expressiveness—an index of the extent to which family

**Figure 8.2** Emotional, cognitive, and attentional mediating links between family and peer systems.

members express emotion in the course of everyday interaction—has emerged as a further link between family and peer systems, providing guidelines for the use of emotion in ongoing social interchanges. The expressiveness concept extends emotional learning beyond the acquisition of specific skills, such as encoding or decoding, to the utilization of rules about emotion in multiple contexts (Halberstadt et al., 2001). Several studies have found cross-generational similarities between mother's (Denham, 1998), father's (Boyum & Parke, 1995), and children's levels of expressiveness. Consistent with the assumption that expressiveness is learned in the family and that children transfer their expressive style to their interactions with others outside the family, several studies (Boyum & Parke, 1995; Cassidy et al., 1992) found links between family expressiveness and peer competence. These studies suggest that family emotional expressiveness may be one pathway by which children learn to understand and express their emotions in a socially appropriate manner.

**Emotional Regulation.** Research suggests that parental support and acceptance of children's emotions is related to children's ability to manage emotions in a constructive fashion. Several investigators (Eisenberg, 2000; Eisenberg & Fabes, 1992; Parke et al., 2006) have found links between the ability to regulate emotional arousal and social competence. Similarly, children who either have limited knowledge of emotional display rules (Saarni, 1999) or are poor at utilizing display rules are less well accepted by their peers (McDowell, O'Neil, & Parke, 2000; McDowell & Parke, 2000). Parental comforting of children when they experience negative emotion has been linked with constructive anger reactions (Eisenberg & Fabes, 1994). Moreover, children's emotional regulation and their knowledge and affective display rule utilization are linked with high positive parental affect and low levels of parental control (McDowell & Parke, 2000, 2005; McDowell et al., 2000). In addition, parental willingness to discuss emotions with their children is related to children's awareness and understanding of others' emotions (Denham, Cook, & Zoller, 1992; Dunn & Brown, 1994). Eisenberg, Fabes, Schaller, and Miller (1991) found that parental emphasis on direct problem solving was associated with sons' sympathy, whereas restrictiveness in regard to expressing one's own negative emotions was associated with sons' physiological and facial indicators of personal distress. These findings are consistent with work by

Gottman, Katz, and Hooven (1997) on parents' meta-emotion. By *meta-emotion* these researchers refer to parents' emotions about their own and their children's emotions, and *meta-cognitive structure* refers to an organized set of thoughts, a philosophy, and an approach to one's own emotions and to one's children's emotions. Gottman et al. (1997), in a longitudinal analysis, found that fathers' acceptance and assistance with children's sadness and anger at 5 years of age was related to their children's social competence with peers at 8 years of age. Moreover, fathers' assistance with anger predicted academic achievement. The gender of child influenced these relationships: When fathers help daughters with sadness, the daughters are rated as more competent by their teachers. When fathers help their daughters regulate anger, girls are rated as more socially competent by their teachers, show higher academic achievement, and their dyadic interaction with a best friend is less negative. Fathers who are more accepting of their sons' anger and assist them in regulating anger have sons who are less aggressive.

Together, these studies suggest that various aspects of emotional development—encoding, decoding, cognitive understanding, and emotional regulation—play an important role in accounting for variations in peer competence. Our argument is that these aspects of emotion may be learned in the context of family interaction and serve as mediators between the parents and peers. At the same time, the contribution of genetics to individual differences in emotionality and emotional regulation probably plays a role in the emergence of these emotional processes (Eisenberg, 2000; Kochanska, 1993). Finally, the direction of effects remains unclear in these relations; probably both parent and child mutually influence each other in the development of affect-management skills.

**Cognitive Representational Models: A Second Mediator between Parents and Peers.** One of the problems facing the area of family peer relationships is how children transfer the strategies they acquire in the family to their peer relationships. Several theories assume that individuals possess internal mental representations that guide their social behavior. Attachment theorists offer working models (Bretherton & Munholland, 1999), whereas social and cognitive psychologists have suggested scripts or cognitive maps that could serve as a guide for social action (Grusec & Ungerer, 2003).

Attachment researchers have found support for Bowlby's argument that representations vary as a func-

tion of child-parent attachment history (see Bretherton & Munholland, 1999). For example, children who had been securely attached infants were more likely to represent their family in their drawings in a coherent manner, with a balance between individuality and connection, than were children who had been insecurely attached (Carlson, Sroufe, & Egeland, 2004).

Research in a social interactional tradition reveals links between parent and child cognitive representations of social relationships. Burks and Parke (1996) found some evidence for similarities between children and mothers in their goals, attributions, and anticipated consequences when they responded to a series of hypothetical social dilemmas. This study suggests that children may learn cognitive representational schemes through their family relationships, although the precise mechanism through which these schemas are acquired is not yet specified.

Next, we turn to an examination of the hypothesis that parents of children of different sociometric status differ in their cognitive models of social relationships. Several aspects of cognitive models including attributions, perceptions, values, goals, and strategies have been explored. Pettit, Dodge, and Brown (1988) found that mothers' attributional biases concerning their children's behavior (e.g., the extent to which they view an ambiguous provocation as hostile or benign) and the endorsement of aggression as a solution to interpersonal problems were related to children's interpersonal problem-solving skill that was related to their social competence. Other evidence suggests that parents hold different patterns of beliefs about problematic social behaviors such as aggression and withdrawal and that these patterns are associated with their children's membership in various sociometric status groups (Rubin & Mills, 1990). This work suggests that parents do have a set of beliefs concerning children's social behavior that may, in part, govern their behavior (Goodnow, 2002; Parke, 1978).

MacKinnon-Lewis and her colleagues (1994) found that mothers' and sons' hostile attributions were significantly related to the coerciveness of their interactions. Moreover, mothers' attributions were related to reports of their children's aggression in their classrooms. Similarly, Rubin, Mills, and Rose-Krasnor (1989) found a link between mothers' beliefs and their preschoolers' social problem-solving behavior in the classroom. Mothers who placed higher values on skills, such as making friends, sharing with others, and leading or influencing

other children, had children who were more assertive, prosocial, and competent social problem solvers.

McDowell, Parke, and Spitzer (2002) explored the links between parent and child cognitive representations of social relationships. Parents and their children responded to vignettes reflecting interpersonal dilemmas by indicating how they may react in each situation. Open-ended responses were coded for goals, causes, strategies, and advice. The cognitive representations of social behavior of both fathers and mothers were related to their children's representations. Moreover, fathers' but not mothers' cognitive models of relationships were linked to children's social competence. Fathers' strategies that were related high on confrontation and instrumental qualities were associated with low teacher ratings of children's social competence. Fathers with relational-prosocial goals have children who are rated as more competent by both teachers and peers. Perhaps fathers are more influential in conflict-laden domains, whereas mothers are more influential in social domains involving personal and relationship issues. These data suggest that fathers' cognitive representations of social relationships are important correlates of children's social competence.

Together, these studies suggest that cognitive models of relationships may be transmitted across generations and these models, in turn, may serve as mediators between family contexts and children's relationships with others outside of the family. Finally, this work implies that *both* children and parents actively construct their own dyadic relationships and other social relationships. Moreover, both are influenced in their behavior with each other by these cognitive constructions. One issue that needs more attention is how child and adult constructions change across development and how the pattern of mutual influence between parent and child changes as the child develops (Kuczynski, 2003; Macoby, 1992). Coordination and coregulation rather than simply a bidirectional pattern of influence probably increasingly characterizes the parent-child relationship in middle childhood and adolescence.

**Attention Regulation: A Third Mediating Mechanism.** In concert with emotional processes, attentional regulatory processes have come to be viewed as another mechanism through which familial socialization experiences may influence children's social competence. These processes include the ability to attend to relevant cues, to sustain attention, to refocus attention

through such processes as cognitive distraction and cognitive restructuring, and other efforts to purposefully reduce the level of emotional arousal in a situation that is appraised as stressful. Attentional processes are thought to organize experience and to play a central role in cognitive and social development, beginning early in infancy. Thus, B. Wilson and Gottman (1994) aptly considered attention regulatory processes as a "shuttle" linking emotional regulation (ER) and sociocognitive processes because attentional processes organize both cognitions and emotional responses and thus influence the socialization of relationship competence. Although studies are only beginning to emerge, evidence suggests that attentional regulation may have direct effects on children's social functioning (Eisenberg, 2000; B. Wilson & Gottman, 1994) and, in some circumstances, attentional control may function in interaction with dimensions of emotionality and social information processing. Other work (Eisenberg & Fabes, 1992) suggests that attentional control and emotional negativity may interact when predicting social competence. Attention regulatory skills appear to be more critical among children who experience higher levels of emotional negativity. Eisenberg, Guthrie, Fabes, Shepard, Losoya, et al. (2000), argued that when children are not prone to experience intense negative emotions, attention regulatory processes may be less essential to positive social functioning. In contrast, the social functioning of children who experience anger and other negative emotions may only be undermined when these children do not have the ability to use attention regulatory processes, such as cognitive restructuring, and other forms of emotion-focused coping (see also, Eisenberg, Cumberland, & Spinrad, 1998).

Attentional processes may work in tandem with emotional regulatory abilities to enhance social functioning (O'Neil & Parke, 2000). Parenting style may be an important antecedent of children's abilities to refocus attention away from emotionally distressing events. Data from fifth graders indicated that when mothers adopted a negative, controlling parenting style in a problem-solving discussion, children were less likely to use cognitive decision making as a coping strategy. Additionally, children were more likely to report greater difficulty in controlling negative affect when distressed. Lower levels of cognitive decision making and higher levels of negative affect were associated with more problem behaviors and higher levels of negative interactions with classmates. Similarly, when fathers adopted a negative, controlling style, children were more likely to use avoidance as a

mechanism for managing negative affect. Additionally, fathers who reported expressing more negative dominant emotions, such as anger and criticism, in everyday intercalations had children who reported greater difficulty controlling negative emotions. Avoidant coping and negative emotionality, in turn, were related to higher levels of parent-reported problem behaviors.

Recent findings from the National Institute of Child Health and Human Development (NICHD) Early Child Care Research Network study of child care and youth development are relevant (NICHD Child Care Research Network, 2003b). The role of attention in a laboratory task as a mediator between parenting and peer outcomes was examined. Parenting was measured by the HOME Observation for Measurement of the Environment (HOME) scale, by maternal sensitivity, and by cognitive stimulation. Attention was indexed by sustained attention and impulsivity. Children viewed a matrix of familiar objects and were required to note when an object appeared and to refrain when a nontarget stimulus was presented. Errors of omission occurred when children responded to a nontarget stimulus. Children who had fewer errors of omission had greater ability to sustain attention; children with errors of commission were more impulsive. Social competence and externalizing behaviors were rated by child-care caregivers at 54 months. There were links between higher-quality family environments and better social competence and lower externalizing. Second, sustained attention and less impulsivity were associated with higher social competence scores. Third, impulsivity served as a mediator between family- and social-outcome measures.

In recent follow-up (NICHD Child Care Network, 2006), attention regulation mediated between mother and father parental sensitivity measures and teacher ratings of children's peer competence and self-reports of loneliness in first grade. In this study, attention was measured by both the Continuous Performance Task (CPT) and by maternal reports of attentional regulatory abilities. Using third grade outcomes of aggression, exclusion by peers, and friendship, and earlier measures (first grade) of mother and father sensitivity predicted these outcomes. Moreover, attentional regulation competence served as a mediator between parenting and later peer outcomes. Together these studies provide evidence for the role of attention as a mediator of the links between family and peer systems.

**Parental Instruction, Advice Giving, Consultation, and Rule Provision.** Learning about relation-

ships through interaction with parents can be viewed as an indirect pathway because the goal is often not explicitly to influence children's social relationships with extrafamilial partners such as peers. In contrast, parents may influence children's relationships directly in their role as a direct instructor, educator, or advisor. In this role, parents may explicitly set out to educate their children concerning appropriate ways of initiating and maintaining social relationships and learning social and moral rules.

Several studies have examined these issues. In a study of parental supervision, Bhavnagri and Parke (1991) found that children exhibited more cooperation, turn taking, and had longer play bouts when assisted by an adult than when playing without assistance. Adult assistance enhanced the quality of play for younger (2 to 3.5 years of age) children more than older (3.5 to 6 years of age) children. Although both fathers and mothers were effective facilitators of their children's play with peers, under natural conditions, mothers are more likely to play this supervisory role than fathers (Bhavnagri & Parke, 1991; Ladd & Pettit, 2002).

The quality of advice that mothers provided their children prior to entry into an ongoing play dyad varied as a function of children's sociometric status (Russell & Finnie, 1990). Mothers of well-accepted children were more specific and helpful in the quality of advice that they provided. In contrast, mothers of poorly accepted children provided relatively ineffective kinds of verbal guidance such as "have fun" and "stay out of trouble." The advice was too general to be of value to the children in their subsequent instructions.

As children grow, caregiver forms of management shift from direct involvement or supervision of the ongoing activities of children and their peers to a less public form of management, involving advice or consultation concerning appropriate ways of handling peer problems. This form of direct parental management has been termed *consultation* (Ladd, & Pettit, 2002). Parents report using verbal guidance (e.g., discussion about future consequences, talk of values, and offering their advice) more often than direct interventions (e.g., limiting the adolescent's activities with peers or inviting friends over to the house to shape peer influence; Mounts, 2000). Parental limiting of activities with peers and inviting children's friends over, however, were reported more frequently when parents attempt to influence friend selection (Mounts, 2000). These indirect forms of supervision that emerge as the child reaches adolescence are linked with positive outcomes. Parental supervision

was positively related to adolescents academic competence and psychological adjustment (e.g., low levels of depression; Furstenberg et al., 1999) and negatively related to children's antisocial behavior and association with delinquent peers in late elementary and middle school (Reid et al., 2002) even though parents are not directly involved (e.g., giving instructions) in children's interactions with peers. Perhaps with older children, an adult's presence keeps the children's behavior in line with parental expectations.

Past research on advice giving often has focused on either the content of parent's advice or the manner in which it is given. There is a shift in recent research toward an integrative approach to this topic. As Grusec and Goodnow (1994) suggested, both style and content need to be considered together in determining the impact of parental advice giving on children's peer outcomes. The combined impact of these two aspects of parental advice giving is just beginning to achieve recognition. In their study of children aged 3 to 5 years, Mize and Pettit (1997) found that maternal information giving and guidance (content) predicted, over and above mothers' warmth and responsiveness (style), children's peer acceptance (as rated by teachers) during a play interaction context. These studies did not assess the ways in which children may be contributing to the advice-giving task. McDowell, Parke, and Wang (2003) found similar results showing that the style and content of peer relationships made independent contributions, after controlling for children's behavior during the task.

Most of the research examining parental advice giving assumed that parents advise children; thus, parents hold the key to socialization when giving advice. Many studies neglect the fact that children often raise the subjects that are discussed in the parent-child interaction. In effect, children are actively contributing to their own socialization by selecting issues on which to receive advice. Moreover, whatever the relations are between parental advice giving and children's social competence, the child necessarily holds the power to put into action any advice that is offered. In this sense, children and parents may find themselves as equal partners in facilitating peer relationships. Again, children are active solicitors of parental responses. Either behavioral characteristics during a parent-child interaction or beliefs about the child's behavior in general may affect the relative quality of the parent-child interaction and thus the effectiveness of advice giving. It is also important to note that children may be more or less receptive to parental advice and will shape their own socialization

experiences by selectively attending to or ignoring parental offers of advice.

Both parents and children, however, may regard explicit parental advice as less necessary and/or less appropriate as children develop adequate social skills. Instead, by middle childhood, provision of advice would be expected to be used by parents for remedial goals in which the advice giving would be highest for children who functioned poorly socially. McDowell et al. (2003) found that when parents offered more advice and more specific advice about peer dilemmas, children were rated as less positive and more negative by teachers and peers. However, children may act as agents of their own development by eliciting more specific advice to compensate for poor social functioning away from the parent. Other evidence suggests that the type of advice changes further as children enter adolescence and develop a future orientation. In adolescence, parents are likely to try to keep their children from being influenced by peers by talking to them about future consequences of their behavior. Mounts (2000) found that 37% of mothers of adolescents used this direct strategy with their ninth-grade children. This "parental guidance" approach (e.g., "My parents tell me who I have for friends will affect my future") was associated with selection of friends with low levels of antisocial behavior and high levels of academic achievement. Advice giving is a bilateral process in which both parents and children are active participants at all stages of the advice process, from selection of topics to acceptance or rejection of advice.

These studies suggest that direct parental influence in the form of supervision and advice giving can increase the competence of young children and illustrates the utility of examining direct parental strategies as a way of teaching children about social relationships. In these studies, the direction of effects is difficult to determine and parents may be responding to their children's level of social skill. Experimental and longitudinal studies would help place these studies on a clearer interpretative footing.

Another avenue through which parents can regulate their children's peer relationships is the provision of rules or guidelines. Rules concerning children's peer relationships include the guidelines regarding what activities the children can engage in and when, with whom, and where they can play. To date, little attention has been given to the role of rules in the development and maintenance of children's peer relationships. Particularly relevant to the links between rules and peer rela-

tionships is the work of Furstenberg et al. (1999), which explores the relations between parents' restrictions on the activities of their adolescents' social behavior and adolescents' social adjustment. The construct of "restrictions" included, among other aspects, monitoring, rules, teaching good judgment, and restriction of activities. A higher number of restrictions was linked to fewer problem behaviors (e.g., school truancy or substance abuse) and higher social involvement with peers. The operationalization of the restrictions construct combined rules with several parenting skills so that the role of rules alone in the regulation of children's behavior with peers is unclear. Simpkins and Parke (2002) explored the relations between parental play rules and sixth-grade children's loneliness, depression, and friendship quality. Boys whose parents had fewer play rules reported lower levels of depression and more conflict in their best friendship. As in other aspects of parental management, the process by which rules are jointly negotiated by children and their parents is poorly understood. Issues of mutual trust, parental perception of the child's level of responsibility, and self-regulatory ability, and, for the child, the perceived fairness of the rules probably all play a role in both the negotiation process and the extent to which the rules are likely to be followed.

#### *Parents as Managers of Children's Opportunities*

Parents influence their children's social relationships not only through their direct interactions with their children but also as managers of their children's social lives (Furstenberg et al., 1999; Parke, Killian, et al., 2003). This parental role is of theoretical importance given the recent claims that parents' impact on children's development is limited and peer group-level processes account for major socialization outcomes (Harris, 1998). In contrast, we conceptualize the parental management of access to peers as a further pathway through which parents influence their children's development (Parke, Killian, et al., 2003). Mothers and fathers differ in their degree of responsibility for management of family tasks; mothers are more likely to assume the managerial role than fathers (Parke, 2002).

Parents make choices about neighborhoods and schools as well as the formal and informal activities in which their children can participate. In these ways, "parents act as designers when they seek to control or influence the settings in which children are likely to meet and interact with peers" (Ladd & Pettit, 2002, p. 286). These design decisions can influence children's social and academic outcomes. Instead of viewing parents as acting alone in their

designer roles, we prefer to view parents and children as co-designers in recognition of children's roles as shapers and negotiators across development. Many decisions—even in the designer domain—are influenced by children's and parents' needs, wishes, and decisions. In this section, we consider each of these aspects of the designer role.

### **Neighborhoods as Determinants of Peer Contact.**

Although it is assumed that parents choose their neighborhoods, many constraints limit the range of locations from which to choose, especially economic (i.e., cost) and geographic (i.e., distance from work or transportation). Choice of neighborhood is not equally available to parents; lower-SES and minority group parents have a more restricted set of options than higher-SES and non-minority parents. However, there is considerable variability in "neighborhood effects" on children because of the ways in which parents manage their children's access to aspects of their neighborhood setting. Neighborhood choice, therefore, is simply one phase of a multiphase process in which choices made by different parents in similar neighborhoods, as well as the initial choice of neighborhood, are important (Furstenberg et al., 1999). A second conceptual assumption about neighborhoods concerns children's role in neighborhood selection. Although children—especially young children—are not usually direct participants in the choice of neighborhoods, their needs, their safety, and their access to other children and play space usually are considered by parents in their deliberations about choice of neighborhood. Adolescents may be more active participants by articulating their concerns about moving to a new neighborhood that, for example, involves loss of community-based friendships and shifts in school district. Testimony to children's power is evidenced by increases in residential mobility of families after children complete high school.

Neighborhoods vary in their opportunities for peer-peer contact. Especially for young children who have limited mobility, neighborhoods form significant portions of their social world. The most systematic evidence concerning the impact of variations in the quality of neighborhood environments comes from Medrich (1982), who isolated a number of factors—safety, terrain, distance from commercial areas, and child population density—that affect the amount and type of peer social experience.

What is the impact of neighborhood variations on peer competence? Bryant (1985) found that accessibility to neighborhood resources is a correlate of socioemotional

functioning. Children who could easily access (by walking or bike) community resources, such as structured and unstructured activities at formally sponsored organizations, were higher both in their acceptance of individual differences and perspective taking. Similarly, using U.S. Census tract data, Coulton and Pandey (1992) found that youngsters in areas with high levels of poverty differed from those in low-poverty areas on several outcomes, including reading scores, birth weight, infant death, and juvenile delinquency. A related Australian study (Homel & Burns, 1989) found that children in the most disadvantaged neighborhoods, reported higher loneliness, feelings of rejection by peers, worry, and lower life satisfaction compared to children in less disadvantaged neighborhoods. Although recent studies find evidence of "neighborhood effects" across a range of developmental outcomes in both adolescents and young children, these effects appear to be modest after taking into account family effects (Leventhal & Brooks-Gunn, 2000). The effects of neighborhoods on children's outcomes are often mediated by parenting practices such as supervision and monitoring. O'Neil, Parke, and McDowell (2001) found that when mothers and fathers perceived their neighborhoods as dangerous and low in social control, they placed more restrictions on their fourth grade children's activities. Parental perceptions were more consistently related to parenting practices than objective ratings of neighborhood quality. Moreover, parental regulatory strategies serve as mediators of the relation between parental perceptions of neighborhood quality and social competence. Mothers and fathers who perceived problems in their neighborhood had children who were more prosocial and less aggressive, but this was mediated by shifts in parental management strategy. Similarly, N. Hill and Herman-Stahl (2002) found that interviewer's ratings of neighborhood safety were associated with mothers' use of hostile socialization strategies. Both mothers and interviewers reports of safety were linked with maternal depression. In turn, mothers' depression mediated the links between neighborhood safety and inconsistent disciplinary practices. Neighborhoods are an important factor in accounting for children's developmental outcomes but much remains to be understood about the mechanisms that account for neighborhood effects and how these mechanisms shift across development.

### **Parents and Children as Partners in Schooling.**

Parents choose not only neighborhoods but also, especially for middle-class families, the type and quality of

day care and elementary schools that their children will attend. These choices make a difference to children's later development. As studies of child care have shown, the quality of and, to some extent, the amount of time in care are linked to children's cognitive and social development (Clarke-Stewart & Allhusen, 2005). Higher quality child care is associated often with higher cognitive functioning. Social behavior, despite the opportunity to have increased peer contact, is less consistently linked with day-care quality: Some evidence suggests that children who are in day care for more than 40 hours per week may show some increases in aggression (NICHD Early Childcare Research Network, 2003a). As children develop, parents select neighborhoods as a function of quality of the schools that are available (Furstenberg et al., 1999). However, "these choices are constrained by existing economic and social opportunities" (p. 226) and are mainly available to middle-class families. Moreover, the ability to choose is not inconsequential because exercising the ability to choose a school has been linked to adolescent academic outcome (Furstenberg et al., 1999). As a reminder that children can play a role in this process of school choice, there is some evidence that children's behavior in school—their successes and failures in both social and academic domains—influences the nature of the parent-child relationship. Repetti (1996) found that children's positive and negative experiences at school during the day altered the nature of parent-child interaction in the home after school. Although the study did not address the issue of the impact on subsequent decisions to change schools due to this school-based child effect on family dynamics at home, consistent negative school experiences may lead parents to consider shifting schools as an option to reduce negative effects on the child and the family.

School choice is not the only way in which families and schools are linked. The extent to which parents are involved in school-related activities (e.g., parent-teacher associations or school conferences) is positively related to children's academic outcomes (Epstein & Sanders, 2002). Practices of partnerships between parents and schools decline across child development. Parents of children in elementary school are more likely to volunteer, attend parent-teacher conferences, and supervise children's homework. In recognition of adolescent's need for autonomy and independence, parental involvement decreases in high school, but young adolescents still want their families to support their learning and activities at home (Epstein & Sanders, 2002). Even older adolescents endorse

parent involvement at school but in different ways than in earlier school grades. These developmental changes can be interpreted as evidence of the child's role in shaping the form that the parent-school partnership will assume at different points in the child's educational career.

**Parents and Children as Active Agents in Involvement in Religious Organizations.** Parental facilitation of children's involvement in religious institutions is another potentially important way in which parents manage their children's lives. It is important to distinguish between the issue of involvement in religious institutions and religious beliefs because these two aspects of religion may have partially independent effects on family functioning and child outcomes (see Mahoney, Pargament, Tarakeshwar, & Swank, 2001, for a review of religious beliefs and parenting practices). Elder and Conger (2000) found that church involvement is a family affair. When both parents attended church on a regular basis, children were more likely to be involved in religious organizations. Similarly, actively involved grandparents tend to have actively involved grandchildren. Church attendance involved more than contact with a broadened network of adults who share similar family and religious values; it also involved exposure to a network of age-mates with common beliefs and values. Involvement in church activities was associated with higher endorsement of not only church but also school, good grades, and—especially for boys—community activities. For those who were less involved in religious activities, athletics and school were given high priority. Religiously involved youth perceived their friends to be less likely to encourage deviant activities, viewed their friends and themselves as less involved in deviance, and were less likely to see friends disapproved of by their parents.

Religious involvement in the 8th grade was predictive of competence by the 12th grade in grades and peer success. Moreover, adolescents who become more religiously involved by the end of high school tend to rank higher on a variety of competence dimensions—from academic and peer success to self confidence and relations with parents. A reciprocal influence model best accounted for those findings. Although the primary flow of influence moved from religious activity and socialization to individual competence in achievement, some adolescents who were successful academically and socially and became more involved in religious activities, further enhanced achievement. Similarly, it is likely that both parents and children are active players

in the process of involvement in religious activities. Although parents—through their own involvement and through their introduction of the child to religious beliefs and functions—play an important initial role, children, and especially adolescents, themselves are central agents in choosing to continue their regular participation in religious institutions. These findings are most easily understood through the lens of the bilateral model that guides our chapter. Finally, Brody, Stoneman, and Flor (1996) found that parental religiousness (frequency of church attendance and importance of religion) was associated with better child adjustment as well. Specifically higher maternal and paternal religiousness was associated with less externalizing problems among 9- to 12-year-olds. The effects were mediated by family cohesiveness and lower marital conflict. However, the relative importance of beliefs or involvement in organized religious activities in accounting for these effects remains unclear.

**Parental Monitoring.** Another way in which parents can affect their children's social relationships is through monitoring of their children's social activities. This form of management is particularly evident as children move into adolescence and is associated with the relative shift in importance of family and peers as sources of social influence. Moreover, direct monitoring is more common among younger children, whereas distal monitoring is more evident among adolescents. Monitoring refers to a range of activities, including the supervision of children's choice of social settings, activities, and friends. Parents of delinquent and antisocial children engage in less monitoring and supervision of their children's activities, especially concerning children's use of evening time, than parents of nondelinquent children (G. Patterson & Stouthamer-Loeber, 1984). Poorly monitored children have lower academic skills and lower peer acceptance (Sandstrom & Coie, 1999), and they participate in more delinquent and externalizing behavior (Xiaoming, Stanton, & Feigelman, 2000). Nor are the effects of monitoring limited to a reduction in the negative aspects of peer relations. As Krappmann (1986) found, preadolescents of parents who were well informed about their children's peer relationships and activities had closer, more stable, and less problem-ridden peer relationships.

Although monitoring has been viewed as a parent to child effect, Kerr and Stattin (2000) have reconceptualized this issue and argued that monitoring is a process that is jointly co-constructed by the parent and child—a

view consistent with the one guiding our chapter. They suggested that monitoring may be a function of the extent to which children share information about their activities and companion choices with their parents. Given this reconceptualization, prior research could be reinterpreted to suggest that children with poorer social adjustment discussed their activities with parents less than did well-adjusted children. Paternal attempts to learn more about their children's activities must be met with the child's own willingness to discuss such information (Mounts, 2000). Schell (1996), in a qualitative study of high-risk adolescents, found that youth often actively thwart their parents' monitoring attempts. For example, they may mislead the parent concerning their destination or location, which makes it difficult for the parents to accurately track the child's activities. As Kuczynski, Marshall, and Schell (1997) noted: "the proactive and management techniques of parents occur in tandem with proactive management techniques of their children" (p. 43). This reconceptualization is consistent with recent findings with adolescents (Mounts, 2000). Parental guidance (e.g., discussion of future consequences of children's relationships or giving advice) rather than monitoring was consistently correlated with less delinquency, less drug use, and children having more friends with high grade point averages and positive attitudes toward school. The role of parents in the regulation of adolescents' peer relationships in adolescence is not to monitor or to "keep track" of their children's activities; parents' role is to listen to children concerning their relationships, give advice on current dilemmas, and discuss future consequences their children might not think about otherwise. Such willingness may be related to temperamental characteristics of the adolescent. Parental knowledge of child behavior in middle childhood has been linked to characteristics such as expressiveness and sociability (Crouter, Helms-Erikson, Updegraff, & McHale, 1999). In sum, the relations between parental monitoring and adolescent peer activity are more complicated than previously thought. This reconceptualization of monitoring as a shared process between a parent and child is consistent with the theme of both parent and child as active agents in the management of children's social lives.

**Recognition of the Interdependence among Components of the Tripartite Socialization Model.** Although we have treated parental style and/or parent-child interaction, advice giving, and parental management as separate influences, these components

often operate together to achieve their effects on children's socialization outcomes. A similar argument has been offered by Grusec and Goodnow (1994) who suggested that parental strategies vary in their effectiveness as a function of the quality of the parent-child relationship. As argued elsewhere, these three components can be usefully viewed as a cafeteria model (Parke et al., 1994).

Two issues need to be addressed. First, are there natural occurring combinations of these components? Second, do the different components moderate the relative effectiveness of each component depending on the level of the other components? To illustrate, Mounts (2002) examined the co-occurrence of different types of parenting management practices—prohibiting, guiding, monitoring, supporting—with various parenting styles (authoritarian, authoritative, permissive, and uninvolved). She found that all parents, regardless of their parenting style, use prohibiting and guiding as management strategies. In contrast, monitoring and supporting are more common in authoritative style homes relative to the other parenting style environments. Several other studies illustrate this interdependence across socialization components by demonstration of the joint contributions of parenting style and practices to child outcomes. Steinberg, Lamborn, Dornbusch, and Darling (1992) found that when parents were authoritative, it reduced the effects of parental school involvement in determining school performance, whereas parental involvement in school had a stronger effect in the presence of authoritative parenting style. Similarly, Mize and Pettit (1997) found that when mothers were low in parental responsiveness (parental style) higher levels of constructive coaching (parental practices) aimed at improving peer relationships were linked to lower levels of aggression than when mothers had low levels of responsiveness and low levels of constructive coaching. In contrast, when mothers had moderate or high levels of responsiveness, their level of coaching was unrelated to the level of children's aggression. In this case, coaching compensated for a less adequate parenting style. Finally, Mounts (2001) demonstrated a moderating role of parental style on the effectiveness of parental management of adolescent peer relationships. Parental style was indexed by authoritative, authoritarian, indulgent, and uninvolved approaches, whereas parental management was represented by guiding, prohibiting, monitoring, and supporting their adolescents' friendships. Monitoring operated differently in the context of dif-

ferent parenting styles: with authoritative parents, high levels of monitoring were associated with lower levels of friends and low levels of drug use. For other parenting styles, there were no links between monitoring and friends or drug use. Perhaps adolescents view monitoring differently (i.e., less intrusive) in the context of an authoritative parenting style—a view consistent with monitoring as a dyadic construct. The link between prohibiting and drug use varied as a function of parental style as well; prohibiting was negatively related to drug use for the authoritarian and authoritative style groups but positively linked for the uninvolved parental style group. Because these effects were evident across 1 year, it suggests that a low level of parental involvement may have created a climate in which parent's efforts to prohibit drove adolescents toward higher levels of drug use over time. This underscores the bidirectionality of influence between parents and children in the socialization process as well. In sum, these studies illustrate the interdependence among various components of our tripartite model and suggest that a full understanding of socialization processes requires attention to the moderating effects among the components.

### *Co-Parenting as a Socialization Strategy*

A recent trend is the focus on co-parenting in recognition that mothers and fathers operate as a parenting team and individual parents (J. McHale & Rasmussen, 1998). This work has identified a variety of forms that co-parenting alliances can assume, including "a pattern signifying antagonistic and adult centered or hostile competitive, co-parenting dynamics, a pattern marked by significant imbalance or parenting discrepancy in levels of parental engagement with the child and a pattern reflecting cooperation, warmth, cohesion, and child centeredness or high family harmony" (J. McHale, Laurretti, Talbot, & Pouquette, 2002, p. 142). These patterns have been observed across studies with infants, preschoolers, and school-age children, and in both European and African American families (Brody, Flor, & Neubaum, 1998; Fivaz-Depeursinge & Corboz-Warnery, 1999). Recent work has moved beyond description and revealed links between early co-parenting dynamics and later indices of social adaptation. J. McHale and Rasmussen (1998) found that hostile-competitive co-parenting during infancy was related to aggression, whereas large parenting discrepancies were related to parent-rated anxiety. Others have found links between problematic family alliances in the 1st year and insecure

mother-child attachments and clinical symptomatology in the preschool years (Fivaz-Depeursinge & Corboz-Warnery, 1999; J. McHale et al., 2002).

Co-parenting accounts for unique variance in child measures and clearly needs to be distinguished from traditional parent-child and marital level processes (J. McHale et al., 2002). Less is known about the processes that control these various patterns of co-parenting, but recent work on gatekeeping (Allen & Hawkins, 1999; Beitel & Parke, 1998) that focuses on ways in which couples facilitate or hinder the involvement of their partner's interactions with their children is promising. The similarities and differences of the co-parenting relationship for intact and nonintact (divorced or single parent) families are poorly understood (Emery, Kitzmann, & Waldron, 1999). Extensions of theory and empirical work to other family forms (foster parents and birth parents; Erera, 1997), parents and grandparents (Smith & Drew, 2002), and lesbian-parenting partners or these partners and a donor father as co-parent (C. J. Patterson, 2002) would help define the uniqueness of co-parenting forms and process in various family types.

#### ***Beyond the Parent-Child Dyad: The Marital Subsystem as a Contributor to Children's Socialization***

In the preceding section, parents were conceptualized as active influences, both directly and indirectly, on the development of children's social competence and understanding of relationships. However, children's experiences in families extend beyond their interactions with parents. Children's understanding of relationships is shaped also through their active participation in other family subsystems (e.g., child-sibling) and through exposure to the interactions of other dyadic subsystems (e.g., parent-parent) or participation in triadic relationships (e.g., child-sibling-parent, child-parent-parent).

#### ***Influence of Marital Satisfaction and Discord on Child Outcomes***

Considerable evidence indicates that marital functioning is related to children's short-term coping and long-term adjustment. Although the size of the associations are not always large, a range of studies link marital discord and conflict to outcomes in children that are likely to impair the quality of interpersonal relationships, including: antisocial behavior; internalizing and externalizing behavior problems; and changes in cognitions, emotions, and physiology in response to exposure to

marital conflict (see Grych & Fincham, 2001, for a recent review). Although less empirical work has been directed specifically toward examination of the "carry-over" of exposure to marital conflict to the quality of children's relationships with significant others (e.g., peers and siblings), exposure to marital discord is associated with poor social competence and adjustment problems (Cummings & Davies, 1994; Davies, Harold, Goeke-Morey, & Cummings, 2002).

#### ***Mechanisms Linking Marital Discord to Children's Adjustment***

Three alternative, but not mutually exclusive, models have been proposed to account for the impact of marital relations on children's developmental outcomes. Until recently, theoretical frameworks typically conceptualized marital discord as an indirect influence on children's adjustment that operated through its effect on family functioning and the quality of parenting (Faubert & Long, 1991). Factors such as affective changes in the quality of the parent-child relationship, lack of emotional availability, and adoption of less optimal parenting styles have been implicated as potential mechanisms through which marital discord disrupts parenting processes. A second model (Cummings & Davies, 1994; Grych & Fincham, 2001) focuses on the *direct effects* of witnessed marital conflict on children's outcomes rather than on the indirect or mediated effects. Recently, Cummings, Goeke-Morey, and Raymond (2004) have proposed a third model: the interrelations among marital quality, parents' psychological functioning, and children's outcomes. Labeled the "parental mental health hypothesis," this alternative focuses on the role of parental psychological functioning in accounting for the effects of marital conflict either as a risk or protective factor.

**Indirect Effects Model.** A sizable body of literature supports the view that these two family subsystems are related. Erel and Burman (1995) completed a meta-analytic review of 68 studies that met a variety of criteria, including independent assessment of marital and parent-child relationships. Their review provided support for a positive relation between the quality of the marital relationship and the quality of the parent-child relationship. As Erel and Burman (1995) concluded:

The composite mean weighted effect size representing the association between marital and parent-child quality was

0.46 or approximately one standard deviation in the direction of more positive parent-child relationships in families with more positive relations and more negative parent-child relationships in families with more negative marital relations. (p. 126)

Even when their meta-analysis was restricted to studies of high-quality research or to studies using independent raters and a between-subjects design, the effect sizes were reduced but remained significant. Their review leaves little doubt about the relation between marriage and parent-child relationships.

Theoretically, several models have been offered to account for these effects—the spillover hypothesis and the compensatory hypothesis. According to the spillover perspective, mood or behavior in one subsystem transfers to another subsystem (e.g., from marital subsystem to parent-child subsystem). In contrast, the compensatory hypothesis suggests that positive parent-child relationships can be maintained even in the face of marital conflict and can serve as a buffer on children (Erel & Burman, 1995). The meta-analysis clearly supports the spillover hypothesis and offers no support for the compensatory concept. Their analysis underscores the difficulty of buffering children from marital conflict and discord. Parents may try to buffer their children by limiting their opportunities to witness marital conflicts and disputes; however, as Erel and Burman (1995) suggest, “they cannot shield them from the negative impact that marital discord has on the parent-child relationships” (p. 128). Unfortunately, Erel and Burman’s conclusions were largely restricted to Caucasian and intact families.

Several factors have been proposed as moderators of the relation between these two subsystems, including gender of parent, gender of child, age of child, and birth order (Cummings et al., 2004). The quality of the father-child relationship is more consistently associated with the quality of the marital relationship and/or with the amount and quality of marital support than is the mother-child relationship (Parke, 2002). Cummings et al. (2004) labeled this view as the “fathering vulnerability hypothesis.” This literature suggests that spousal support is more critical for adequate parenting on the part of fathers than mothers. As marriages deteriorated, men became more negative and intrusive fathers, whereas mothers were less affected by shifts in marital quality (Belsky, Youngblade, Rovine, & Volling, 1991). Moreover, recent meta-analysis (Krishnakumar & Buehler, 2000) of the relation between interparental

conflict and parenting supported “the fathering vulnerability hypothesis” including relations with a variety of aspects of parenting, including control, acceptance, harsh discipline, and overall quality of parenting. At the same time, many studies show “parenting vulnerability” (Cummings et al., 2004) in which marital discord affects both mothering and fathering. However, when gender differences do occur, they favor the fathering vulnerability view, with less support for the “mothering vulnerability hypothesis” (Cummings et al., 2004).

A number of factors may aid in explaining the greater vulnerability of fathers. First, father’s level of participation is, in part, determined by the extent to which the mother permits participation (Beitel & Parke, 1998). Second, because the paternal role is less well articulated and defined than the maternal role, spousal support may serve to help crystallize the boundaries of appropriate role behavior (Parke, 2002). Third, men have fewer opportunities to acquire and practice skills that are central to caregiving activities during socialization and therefore may benefit more than mothers from informational (i.e., cognitive) support (Parke & Brott, 1999).

Even when research indicates that both mother-child and father-child relationships are both associated with marital relations, mothers and fathers may influence their children’s outcomes in different ways. Gottman et al. (1997) found that when parents used a mutually hostile pattern of conflict resolution, fathers were more likely to be intrusive and children were more likely to express anger during a parent-child interaction task. In addition, fathers’ intrusiveness predicted more negative peer play and more aggressive play with a best friend. Interestingly, an individual parent’s style of handling conflict may be related to the quality of his or her *partner’s* relationships with children in the family. When fathers were angry and withdrawn in a conflict resolution task, mothers were more critical and intrusive during interactions with their child. Maternal criticism and intrusiveness, in turn, were associated with unresponsiveness or “tuning out” by the child during mother-child interactions and higher levels of teacher-rated internalizing symptoms (see also Cowan, Cowan, Schulz, & Heming, 1994).

Family systems theory suggests that marital discord not only interferes with the mother-child or father-child relationship but also impairs qualities of the mother-father-child triadic relationship by interfering with the effectiveness of how the mother and father work together with the child (Cox, Paley, & Harter, 2001). Westerman

and Schonholtz (1993) found that fathers', but not mothers', reports of marital disharmony and disaffection were significantly related to the effectiveness of joint parental support toward their child's problem-solving efforts. Joint parental support was, in turn, related to fathers' and teachers' reports of children's behavior problems. As Gottman (1994) has shown, women tend to engage and confront, whereas men tend to withdraw in the face of marital disharmony. Men's lack of involvement in the triadic family process may account for these findings.

Although much of the prior work has focused on the transfer of negativity between marital and parent-child subsystems, some evidence suggests that marital satisfaction is a predictor of positive parenting (Russell, 1997). For mothers, but not fathers, greater marital satisfaction was linked to higher levels of warmth, affection, positive involvement, and overall positive parenting.

**Direct Effects of Marital Relationships on Children's Outcomes.** Despite progress in elucidating specific parenting processes that are impaired by interparental conflict, parental conflict is also associated with behavior problems independent of its influence on the parent-child relationship. Accordingly, attention has turned to elucidating specific processes by which the marital relationship itself *directly* influences children's immediate functioning and long-term adjustment. A parallel research trajectory has been a movement away from a focus on global measures of marital satisfaction to a focus on specific aspects of marital interaction that are most likely to influence children's immediate cognitive, emotional, and physiological functioning. These immediate responses, or "microprocesses," have been hypothesized to be critical links to children's long-term social adjustment when interparental conflict exists (Grych & Fincham, 2001). Recent lab analog studies show that the form of expression of marital conflict plays a critical role in how children react. More frequent interparental conflict and more intense or violent forms of conflict have been found to be particularly disturbing to children and likely to be associated with externalizing and internalizing difficulties (Cummings et al., 2004). McDonald, Jouriles, Norwood, Ware, and Ezell (2000) found that father's interparental aggression was related to children's internalizing problems. Conflict that was child related in content was more likely than conflict involving other content to be associated with behavior problems in children, such as greater shame, re-

sponsibility, self blame, and fear of being drawn into the conflict (Grych, & Cardoza-Fernandez, 2001).

Resolution of conflict, even when it was not viewed by the child, reduces children's negative reactions to exposure to interadult anger and conflict. Exposure to unresolved conflict has been found to be associated with negative affect and poor coping responses in children (Kerig, 1996). In addition, the manner in which conflict is resolved may also influence children's adjustment. Katz and Gottman (1993) found that couples who exhibited a hostile style of resolving conflict had children who tended to be described by teachers as exhibiting antisocial characteristics. When husbands were angry and emotionally distant while resolving marital conflict, children were described by teachers as anxious and socially withdrawn.

Conflict is inevitable in most parental relationships and is not detrimental to family relationships and children's functioning under all circumstances. However, disagreements that are extremely intense and involve threat to the child are likely to be more disturbing to the child. In contrast, when conflict is expressed constructively, is moderate in degree, is expressed in the context of a warm and supportive family environment, and shows evidence of resolution, children may learn valuable lessons regarding how to negotiate conflict and resolve disagreements (Cummings & Davies, 1994).

**Parental Mental Health and Marital Quality.** Support is beginning to emerge for the view that parental psychological functioning may help account for the effects of marital conflict on children's functions. Consistent with a view of parental psychopathology as a risk factor for children, family discord mediated the effects of maternal depressive symptoms on adolescent girls' social and emotional adjustment (Davies & Windle, 1997). In a later study, marital distress mediated the effects of maternal depression on male and female adolescent externalizing, whereas maternal depression mediated the impact of marital distress on adolescent depressive symptoms (Davies, Dumenci, & Windle, 1999). Other work provides support for the links among poor parental functioning (parental dysphoria), marital conflict, and children's adjustment (DuRocher Schudlich & Cummings, 2003). In this case, depressive conflict style mediated the relations between parental dysphoria and internalizing problems of 8- to 16-year-old children. Consistent with a protective perspective when fathers are supportive of their partners during marital conflict,

the impact on the children is reduced (Huffman & Cummings, 2002). Although this mental health perspective is gaining some support, a wider range of mental health problems needs to be examined to determine their links with both marital conflict and children's adjustment. Moreover, the relative importance of this perspective for the direct versus indirect models of influence is not yet established.

**Recent Progress in Methodology and Theory.** A noteworthy methodological advance is the evaluation of the impact of marital conflict not just through the use of lab analog or questionnaire approaches but the use of parental diary reports of naturally occurring incidents of marital conflict in the home. In support of earlier lab analog studies (Cummings & Davies, 1994), these studies suggested that everyday marital conflict (Goeke-Morey, Cummings, Harold, & Shelton, 2003) and marital physical aggression (O'Hearn, Margolin, & John, 1997) were associated with negative emotional and behavioral reactions. In contrast, parental support and affection were linked with children's positive reactions (Goeke-Morey et al., 2003). These studies increase the ecological validity of the prior findings and the generalizability of the prior work to naturalistic family contexts.

Several competing theoretical frameworks have emerged that focus on cognitive-processing or emotional-regulatory mechanisms. Using a cognitive contextual model, Grych and Fincham (Grych & Cardoza-Fernandes, 2001; Grych & Fincham, 1990) have focused on the cognitive and affective meaning that exposure to conflict has for the child. Davies and Cummings (1994) have offered an emotional security hypothesis that suggests that marital conflict negatively affects children's emotional regulatory abilities, influences children's motivation to regulate their parents' behaviors, and alters their cognitive representations of family relationships. A third position (Crockenberg & Langrock, 2001) focuses on the social learning role of modeling and the role of specific emotions, such as fear and anger, in accounting for the effects of marital conflict on children's adjustment.

In a recent test of competing theoretical positions (i.e., social learning, cognitive appraisal, and emotional security), Davies et al. (2002) found that children responded to interparental conflict with fear and regulation efforts (avoidance or intervention)—reactions that are consistent with emotional security theory. In contrast, the social learning theory prediction (Crocken-

berg & Langrock, 2001) that children would display anger in response to conflict and that they would imitate same-sexed parents was not supported. However, the value of distinguishing among specific types of emotions, such as fear versus anger, rather than on undifferentiated negative affect was clearly supported—a position stressed by Crockenberg's specific emotions perspective on this issue (Crockenberg & Langrock, 2001). In a follow-up study of this sample, Davies et al. found further support for the emotional security position. Child emotional security (assessed by emotional, reactivity, behavioral regulation, and internal representations) mediated the links between interparental conflict and internalizing and externalizing symptoms across a 2-year period. Although the models provided stronger support for the emotional security predictions than cognitive appraisal processes, both sets of processes received some support. In sum, more work is needed before definitive conclusions concerning the theoretical power of these competing, even if overlapping, theoretical perspectives can be drawn. Moreover, as others (Crockenberg & Langrock, 2001) have argued it is critical to examine links among marital conflict, child adjustment, and specific goals (versus a general emotional security goal) that are both directly relevant to emotional security (e.g., worries about family dissolution or fears about being involved in the conflict) and nonsecurity-related concerns (e.g., being a partner in family decision making). It is critical to integrate the recent work on emotional regulation and coping (Eisenberg, 2000; Kerig, 2001) more centrally into these theoretical debates (e.g., Crockenberg & Langrock, 2001). Finally, prior work has been largely developmental and less is known about the impact of exposure to marital conflict on adolescents, especially the effects on their own emerging friendships and close same-sex and opposite-sex relationships.

### **The Sibling System as a Contributor to Children's Socialization**

Descriptions of the normative patterns that characterize sibling relationships over the course of development suggest that, in addition to parents, siblings play a critical role in the socialization of children. Most children are likely to spend more time in direct interaction with siblings than parents and significant others (Dunn, 1993; Larson & Richards, 1994) and that interactions with siblings provide a context for the expression of a range of

positive social behaviors as well as numerous conflictual encounters and experiences with conflict resolution (Dunn, 1993). Further, this array of interactions between siblings has been found to be typified by greater emotional intensity than the behavioral exchanges that characterize other relationships. Developmental shifts in sibling relationships suggest that perceptions of warmth and conflict between siblings declined over time, between late middle childhood and early adolescence (Slomkowski & Manke, 2004). A decline in intimacy in sibling relationships is evident from preschool to early adolescence (Dunn, Slomkowski, Beardsall, & Rende, 1994). However, gender influences these developmental patterns: sisters reported more warmth and self-disclosure over this period (Dunn et al., 1994; Slomkowski & Manke, 2004). Despite these shifts, wide individual differences in the quality of sibling relationships and recent evidence suggests change in quality of sibling relationships continues during adolescence (Conger, Bryant, & Brennom, 2004).

Sibling relationships have been hypothesized to contribute to children's socialization in a number of significant ways. A social-learning framework analogous to the one posited to explain parental contributions to the development of children's social competence (Parke & O'Neil, 1999) predicts that through their interactions with siblings children develop specific interaction patterns and social-understanding skills that generalize to relationships with other children. Relationships with siblings also may provide a context in which children can practice the skills and interaction styles that have been learned from parents or others. Older siblings function as tutors, managers, or supervisors of their younger brother's or sister's behavior during social interactions (Edwards & Whiting, 1993) and may function as gatekeepers who extend or limit opportunities to interact with other children outside of the family (Zukow-Goldring, 2002). Also paralleling the indirect influence that the observation of parent-parent interaction has on children, a second avenue of influence on children's development is their observation of parents interacting with siblings. These interactions have been hypothesized to serve as an important context in which children deal with issues of differential treatment and learn about complex social emotions such as rivalry and jealousy.

### *Influence of Siblings on Child Outcomes*

Children's experiences with siblings provide a context in which interaction patterns and social understanding

skills may generalize to relationships with other children. According to Stocker and Dunn (1990), interactions with siblings provide a setting in which children "develop social understanding skills which may enable them to form particularly close relationships with a child of their choice, a close friend."

Studies show only modest evidence of straightforward "carryover" of interaction styles between children's relationships, and when associations emerge they may be complicated by birth order effects and other processes (Dunn, 1993, 2004; Stocker & Dunn, 1990). Adding another complexity to the picture of how sibling and peer relationships are linked are findings from studies, which suggest that sibling relationships may play a role in compensating for other problematic relationships by providing an alternative context for experiencing satisfying social relationships and protecting children from adjustment difficulties. East and Rook (1992), for example, found that children who were socially isolated in their peer relationships were buffered from adjustment problems when they reported positive relationships with a favorite sibling. Similarly, Stocker (1994) reported support for the compensatory role of at least one positive relationship (sibling, friend, or mother) as protection from the development of behavioral conduct difficulties.

The prosocial or deviant interest and activities of siblings are important determinants of the positive or negative influence of siblings on one another. Adolescents who have both close and satisfying relationships and share common deviant interests with their older brothers may be at increased risk for antisocial delinquent behaviors, higher rates of problem behaviors, and problematic interaction patterns with romantic partners (Slomkowski, Rende, Conger, Simmons, & Conger, 2001). Just as for peer-peer relationships, both the type of behavior that they engage in and the quality of the ties between siblings need to be understood before the positive or negative impact of sibling relationships can be predicted.

In view of our focus on bidirectionality of influence, it is important to consider the impact of friendships on sibling relationships. Kramer and Gottman (1992) examined the role that positive relationships with peers play in children's adaptation to the birth of a new sibling. Children who displayed a more positive interaction style with a best friend and who were better able to manage conflict and negative affect, behaved more positively toward their new sibling at both 6 months and 14 months.

They suggest that management of conflict, a valuable skill when interacting with siblings, may be more likely to be learned in interactions with peers than in direct interactions with parents. Recently, Kramer (2004) has developed a social skill training program aimed at improving children's relationships with their siblings. In comparison to a control group of 4- to 6-year-olds, children with a younger sibling who received social skills training showed more positive and less negative sibling relationships and more perspective taking. Although the processes that underlie the success of this program are not yet specified, early evidence suggests that emotional regulatory and attentional factors that are important correlates of peer competence (Eisenberg, 2000; Parke et al., 2006) may play a role in harmonious sibling relationships as well. Brody, Stoneman, Smith, and Gibson (1999) found that 9- to 12-year-old African American children who were higher in self-regulation (e.g., ability to set and attain goals, plan, and persist) experienced more harmonious and less conflictual sibling relationships. Similarly, Volling, McElwain, and Miller (2002) found that preschool-age older siblings who were higher in emotional understanding were less likely to show behavioral dysregulation and negative emotions in a social triangle paradigm in which the mother directed her attention to a younger sibling. Moreover, higher behavioral regulation was associated with more positive sibling-sibling relationships.

The challenge is to discover the contexts under which strong, weak, or compensatory connections may be expected between relationship systems and the processes through which children's experiences with siblings are translated into relationship skills that are used in other relationships. For example, greater generalization of hostile, aggressive interaction styles in both sibling and peer systems may emerge when children lack adequate relationship skills or when children are experiencing stressful, negative family relationships (Dunn, 1993, 2004). In contrast, under other circumstances, the association between sibling relationships and relationships outside the family may be moderated by a number of features that uniquely characterize each relationship. As Dunn (1993) has argued, friendship involves a mutual and reciprocated relationship with another individual, whereas siblings do not necessarily feel this way about one another. In contrast to sibling-sibling relationships, friend and peer relationships represent a more unique combination of backgrounds, experiences, and temperaments that may generate interaction styles that are the result of two unique individuals' approach to re-

lationships. Further, there appear to be different role expectations for sibling versus friend relationships that may differentially influence interaction styles. There is a need to systematically examine the moderating and mediating influences of these factors to uncover normative patterns of associations between sibling and peer relationships.

### *Siblings as Managers of Children's Social Lives*

Just as parents function as managers of children's social lives, siblings in many cultures perform similar management functions in relation to their younger siblings. Cross-cultural work indicates that in African, Polynesian, and Mexican cultures children, especially girls, become involved in sibling caretaking and teaching activities at a relatively early age (Weisner, 1993). Maynard (2002) found that by 4 years of age children took responsibility for initiating teaching situations (e.g., weaving) with their toddler siblings and that by 8 years of age children become highly skilled teachers of culturally relevant skills. Relatively little is known, however, about the caregiving role of siblings in contemporary European American families. Patterns of sibling interaction in New England families suggest that formal caregiving responsibilities may not be as common in American culture as in other cultures (Edwards & Whiting, 1993). However, Bryant (1989) suggests that although parents may not formally assign caretaking duties to children, children frequently voluntarily assume the roles of caretaker, tutor, and teacher of younger siblings and make unique contributions to the socialization of young children. Most work examining these roles has focused on the influence that instruction from older siblings may have on children's cognitive development (Rogoff, 1990, 2003). Relatively little is known about the role that siblings play as supervisors, managers, or advisors of children's social lives. Given the amount of time that most children spend in the company of siblings, this is an area that is ripe for future investigation.

### *Future Directions for Sibling Research*

More fruitful investigation of the links between relationships may come with movement from a socialization framework to a relationships framework. Dunn (1993) notes that one disadvantage of a socialization approach is that it does not adequately take into account that even when a child acquires social competencies through interactions in one relationship, he or she may not be motivated to apply these skills in another rela-

tionship. In contrast, a relationships perspective takes into account that each relationship reflects a unique set of demands and rewards as well as different challenges to a child's sociocognitive abilities. This may lead to the generation of questions concerning the unique aspects of child (e.g., temperament, attachment security, or self confidence), the relationship partner, the dynamic of the relationship itself, and the broader social ecology (e.g., family stress or life transitions), which may contribute to a child being motivated or disinclined to behave in a socially competent manner. As Dunn (1993) points out, the goal is to specify "for *which* children, at *which* stages of development, *which* dimensions of particular relationships are likely to show associations with other relationships" (p. 125). A final value of the renewed focus on siblings is the contribution that this work is making to our understanding of the relative roles of genetics and environment in studies of socialization and development (Dunn, 1993; Plomin, 1994).

### **The Family Unit as a Contributor to Children's Socialization**

Parent-child, marital, and sibling influences are clearly the most well-researched aspects of socialization. However, consideration of these units of analysis alone is insufficient because they fail to recognize the family unit itself as a separate and identifiable level of analysis (Minuchin, 2002; Parke, 1988). Consistent with a systems theory perspective (Sameroff, 1994), the properties, functions, and effects of the family unit cannot necessarily be inferred from these smaller units of analysis. Families as units change across development in response to changes in the individual members, life circumstances, and scheduled and unscheduled transitions. Families develop distinct "climates" (Moos & Moos, 1981), "styles" of responding to events (D. Reiss, 1989) and distinct "boundaries" (Boss, 1999), which provide differing socialization contexts for the developing child. Several investigators (Fiese et al., 2002; D. Reiss, 1989) have argued that the family regulates the child's development through a range of processes, including myths, stories, and rituals. Recent evidence suggests the potential importance of these family level processes for understanding socialization in the family.

*Family myths:* Myths refer to beliefs that influence family process, provide continuity across generations, and are generally not open to discussion or debate (Sameroff,

1994). Wamboldt and Reiss (1989) argue that family myths influence mate selection and marital satisfaction. Individuals can set aside destructive family myths by marrying a person with a different and perhaps healthier history of family myths. To date, there is little direct evidence of the impact of family myths on children's development.

*Family stories:* Family stories have received more attention as vehicles for socialization of young children (Pratt & Fiese, 2004). Stories are vehicles for the transmission of family values and for teaching family roles. The study of stories as socialization vehicles has taken a variety of forms—in part, depending on the disciplinary perspective of the investigator. Culturally-oriented investigators (e.g., Miller & Sperry, 1987) have established that stories occur in naturalistic contexts in exchange between parents and children or while children are present. In home observations of African American toddlers in south Baltimore, they found that mothers told informal narratives in the presence of their children about events in which someone became angry or responded with verbal or nonverbal aggression. Through these stories, children learn to distinguish between justified and unjustified anger.

Family of origin experiences may be transmitted across generations through stories and shared memories and shape contemporary interaction between family members. Fiese et al. (1999) provided a useful framework for studying family stories by focusing on three narrative dimensions: (1) narrative coherence, (2) narrative styles, and (3) relationship beliefs that characterize the form that the content of family stories assumes. This report provides evidence of the value of this approach for understanding premarital couples (Wamboldt, 1999), family dinner interactions (Fiese & Marjinsky, 1999), couples with an adopted child (Grotevant, Fravel, Gorall, & Piper, 1999), and depressed couples (Dickstein, St. Andre, Sameroff, Seifer, & Schiller, 1999). This approach yielded important insights into child functioning attitudes toward open versus closed adoption, marital satisfaction, and diagnosis of depression (Fiese et al., 1999). Stories are related to family interaction patterns and are linked to children's social competence as well. Putallaz, Costanzo, and Smith (1991) found that mothers with predominantly anxious/lonely recollections of their own childhood experiences with peers took an active role in their children's social development and had the most socially competent children. However, these mothers may be compensating for their

own difficult childhoods. Although mothers with positive memories also had socially competent children, mothers with memories of peer rejection had the least socially competent children. Later work (Putallaz, Klein, Costanzo, & Hedges, 1994) involving parent narrations of videotaped interaction of their child with a peer confirmed that mothers and fathers interpretative narrations were shaped, in part, by their recollections of their own childhood peer experiences. Similarly, Prinstein and La Greca (1999) found that mothers of well-liked kindergarteners had positive childhood peer memories, whereas mothers with anxious peer-related memories had less well-liked children. More work is needed to specify when childhood social adversity leads to compensatory reactions and when it leads to intergenerational continuity of social difficulties (see Grimes, Klein, & Putallaz, 2004, for a recent review).

*Family rituals and routines:* Rituals have been recognized for decades as an important aspect of family life (Bossard & Boll, 1950), but only in the past decade has the socialization function of rituals and routines become apparent (Fiese, 2006a, 2006b; Fiese et al., 2002). Fiese et al. (2002) argue that routines and rituals can be contrasted along the dimensions of communication, commitment, and continuity:

Routines typically involve instrumental communication in conveying information that is “what needs to be done.” The language of routines is direct, implies action, and often includes designation of roles. Routines involve a momentary time commitment and once the act is completed there is little afterthought. Routines are repeated over time, with little alteration, and can be directly observable by outsiders. Rituals, on the other hand, involve symbolic communication and convey this is “who we are as a group.” There is an affective commitment that leaves the individual feeling that the activity has a rightness and provides a sense of belonging. When rituals are disrupted there is a threat to group cohesion. (p. 382)

Family routines are associated with better child health and better behavioral regulation in intact families (Fiese et al., 2002). For example, families who observe medication routines are more likely to report higher adherence to medical regimens concerning the management of asthmatic children and, in turn, the children have less asthma-related illness (Fiese, 2006a). Similarly, routines serve a protective function and are linked to better adjustment for both parents and children in single parent, divorced, and remarried households (Fiese et al., 2002).

Wolin, Bennett, and Jacobs (1988) have identified three types of family rituals: (1) family celebrations (e.g., holidays like Christmas), (2) rites of passage (e.g., weddings), (3) family traditions (e.g., birthday customs or family vacations). Failure to attend an important family event, such as a wedding, often indicates a shift in family alliances and definitions of who is in or out of the family (Fiese, 2006a, 2006b). Rituals serve a protective function as well (Fiese et al., 2002), and Wolin, Bennett, and Jacobs (1988) found that children who came from families that were able to preserve family rituals, such as holiday routines, were less likely to become alcoholic as adults. Other studies (Fiese et al., 2002) report that families who attach more meaning to their rituals have adolescents who are higher in self-esteem. In sum, rituals and routines are powerful indices of family functioning and may serve as protective factors for the child.

Questions remain about the uniqueness of rituals relative to other forms of family patterns or child-rearing practices. Are rituals independent vehicles of socialization or merely a reflection of more central causal influences such as the quality of the parent-child relationship (Fiese et al., 2002)? For example, rituals may be less likely in families of alcoholics, which suggest that the degree of alcoholism, either alone or in combination with the lack of rituals, may contribute to future drinking problems. Evidence is needed concerning the contribution of family level variables independently of individual or dyadic levels of analysis. Similarly, the direction of causality in these studies remains unclear. Do harmonious families participate more in family rituals, or does active participation contribute to increased family well-being? Although the answers to these questions are unclear, it is evident that we need to expand our repertoire of avenues through which socialization is enacted in families. Finally, the origin of family level differences is an issue that has received little attention. Given demonstrations (e.g., Plomin, 1994) that genetics may play a role in variations in measures of family home environments, answers are most likely to derive from designs that recognize the contributions of both genetic and environment factors in the emergence of family level differences.

### **Putting the Pieces Together: Toward a Multiple Sources Model of Socialization in the Family**

Our family systems viewpoint argues for the construction of a comprehensive model in which the contribution of parent-child, parent-parent, and sibling relationships

are all recognized. Figure 8.3 outlines a comprehensive model of family socialization that includes the influence of all family members. To date, few studies have simultaneously addressed how these subsystems combine to produce their impact on children's relationship learning. Little is known about the relative weighting of parent-child relationships versus other family relationships (Parke & O'Neil, 1999). Nor do we understand how the impact of these different relationships changes as the child develops. The most crucial issue remains the specification of the pathways through which these different relationships exert their influence. In our model, multiple pathways are possible and there is support for both direct and mediated effects. As noted earlier, marital relationships exert both direct (e.g., witnessed effects) and indirect effects (e.g., marital relationships influence parent-child patterns). Similarly, parent-child relationships could influence marital relationships. For example, a disciplinary encounter with a difficult-to-control child could begin a marital conflict due to disagreement about the child's misbehavior or management of the child, the carryover of negative mood, or the alignment of parent and child against a third party. Less is known about the impact of parent-child relationships on marital interactions than the reverse.

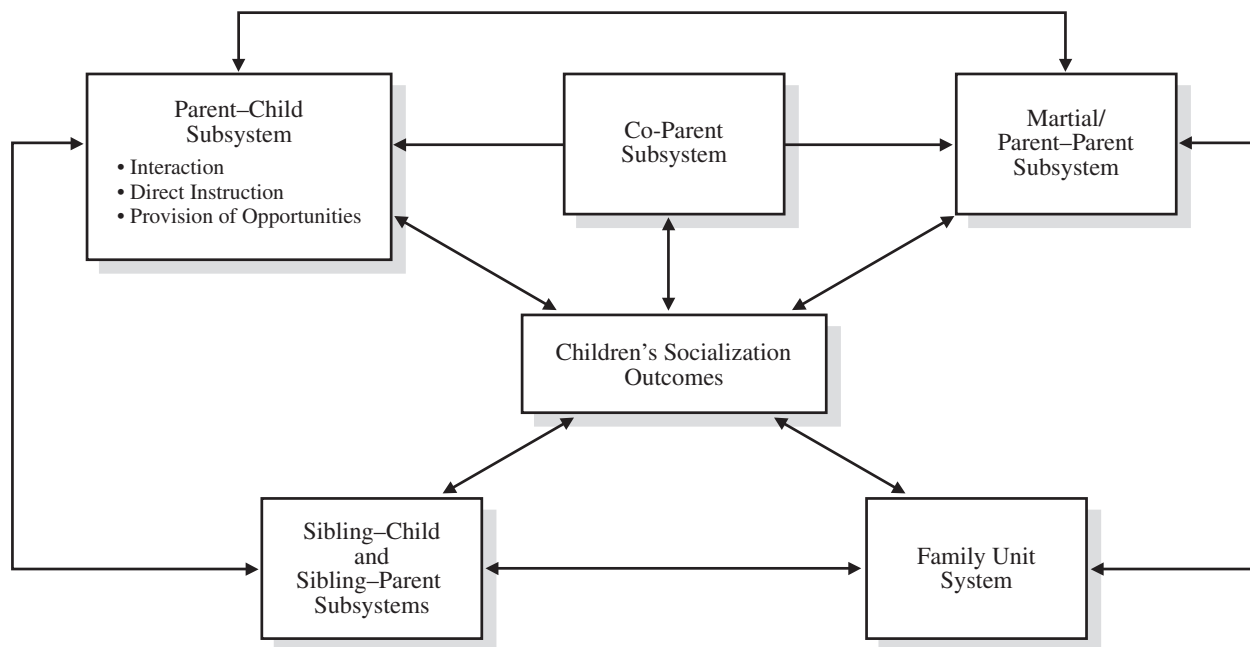

Moreover, recent research has begun to identify individual differences across families or family typologies as well as at the level of family subsystems such as mari-

tal dyads (Cook, 2001). As a next step, can we characterize families usefully by the relative importance of various subsystems? Some families may invest heavily in directly parenting their children but tend to protect their children from their marital problems. Earlier evidence suggests that exposure to marital conflict is higher for boys than girls (Hetherington & Kelly, 2001). Similarly, some families may encourage close sibling-sibling relationships, whereas others tend to encourage sibs to form separate social spheres. This kind of social arrangement will result in different types of socialization outcomes.

Do all combinations produce equally socially competent children, or are some ingredients in this mix more important than others? Do different combinations produce different, but equally well-adjusted, children in their social relationships? Can children in a family with a poor marriage compensate by investing "relationship energy" into another subsystem such as the sibling-sibling or parent-child system? Studies of divorce (Hetherington & Kelly, 2001) suggest that a close sibling-sibling relationship can help buffer children during a stressful divorce.

## DETERMINANTS OF FAMILY SOCIALIZATION STRATEGIES

One of the major advances in the field has been recognition of the importance of understanding the determinants

**Figure 8.3** Model indicating the hypothesized relations among family subsystems and children's socialization outcomes.

of parenting behavior (Belsky, 1984). For a long time, developmentalists were concerned about the impact of particular styles or practices on children. There was less concern with the conditions that alter parenting behaviors themselves. Several trends have converged to stimulate this interest: First, the recognition of child effects (Bell, 1968) led to a reevaluation of the role of the child in eliciting and shaping parental behaviors. Second, a renewed interest in contextual-ecological issues (Bronfenbrenner, 1989) played a role. Third, closely linked is the increased focus on how cultural, racial, and ethnic background modify parenting behavior (Garcia Coll & Magnuson, 1999). Fourth, interest in the life-course perspective (Elder, 1998) has led to a focus on how timing of entry into parenting roles alters the enactment of parental behaviors. Fifth, recognition of the role of parental cognitions (e.g., goals, values, and attributions) has fueled interest in how cognition shapes parental behavior (Dix & Branca, 2003).

In this section, a variety of factors are considered. Belsky (1984) proposed a three-domain model of the determinants of parenting, which included the personal resources of the parents, the characteristics of the child, and the contextual sources of stress and support. Some of the work relevant to this model is reviewed and recent work on ethnic variations in parenting is reviewed to expand on this earlier theoretical scheme.

### Child Characteristics

Child characteristics take two forms: (1) universal predispositions that are shared by all children and (2) individual differences in particular characteristics. An impressive amount of evidence has documented that infants are biologically prepared for social, cognitive, and perceptual challenges and these prepared responses play a significant role in facilitating children's adaptation to their environment. This evolutionary approach has continued to receive support (Geary & Bjorkland, 2000). Under the influence of recent advances in behavior genetics (e.g., Plomin, 1994), there is increasing recognition of the role of individual differences in a wide variety of behavioral characteristics in shaping parental socialization strategies. Perhaps the most well-researched determinant of parenting behavior is child temperament (Putnam, Sanson, & Rothbart, 2002). Although debates about the relative contributions of genetic and experimental factors to the emergence of individual differences in temperament continue (Reid

et al., 2002), temperament plays an important role as a determinant of parental socialization tactics. Infants with difficult temperaments elicit more arousal and distress from caregivers than less difficult infants (Putnam et al., 2002). Children who are more difficult may elicit increasingly coercive strategies from parents (Reid et al., 2002). Alternatively, fearful children may respond optimally to subtle parental socialization strategies (Kochanska, 1997). Other characteristics, in addition to temperament, have been examined, including activity level, social responsiveness, and compliance level. In general, the more active, less responsive, and more non-compliant children elicit more negative parenting and more negative parental arousal and affect (Crouter & Booth, 2003). The impact of these individual differences on parental socialization behavior is not independent of environmental conditions. Crockenberg and Leerkes (2003) showed that the impact of a difficult infant temperament on the parent-infant attachment relationship varied as a function of the degree of social support available to the mother, which underscores the potential modifiability of temperament-based influences.

### Personal Resources

Several studies support the prediction that personal resources—conceptualized as knowledge, ability, and motivation to be a responsible caregiver—alter parenting behaviors (Belsky, 1984). Particularly striking are recent studies of how parental psychopathology, such as depression, will alter parenting behavior (Goodman & Gotlib, 2002). From early infancy onward, the patterns of interaction between depressed and nondepressed parents (usually mothers) and their offspring are less positive, less stimulating, and less contingent. In turn, their infants showed less attentiveness, fewer contented expressions, more fussiness, and lower activity levels (Field, 1992). Differences are particularly evident when depression is protracted and not merely transient (Campbell, Cohn, & Meyers, 1995).

These differences in interaction may place the infant at risk for later developmental problems. Infants of depressed mothers are more likely to develop insecure attachments (Goodman & Gotlib, 2002). Recent investigations have found links between severe and chronic depression and disorganized attachment behavior (Lyons-Ruth, Lyubchik, Wolfe, & Bronfman, 2002). This attachment category refers to infants who lack a coherent strategy for accessing their attachment fig-

ures and who show confused, conflictful, and fearful behavior in the Strange Situation (see Thompson, Chapter 2, this *Handbook*, this volume). Nor are the effects on child-parent attachment restricted to infancy. Teti, Gelfand, Messinger, and Isabella (1995) found a similar pattern of insecure attachment among preschool-age children of depressed mothers. Although no follow-up studies have revealed the long-term outcomes for these children, other studies of children with poor attachment histories reveal that these children are at risk for later relationship difficulties in adolescence (Carlson et al., 2004). Others' personal problems (e.g., antisocial personality disorder or schizophrenia; limited education and poverty) contribute to poorer parenting (Cummings et al., 2004). At the same time, positive personal characteristics (e.g., high intelligence and self-regulation) and a transpersonal orientation (i.e., a focus on family, work, and child rearing) are linked with better quality parenting (Pulkkinen, Nurmi, & Kokko, 2002). Just as with individual differences in infants and children, recent theorists have argued that some of these individual differences across parents, such as depression and proneness to abuse or coerciveness, may, in part, be genetically based (Caspi et al., 2002). Studies addressing the interplay among genetically based individual differences among infants and parents and environmental factors that enhance or suppress the influence of these characteristics would be valuable.

### *Parents, Children, and Social Capital*

The concept of social capital considers the relations among people, institutions, and organizations of the community outside the immediate family structure. As described by Coleman (1988), social capital is both the flow of information and the sharing of norms and values that serve to facilitate or constrain the actions of people who interact in the community's social structures (e.g., schools, places of worship, or business enterprises). Children benefit from the presence of norm and value consensus among members of their family and the wider community (Coleman, 1988). Monitoring of children is facilitated, as is their socialization, through multiple efforts of network members who hold shared family community norms and values (Elder & Conger, 2000). Moreover, if a child's own family is negligent in fulfilling the socialization role, other adults are available to assume the responsibility.

One important aspect of social capital is the network of social relationships in which families are embedded.

Parents' own social networks of other adults, as well as the child members of parental social networks, provide a source of possible play partners for children. Cochran and Niego (1995) suggested several ways in which these two sets of relationships may be related. First, the child is exposed to a wider or narrower band of possible social interaction partners by exposure to the members of a parent's social network. Second, the extent to which the child has access to the social interactions of his or her parents and members of their social network may determine how well the child acquires a particular style of social interaction. Third, in view of the social support function of social networks, parents in supportive social networks may be more likely to have positive relationships with their children, which may positively affect the child's social adjustment both within and outside the family. Cochran and Niego (1995) reported that there is overlap between parent and child social networks; thirty percent to 40% of 6-year-olds' social networks were also included in the mothers' networks. Children often listed other children as play partners who were children of their mother's friends. Finally, the overlap was higher for relatives than nonrelatives, but both kin and nonkin adult networks provided sources of peer play partners for young children.

Community networking has implications for youth development. Adolescent boys were found to have better school performance and attendance and more positive social behavior when their social networks included large numbers of nonrelated adults (Cochran & Bo, 1989). In a study by Fletcher, Darling, Steinberg, and Dornbusch (1995), when nonrelated adults such as adolescent's friends' parents were perceived as authoritative in their parenting style, adolescents were lower in delinquency and substance abuse, especially when they perceive their own parents to be authoritative. Another way these two networks may be linked was proposed by Coleman (1988), who argued that when both parents and their children are acquainted with other parents and their children, they form network closure. When network closure exists, more shared values and more social control over their offspring are likely, which would be related to better social outcomes. Darling, Steinberg, Gringlas, and Dornbusch (1995) found that social integration (as indexed by network closure) and value consensus were related to adolescent social and academic outcomes. Adolescents who reported high degrees of contact among their parents, their own friends, and their friends' parents were less deviant and higher in

academic achievement than their peers who were less socially integrated.

The quality of adult social networks is related to children's social behavior. In an Australian study, Homel, Burns, and Goodnow (1987) found positive relations between the number of "dependable" friends that parents report and 11-year-old children's self-rated happiness, the number of regular playmates and maternal ratings of children's social skills. Recently, Simpkins, O'Neil, Lee, and Parke (2005) found that the more parents enjoyed their own friends, the less the child was disliked and perceived as aggressive by peers. The more contact the parents had with relatives, the less disliked children were by their peers.

Moreover, the quality of the relationship that adults develop with friends in their social network is an important correlate of their children's friendship quality. Doyle and Markiewicz (1996) found that mothers who perceived their own best friends as providing more stimulating ideas and activities but also felt less secure in their friendships had children who experienced more closeness with their best friend. If mothers felt less secure about their best friendship, their own children were more likely to have a best friend. The findings concerning the links between lack of mothers' security about their friendships is consistent with work on maternal recollections of their childhood peer experiences (Putallaz et al., 1991), which supports a compensatory model of parenting. More recently, Simpkins and Parke (2001) found that the quality of both maternal and paternal concurrent friendships was related to children's friendship quality. As these studies illustrate, the quality and scope of adult friendship and social networks are important correlates not only of children's peer competence but also of their friendship qualities.

In sum, the social capital in a community can aid parents' socialization of their children through several pathways. First, when parents and children have community ties, more social support is available. Second, parental awareness of community services and their participation in shaping the institutions of the community promote the maintenance of values and norms that influence their children. Third, parental participation with their children enables closer supervision of children and reduces the time children spend with their own peers. The concept of social capital embodies the notion not only that parenting is a community enterprise (Elder & Conger, 2000) but also that children and adults are ac-

tive players in the distribution of social capital. More attention needs to be given to children's role as active agents in this process.

### **Socioeconomic Status as a Determinant of Family Socialization Strategies**

There is a long history of research concerning the links between socioeconomic status (SES) and/or social class and parenting beliefs and practices. Although the debate concerning the best strategy for measuring SES continues (Bornstein & Bradley, 2003; Entwisle & Astone, 1994), most scholars agree that SES is multiply determined, and therefore the links with parenting are likely to be multiple as well. Second, in contrast to traditional assumptions that SES is a static state, most (e.g., Featherman, Spenner, & Tsunematsu, 1988; Hoff et al., 2002) argue that SES is a dynamic concept. Over the course of childhood and adolescence, families change social class and change is greatest in the youngest ages. Over 50% of American children change social class prior to entering school (Featherman et al., 1988).

Despite the controversies surrounding the interpretation of this variable, there are SES differences in parental socialization practice and beliefs (Hoff et al., 2002). First, SES differences in parenting style have been found. Lower-SES parents are more authoritarian and more punitive than higher-SES families (Kelley, Sanchez-Hucies, & Walker, 1993; Straus & Stewart, 1999). Second, interaction styles differ across SES levels. Lower-SES mothers are more controlling, restrictive, and disapproving than higher-SES mothers (Hart & Risley, 1995). Additionally, there are more SES differences on language measures than on nonverbal measure with higher-SES mothers being more verbal than lower-SES mothers (Hart & Risley, 1995; Hoff et al., 2002). "Higher SES mothers not only talk more, but provide object labels, sustain conversational topics longer, respond more contingently to their children's speech, and elicit more talk from their children than lower SES mothers" (Hoff-Ginsberg & Tardif, 1995, p. 177). Some SES differences are independent of race and poverty. In China, where there are relatively small differences in income across groups who vary in terms of education, Tardif (1993) found that less educated parents used more imperatives with their toddlers than better educated mothers. Similarly, Hess and Shipman (1965) in their early classic studies of cognitive socialization

found clear SES differences in African American lower-class and middle-class families.

Parental cognitions—ideas, beliefs, values—clearly play a major mediating role in accounting for SES differences (Bornstein & Bradley, 2003). Similarly, self-efficacy mediates between SES and parenting goals and practices (Brody, Stoneman, Smith, & Gibson, 1999). Second, ecological factors, such as neighborhood conditions, play a role. One of the challenges is to determine the roles of parental ideas and beliefs and the ecological conditions under which families are operating in determining parental socialization strategies. A more detailed exploration of socioeconomic circumstances is clearly a first step. Perhaps extreme circumstances, such as unsafe and dangerous living conditions, will override parental beliefs and play a more determining role, whereas beliefs may play a role under less extreme conditions. Specification of the types of parenting behavior, which are altered by different factors, is also of interest. Perhaps, differences in verbal stimulation will not vary across contexts in class, but control strategies may be more responsive to environmental circumstances.

## THE IMPACT OF SOCIAL CHANGE ON FAMILY SOCIALIZATION

Families are not static but dynamic and are continuously confronted by challenges, changes, and opportunities. A number of society-wide changes have produced a variety of shifts in the nature of family relationships. Fertility rates and family size have decreased, the percentage of women in the workforce has increased, the timing of onset of parenthood has shifted, divorce rates have risen, and the number of single-parent families have increased (Teachman, Tedrow, & Crowder, 2000). These social trends provide an opportunity to explore how families adapt and change in response to these shifting circumstances and represent natural experiments in family adaptation. Moreover, they challenge our traditional assumptions that families can be studied at a single point in historical time because the historical contexts are constantly shifting. Our task is to establish how socialization processes operate similarly or differently under varying historical circumstances. In this section, one issue from this myriad of changes, the effects of recent shifts in family employment and unemployment patterns

are explored to illustrate the impact of social change on family relationships (for reviews of other issues such as timing of parenthood, see Moore & Brooks-Gunn, 2002; for divorce, see Clarke-Stewart & Brentano, 2006; Hetherington & Kelly, 2001). Some of these changes are scheduled or planned such as reentry into the workforce or delaying the onset of parenthood; other changes, such as job loss or divorce, are unscheduled or nonnormative transitions. According to a life-course view both scheduled and unscheduled transitions need to be examined (Elder, 1998) to fully appreciate how these different types of change alter family socialization strategies. These family transitions are adult-focused in contrast to child-focused transitions (e.g., entry to day care or junior high school) and underscore our assumption that adult developmental issues need to be directly addressed to understand how these transitions alter parental socialization beliefs and behaviors. At the same time, child developmental status will play a major role in determining how adults respond to these transitions. We argued earlier it is insufficient to focus on individual levels of analysis—either adult or child. Instead, individual, dyadic, triadic, and family units each follow their own developmental trajectory and the interplay among these separate developmental trajectories can produce a diverse set of effects on the functioning of the units themselves. In addition, the role that these units (i.e., individual, dyad, or family) play in modifying the impact of family transitions will vary as a result of these interlocking developmental curves. Both the timing and nature of family transitions and reactions to these alterations will be determined by the points at which particular individuals, dyads, triads, or families fall along their respective developmental life-course trajectories. Moreover, individual families can vary widely in the particular configuration of life-course trajectories. The central premise is that the particular configuration of these multiple sets of developmental trajectories needs to be considered to understand the impact of societal change on families.

### Women's and Men's Employment Patterns and Family Socialization

The relations between employment patterns of both women and men and their family roles are increasingly being recognized (Deutsch, 1999; Hoffman, 2000). In this section, a variety of issues concerning the links

between the worlds of work and family are considered to illustrate the impact of recent shifts in work patterns on both men's and women's family roles. We examine the impact of changes in maternal employment on both quantitative and qualitative aspects of mother and father participation and the influence of variations in family work schedules.

Since the 1960s, there has been a dramatic shift in the participation rate of women in the labor force. The rise has been particularly dramatic for married women with children. In the United States in 1998, over 75% of married women with school-age children and over 63% of mothers with children under age 6 were in the paid workforce. In contrast, in 1960 fewer than 19% of mothers with children were employed (Statistical Abstracts, 1999). How have these shifts affected the quantity and quality of the mother's and father's contribution to family tasks such as housework and child care, and what are the implications for children's development?

### ***Maternal Employment and Children's Development***

How does maternal employment alter mother-child involvement? There is little difference in the amount of time that mothers spend with their children or in the types of activities engaged in dual or father-only employed families (Gottfried et al., 2002). According to Bianchi (2000), between 1981 and 1997, there was little change in mother's time with children even though there were dramatic increases in maternal employment. Similar findings have been reported for the United States (Galinsky & Swanberg, 2000) and Germany (Ahnert, Rickert, & Lamb, 2000). Moreover, there are few negative outcomes of maternal employment on children, in part, because "there has been reallocation of mothers' time and priorities, delegation of family work to others, increased preschool enrollment of children of employed and nonemployed mothers and redefinition of parenting roles" (Gottfried et al., 2002, p. 214).

Several domains of children's development have been examined including gender roles, achievement, and behavior problems. Maternal employment is associated with more egalitarian views of sex roles by their children, particularly by their daughters (Hoffman & Youngblade, 1999). In middle-class families, maternal employment is related to higher educational and occupational goals in children (Hoffman & Youngblade,

1999). Sons of working mothers, in contrast to sons of unemployed mothers, not only perceive females as more competent, but also view men as warmer and more expressive. Moreover, duration of employment among African American mothers is associated with longer school attendance in their daughters; no link was found for European American mothers (Wolfer & Moen, 1996).

One of the limitations of earlier studies was the lack of long-term follow-up to assess delayed effects of earlier maternal employment on children's development. In a longitudinal study, Gottfried et al. (2002) found that maternal employment was not related to children's development across age (infancy to age 17), developmental domain, and gender. Moreover, prospective analyses indicated that there were no sleeper effects associated with maternal employment. The children of employed and nonemployed mothers were similar in cognitive, socioemotional, academic, motivational, and behavioral domains from infancy through adolescence. This conclusion is not surprising given that the home environment and parenting of employed and nonemployed mothers were very similar in stimulation, nurturing, parent-child interactions, and family climate. The pattern of findings suggests that variations in employed and nonemployed mothers are more significant for child outcomes than differences between groups. In support of this shift away from a "social address" model to a process-oriented approach, Gottfried et al. (2002) found that processes such as parental involvement and the quality of the home environment were clearly linked to children's development—regardless of maternal employment status.

Cohort effects need to be considered in interpreting these findings. As maternal employment becomes more common, the differential effects on select areas of development (e.g., sex roles and independence) may decrease. In part, this may be due to the fact that the shift in maternal employment is part of a changing set of cultural attitudes concerning male and female roles that all children, regardless of their family employment arrangements, are exposed to.

There is some evidence that the child-rearing practices of working mothers may differ from those of nonemployed mothers, particularly in the area of independence training. Except in cases where mothers feel guilty about leaving their children to work, employed mothers encourage their children to become self-sufficient and independent and to assume responsibil-

ity for household tasks at an earlier age (Hoffman & Youngblade, 1999). This early independence training may be beneficial in leading to high achievement motivation, achievement behavior, and competence (Hoffman & Youngblade, 1999). Finally, mothers' satisfaction with their employment is related to child outcomes as well in Korean immigrants (K. Kim & Honig, 1998) and European Americans (Gottfried et al., 2002).

In summary, the results of studies of maternal employment suggest it does not usually have detrimental effects on children; positive consequences have usually been obtained, especially for girls. However, the effects of maternal employment can be evaluated only in relation to other factors, such as the reason why the mother is working, the mother's satisfaction with her role, the demands placed on other family members, the attitudes of the other family members toward the mother's employment, and the quality of substitute care and supervision provided for the children.

#### ***Quality of Mother and Father Work and Family Socialization***

Instead of examining whether one or both parents are employed, researchers have begun to address the impact of the quality and nature of work on both mother and father parenting behavior. This shift in focus is due to the fact that many workers experienced an increase in work hours, a decrease in job stability, a rise in temporary jobs, and, especially among low-wage workers, a decrease in income (Mishel, Bernstein, & Schmitt, 1999). As Crouter (1994) noted, there are two types of linkage between family and work. One type of research focuses on work as an "emotional climate," which may have carryover effects to the enactment of roles in home settings. The focus is generally on short-term effects. A second type of linkage focuses on the type of skills, attitudes, and perspectives that adults acquire in their work-based socialization as adults and how these variations in job experience alter their behavior in family contexts. In contrast to the short-term perspective of the spillover of emotional climate research, this type of endeavor involves more enduring and long-lasting effects of work on family life.

Work in the first tradition has been conducted by Repetti (1994) who studied the impact of working in a high-stress job (air-traffic controller) on subsequent family interaction patterns. She found that the male air traffic controllers were more withdrawn and less angry

in marital interactions after high-stress shifts and tended to be behaviorally and emotionally withdrawn during interactions with their children as well. Distressing social experiences at work were associated with higher expressions of anger and greater use of discipline during interaction with the child later in the day. Repetti and Wood (1997) found similar effects for mothers who withdrew from their preschoolers on days when the mothers experienced greater workloads or interpersonal stress on the job. Similarly, Crouter, Bumpus, Maguire, and McHale (1999) found that parents who reported high work pressure and role overload had more conflicts with their adolescents.

Other research suggests that positive work experiences can enhance the quality of fathering. Grossman, Pollock, and Golding (1988) found that high job satisfaction was associated with higher levels of support for their 5-year-olds' autonomy and affiliation, despite the fact that positive feelings about work were negatively related to the quantity of time spent interacting with their child. This finding underscores the importance of distinguishing quantity and quality of involvement.

In contrast to the Repetti studies, the Grossman et al. study focused on general job satisfaction and demandingness rather than daily fluctuations in the level of positivity or negativity experienced in the work setting. Future studies need to assess these two aspects of job-related affect and involvement separately.

Research in the second tradition of family work linkage (the effects of the nature of men's occupational roles on their fathering behavior) dates back to the classic work of Kohn (1995). Several researchers extended this work by focusing on the outcomes of job characteristics for children's development. Cooksey, Menaghan, and Jekielek (1997) found that children had fewer behavior problems when their mother's work involved more autonomy working with people and more problem-solving opportunities. Similarly, fathers with greater job complexity and autonomy were less authoritarian (Grimm-Thomas & Perry-Jenkins, 1994) and responded with greater warmth to their children and with more verbal explanations (Greenberger, O'Neil, & Nagel, 1994). However, the process probably operates in both directions: The home experience of parents affects their job performance as well. Arguments at home with a wife or with a child were negatively related to work performance (Frone, Yardley, & Markel, 1997). These studies underscore the importance of moving beyond

employment status per se to a detailed exploration of the nature of work in studies of family work linkages.

### Job Loss and Unemployment

Another unscheduled transition that has received attention is the impact of job loss on families (Conger & Elder, 1994; McLoyd, 1998). Several aspects of the parent-child relationship are altered by economic stress including parenting style, parent discipline, parental problem solving, and levels of parent-child conflict and monitoring. Parenting behavior is adversely affected as indexed by increased parental hostility and less consistent, less effective, harsher discipline (Conger & Elder, 1994; Elder, 1974; McLoyd, 1998). Recent extensions of this basic finding to African Americans (Conger et al., 2002) and Mexican Americans (Parke et al., 2004) have been reported. Moreover, under conditions of stress, parental monitoring will be adversely affected with less vigilance on the part of the parent (Crouter, MacDermid, McHale, & Perry-Jenkins, 1990). Although conditions of unemployment or underemployment increase fathers' availability and involvement in child care, unemployed fathers report fewer nurturing behaviors than employed fathers (Harold-Goldsmith, Radin, & Eccles, 1988). Recent research has focused on modifying and mediating variables. Several studies indicate that social support has a positive impact on parent-child relationships under conditions of stress (Conger & Elder, 1994; McLoyd, 1998). Child temperament and physical attractiveness also modify parenting practices. Temperamentally difficult children are treated more harshly by unemployed fathers than temperamentally easy offspring (Elder, Nguyen, & Caspi, 1985). Although physically unattractive daughters are treated more harshly than attractive girls, in some cases they received more support and less harshness (Elder et al., 1985). The quality of the prior father-child relationship is another determinant of how stress impacts changes in the father-child relationship. A positive relationship prior to job loss served as a protective factor in buffering the child from deterioration of the father-child relationship (Elder et al., 1985). Similarly, a positive (warm and affectionate) mother-child relationship reduced harsh treatment of the child by the father (Elder et al., 1985).

A variety of adverse effects on children accompany unemployment and economic stress, including increased depression and loneliness and lowered self-esteem (McLoyd, 1998). Gender differences are evident as well.

Girls respond to stress with internalizing problems, whereas boys tend to show externalizing behaviors (Conger & Elder, 1994). Recent longitudinal studies confirm earlier cross-sectional findings. Conger, Ge, Elder, Lorenz, and Simons (1994) interviewed parents and their adolescents over a 3-year period (seventh to ninth grades). Economic pressure at Wave 1 directly impacted parent-child financial conflict at Wave 2, which was related to adolescent internalizing and externalizing behavior at Wave 3. Moreover, these investigators found support for an indirect path between parental depressed mood and marital conflict, and, in turn, altered parental hostility was linked to adolescent internalizing and externalizing. Even though there were predictable gender differences in levels of symptomatology for boys and girls (i.e., greater externalizing for boys and greater internalizing for girls) the paths were similar for both sexes. Similar support for an indirect pathway model comes from McLoyd's (1998) examination of the impact of unemployment among African American single mothers on parenting and adolescent socioemotional functioning, as well as the Conger et al. (2002) report of the impact of economic pressure on 10- and 11-year-old African American children. Finally, Parke et al. (2004) have found that the economic stress model explains the impact of economic pressure on family processes and child outcomes in Mexican American families as well.

In summary, studies of the impact of unemployment have clearly been fruitful avenues for exploring how families adapt and cope in response to stressful change and underscore the value of a family systems approach to the study of socialization.

### Single versus Multiple Transitions

To date, societal changes, such as shifts in the timing of parenting, work participation, or divorce, have been treated relatively independently, but these events co-occur rather than operate in any singular fashion. As earlier work (Simmons & Blyth, 1987) on the impact of multiple transitions, such as the onset of puberty and entry into junior high school, on children's adjustment has found, co-occurrence of several changes can have a cumulative impact on the adolescent's adaptation. Similarly, as the number of environmental risk variables increase, the level of family functioning and child outcomes decrease (Sameroff, 1994). One would expect that the co-occurrence of the arrival of a new infant ac-

accompanied by job loss would have different effects than either of these events occurring singly. Moreover, the impact of any historical change may be different as a result of its occurrence in the same period as another change or changes. For example, women's increased presence in the workplace and delay in the onset of parenthood vary, and probably each event has different meaning without the other change. This implies the research need for multivariate designs to capture the simultaneous impact of multiple events on family socialization strategies.

### Children and Families of Color in the United States: Issues of Race, Ethnicity, and Culture

Every 10 years, the Census Bureau reaffirms the concept of race, which has a long legacy in this country. Although race has no scientific basis, it is nevertheless a potent social construction that impacts the lives of all people in the United States, especially those considered to be non-White. In the recent past, non-White groups were generally referred to as ethnic minorities. However, because Whites, or European Americans, can also claim ethnic group membership (Waters, 1990), the term *ethnic minority* does not accurately capture the most salient aspects in the lives of non-Whites, which distinguish them from the White population—skin color and physical appearance. For this reason, the term *people of color* has gained greater acceptance as the preferred designation for groups typically considered ethnic minorities—American Indians, African Americans, Latinos, and Asian Americans. The histories of these groups are different but share common experiences of exploitation and subordination by the White majority: (a) the forceful removal of American Indians from their ancestral homelands and relocation on reservations, (b) the enslavement of African Americans and segregation after their emancipation, (c) Latinos' incorporation through military conquest of the Southwest and ambivalent immigration policies, and (d) racist immigration policies toward Asians and their internment during World War II. In addition, mixed race children and families, who now make up 2.4% of the U.S. population (U.S. Bureau of the Census, 2001a), should be included as people of color. Often, these children and families of color experience prejudice and discrimination based on anti-miscegenation attitudes (Root, 1992).

Nationally, people of color today comprise approximately 35% of the U.S. population, and it is estimated that by the year 2020, 40% of all children will be African American or Latino. Child development research, to be relevant in this country, must be more inclusive of children of color and their unique developmental challenges. Parke (2004b) noted the responsibility that the field of child development has to the growing number of children of color:

In view of these demographic shifts there is both an opportunity to evaluate the generalizability of our assumptions about developmental processes and a moral obligation to understand better a larger segment of our population. (p. 10)

Ethnicity refers to an individual's membership in a group sharing a common ancestral heritage based on nationality, language, and culture (Betancourt & Lopez, 1993). Psychological attachment to the group is also a dimension of ethnicity, referred to as ethnic identity (Phinney, 2003). Sometimes ethnicity includes a biological (F. Barth, 1969), or racialized component, that is evident in the phenotype of the group members. Culture is a multidimensional construct referring to the shared values, behaviors, and beliefs of a people that are transmitted from one generation to the next. Unlike ethnicity and race, which are usually self- and other-ascribed attributes, respectfully, culture is learned behavior and can thus vary both across and within ethnic and racial groups. For this reason, it is invalid to equate ethnicity and race with culture. Although in some populations there is an overlap in race, ethnicity, and culture, this convergence should neither be taken for granted nor any of these three attributes considered as a proxy for the other. Consequently, researchers should describe in detail the self-ascribed ethnicity of respondents, their commonly ascribed racial classification, and salient cultural characteristics as determined by appropriate measures of acculturation.

The terminology regarding race, ethnicity, and culture is changing as a result of demographic shifts and more informed awareness of how these factors contribute to development. Nevertheless, *minority group status* in the form of powerlessness and discrimination (Greenfield & Cocking, 1994) is still prevalent among non-White groups in society. Therefore, to maintain consistency between past and present group designations in the literature, the terms *minority group*, *ethnic minority*,

and *people of color* will be used interchangeably, when appropriate, in the remaining section of this chapter.

### ***Conceptual and Methodological Issues for Studying Children and Families of Color***

Recent cross-cultural and intracultural theories have emphasized the importance of socialization goals, values, and beliefs as organizing principles for understanding cultural variations (Harkness & Super, 1995). In contrast to the older cultural deficit models of socialization, the recent models emphasize how ecological demands shape socialization goals, values, and practices, and are viewed as adaptive strategies to meet the demands of the ecological settings. Ecological (Bronfenbrenner, 1989) and family systems perspectives (Minuchin, 2002) have been useful in explaining how socialization goals for children derive from their parents' experiences with adaptive strategies that have helped them meet the challenges faced as people of color (Harrison, Wilson, Pine, Chan, & Buriel, 1990). Furthermore, Rogoff (2003) notes that to achieve a valid understanding of development in its cultural context, it is helpful to separate value judgments from observation of events:

Interpreting the activity of people without regard for *their* meaning system and goals renders observations meaningless. We need to understand the coherence of what people from different communities *do*, rather than simply determining that some other group of people *do not* do what "we" do, or do not do it as well or in the way that we do it, or jumping to conclusions that their practices are barbaric. (p. 17)

Earlier cultural deficit perspectives were reinforced by the popularity of two-group studies that compared samples of European Americans with ethnic/racial minorities and assumed that differences between the groups were cultural in nature. In effect, ethnicity and race were equated with culture as if all members of an ethnic/racial group were equally involved with the culture of their group. An assumption of these studies was that people of color needed to assimilate or become like European Americans to correct deficiencies in their development (Ramirez & Castaneda, 1974; Rogoff, 2003). More recently, the focus on families of color has shifted away from majority-minority comparisons toward within-group studies (Garcia Coll & Magnuson, 1999;

Parke, 2004b). Such studies tell us how within-group cultural variations may account for differences in outcomes among children of the same ethnic/racial group.

One of the problems in cross-cultural or intracultural research about different ethnic groups is the issue of the equivalence of measures across groups. Because most standard measures of family functioning are developed and standardized in White middle-class populations, efforts have been made to develop culturally and linguistically equivalent measures. One innovation is the use of focus groups consisting of members of the ethnic/racial group of interest to generate items and issues that are culturally relevant (De Ment, Buriel, & Villanueva, 2005; Gmel, Tinsley, Clark, & Parke, 1998; Vazquez-Garcia, Garcia Coll, Erkut, Alarcon, & Tropp, 1995). Focus groups are also being used as an integral part of the scale-construction process; they make recommendations for wording changes and identify culturally inappropriate items. Another innovation is the use of translation and back translation to ensure that the meaning is retained in the translation process. In addition, a dual-focus approach (Vazquez-Garcia et al., 1995) is being used in which new concepts and items that arise in the course of the translation process are generated simultaneously in both languages. Work by Knight and colleagues (Knight, Tein, Prost, & Gonzales, 2002; Knight, Virdin, & Roosa, 1994) have provided models for establishing scalar equivalence of commonly used questionnaires for assessment of family functioning. Recent advances in scaling have been applied to this issue as well. Specifically, Reise and his colleagues (Flannery, Reise, & Widaman, 1995; S. Reise, Widaman, & Pugh, 1993) have utilized item response theory (IRT) techniques to address the equivalence of scales across groups. The utility of this approach for establishing gender equivalence (Flannery et al., 1995) and cross-cultural equivalence (e.g., China versus the United States; Reise et al., 1993) suggests that this strategy can be used to establish scalar equivalence across different ethnic groups in our own culture.

The methodological issues involved in doing research with families of color are multifaceted (Bernal, Trimble, Burlew, & Leong, 2003; Betancourt & Lopez, 1993; McLoyd & Steinberg, 1998). In addition to language and scalar equivalence issues, other methodological issues need to be considered. First, families of color are comprised of diverse populations whose presence in the United States has come about through conquest (Ameri-

can Indians), involuntary immigration through slavery (African Americans), and voluntary immigration (Asian Americans and Latino Americans). The nature of these groups' incorporation into the United States has necessitated diverse adaptation strategies, making it useless to combine members of these groups into a single research sample. Even among contemporary immigrant groups, such as Mexican Americans and Chinese Americans, there are communities whose members have lived in this country for several generations. Consequently, researchers need to identify the generation of their samples and their length of U.S. residence (for immigrants) and to avoid overgeneralizations to all members of the group. Researchers must also not overgeneralize cultural characteristics from the country of origin to members of the group who have lived in the United States for generations and who have culturally adapted to new ecological challenges.

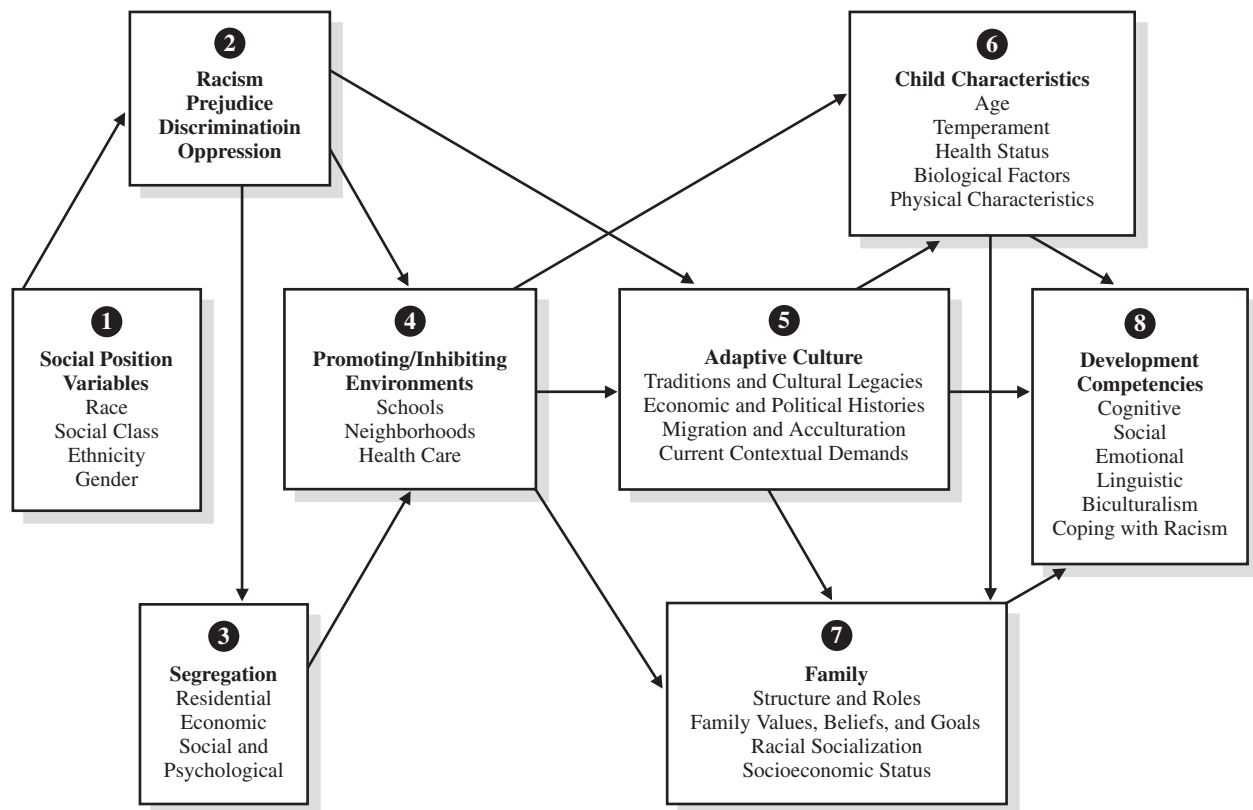

Among the dominant ethnic/racial groups in the United States, there is considerable within-group diversity related to national origin and tribal affiliation that could help researchers understand within-group differences in outcomes. For example, combining Korean Americans and Vietnamese Americans together as "Asian Americans," or Mexican Americans and Cuban Americans as "Latinos," can mask historical, language, and social class variables that may contribute to differences in outcomes among members of these groups. Researchers need to identify the national origins of participants in their ethnic/racial sample, and recognize any cultural and sociodemographic variables that may contribute to within-group differences.

The complexity of diversity means that some children of color either belong to two or more ethnic/racial groups or claim an identity that is not consistent with our ethnic/racial categorization system based primarily on color. For example, many biracial children, despite a phenotype of color, claim the ethnic/racial identity (and cultures) of both their colored and white parents. In other cases, children of color may claim an ethnic identity not typically associated with their phenotype. Thus, some Afro-Latinos from Puerto Rico or the Dominican Republic may self-identify as Latinos, whereas they are identified as African American on the basis their skin color. Researchers need to allow children and families of color to self-identify rather than to assume membership in a racial/ethnic group on the basis of phenotype or surname.

Many children of immigrant families learn English as their second language. Although many speak English at school, they may not be proficient in literacy skills such as reading and writing (Gandara, 1997; Hakuta, Butler, & Witt, 2000). It is imperative to obtain information about children's English language proficiency if they come from homes where parents are immigrants. One in five children in this country comes from homes where at least one parent is an immigrant (U.S. Census Bureau, 2002).

Sample specification should include information on social class, group density, and region of the country, as these variables can impact on within-group differences in outcomes. Social class, based on education and income, can differentiate members of a group sharing a common ethnic/racial identity. Social class can impact cultural orientations in counterintuitive directions, such as higher social class Mexican Americans engaging in more familism (Keefe & Padilla, 1987) and less utilization of professional child-care centers (Buriel & Hurtado-Ortiz, 2000). Due to immigration and mobility, regions of the country are experiencing population booms involving new groups of people of color, such as the influx of Latinos into the South and the Northeast. Because these new groups are acculturating in unfamiliar environments, lacking high densities of same-group members and familiar social supports, their acculturation pathways and outcomes may be different from those of group members in other parts of the country. Geographic location is also important to consider in research with mixed-race populations. As Root (1999) notes, for example, being Asian American and growing up in Honolulu is a different experience than growing up in Los Angeles or Minneapolis. Finally, researchers should take advantage of the natural experiments arising from immigration that produce emic- or group-specific behaviors that have not been considered in traditional developmental theories and models (Buriel, 2003; Parke, 2004b). Examples of research in this vein include children who interpret for their immigrant parents (Buriel, Perez, DeMent, Chavez, & Moran, 1998), Chinese-American reconstructions of the meaning of authoritative parenting as a form of training (Chao, 1994), and a heightened sense of family obligation among children of immigrants (Fuligni, Tseng, & Lam, 1999).

These diverse conceptual and methodological issues represent distal and proximal ecological factors impacting on the lives of children and families of color.

**Figure 8.4** Integrative model for the study of developmental competence in minority children. *Source:* “An Integrative Model for the Study of Developmental Competencies in Minority Children,” by C. Garcia-Coll et al., 1996, *Child Development*, 67, pp. 1891–1914.

Garcia Coll et al. (1996) have provided a conceptual model for studying developmental competencies in children of color that includes many of the ecological factors presented here (see Figure 8.4). This model outlines relevant sociocultural and demographic variables and their contribution to child outcomes.

#### ***Acculturation and Assimilation in U.S. Society***

European immigrants to the United States at the turn of the past century underwent acculturation and assimilation in their transformation into European Americans. Acculturation is a process of learning the language, values, and social competencies of the larger society. Assimilation is a possible outcome of acculturation that involves the replacement of the ancestral culture with the culture of the host society (Ramirez, 1983). As European immigrants and their descendants acculturated and replaced their immigrant culture with the mainstream culture, and were accepted as Americans by the larger society, they achieved assimilation. For most European immigrants, the process of

assimilation was completed by the second generation. Assimilation was motivated both by the desire to become part of the mainstream and to eliminate societal discrimination against ethnic immigrants (A. Portes & Rumbaut, 1990). Assimilation was aided by their European phenotype, which they shared with members of the larger society, who were themselves descendants of earlier English and German immigrants. Although ethnicity persists in varying degrees among assimilated European Americans, it is largely a symbolic ethnicity or an optional vestigial attachment to a few ethnic symbols that impose little cost on everyday life (Waters, 1990).

Racial, ethnic, and cultural variation from the European American mainstream remain enduring issues for peoples of non-European descent, including American Indians, Latinos, African Americans, and Asian Americans. Although these groups have been in contact with European Americans for centuries, and have acculturated to varying degrees, they have not assimilated. The non-European phenotype of these groups (and other

group markers related to physiognomy, religion, and social class) heightens awareness of their racial and ethnic “otherness,” that is associated with beliefs about their behaviors. Often, these beliefs are stereotypes that disparage the lives and cultures of ethnic/racial minorities and limit access to European American society (Padilla & Perez, 2003). According to some theorists, these forms of racism elicit reactionary behaviors that eventually become incorporated as part of the minority group’s culture. Ogbu (1991) describes the tendency of some “caste-like” minorities to develop secondary cultural characteristics that include an oppositional identity against the achievement values of European Americans. Jones (2003) theorizes that “Culture can be defined as both an antecedent and consequent of behavior” (p. 282), and as a result, “Reactions to racial biases and stereotypes *produce* the very racial differences that the stereotypes presuppose” (p. 282). As individual members of ethnic minority groups internalize European Americans’ stereotypes (Buriel & Vasquez, 1982), they may lead to self-fulfilling prophecies. Steele’s (1997) research on stereotype threat describes this situation with African Americans in test-taking situations. Racial stereotyping can also negatively affect young African American children’s occupational aspirations (Bigler, Averhart, & Liben, 2003).

### Socialization of Children of Color

As with most children, the socialization of children of color usually takes place in a family setting that includes adult caregivers. These adult caregivers are usually biological parents but may include grandparents, relatives, godparents, and other adults who are not biologically related to the children. In some Mexican immigrant families, older children have responsibility for the care and conduct of younger siblings (Valdes, 1996). In addition to ensuring children’s physical health and survival, parents attempt to inculcate in children values and behaviors that help them adapt to their environment as it is perceived by the parents. The parents’ history of interaction with the larger sociocultural context, including their awareness of their ethnic/racial group’s history in the larger society, affects the manner in which they socialize their children. An important dimension of socialization in ethnic minority families is teaching children how to interact effectively in dual cultural contexts; the context of their ethnic/racial group and the context of the larger European American society (Boykin & Toms,

1985). Harrison et al. (1990) have adopted an ecological orientation that views the socialization of ethnic/racial minority children by the interconnectedness between the status of ethnic/racial minority families, adaptive strategies, socialization goals, and child outcomes. Family status involves socioeconomic resources available to group members such as housing, employment, health care, and education. Despite considerable within-group diversity in SES, a growing number of ethnic minority children live in poverty (National Center for Children in Poverty, 2000). Adaptive strategies are the cultural patterns that promote the survival and well-being of group members. Some of these cultural patterns are adaptations of the original ethnic/racial culture to life circumstances in the United States. Other cultural patterns may arise as a result of coping with the conflicting behavioral demands of being an ethnic/racial minority in a predominately European American society. Thus, biculturalism, which is the simultaneous adoption of two cultural orientations, arose originally in response to conflicting cultural demands but is now part of what constitutes the ethnic minority/racial culture. Biculturalism, for example, characterizes the lives of many Mexican American and other ethnic/racial minorities (LaFromboise, Coleman, & Gerton, 1993). In addition to family extendedness and biculturalism, other adaptive strategies include role flexibilities and ancestral worldviews. Emerging out of the adaptive strategies of adults are the socialization goals that they endeavor to inculcate in children to help them meet the ecological challenges they will face as ethnic/racial minorities. Ethnic/racial pride and interdependence are two socialization goals that enable ethnic/racial minority children to function competently as members of both their minority and majority cultures (Harrison et al., 1990). Ethnic/racial pride imparts a sense of personal self-worth in the face of societal prejudice and discrimination (Walker, Taylor, McElroy, Phillip, & Wilson, 1995). Interdependence sustains effective intergroup relations that strengthen ethnic/racial group solidarity (Staples & Johnson, 1993).

### Families of Color

Between 1990 and 2000, all groups of people of color increased in size, whereas the number of Whites decreased from 80% to 75% of the U.S. population (U.S. Bureau of the Census, 2000). The percentage of African Americans and American Indians rose slightly from 12.1% to 12.3% and from 0.8% to 0.9%, respectively.

Asian Americans and Latinos had the greatest population increases in the past decade, growing from 2.8% to 3.6% and 9.0% to 12.5%, respectively. Latinos now are the largest minority group in the nation and account for more than half of all new births in California (Richardson & Fields, 2003). Whites have a higher median age and a smaller percentage of children under the age of 18 (37.7 years and 23.5%, respectively) than all groups of people of color: African Americans (30.2 years and 31.4%, respectively); American Indians (28 years and 33.9%, respectively); Asian Americans (32.7 years and 24%, respectively); and Latinos (25.8 years and 35%, respectively; U.S. Census Bureau, 2002). This demographic shift is visible in public schools where nationally approximately 40% of students in kindergarten through 12th grade are children of color (Young, 2002).

The growth of the Asian American and Latino populations was due in large measure to increases in immigration. Overall, foreign-born persons constitute 56 million people with more than half coming from Latin America and a quarter from Asia. In 1997, the majority (61%) of Asian Americans were born in foreign countries (U.S. Bureau of the Census, 1999; 2001b). As immigrant groups, Latinos and Asian Americans share common characteristics, including diverse subpopulations with distinct histories, non-English native languages, and relatively young age. Both groups include economic immigrants who seek a better quality of life and political immigrants who seek refuge from persecution in their countries of origin. Owing to their different motivations for immigration, economic and political immigrants may have different adaptation strategies that influence their socialization goals. For example, compared to economic immigrants, adult political immigrants expecting to return to their countries of origin may be more discouraging of their children's acculturation in areas such as individualism and autonomy (Rumbaut, 1995).

The influx of Latino and Asian immigrants into this country means that these two groups will be constantly characterized by within-group differences in generational status and degree of acculturation. First-generation immigrant parents generally acculturate more slowly than their children (Szapocznik & Kurtines, 1980), particularly after the onset of children's schooling. Yet, despite the more rapid acculturation of children in immigrant families, the socialization of these children is heavily influenced by the socialization goals of their parents' culture and the adaptive strategies de-

veloped by immigrants in this country. As the children of immigrants start their own families, their children, the third generation, are socialized in family ecologies that are socioculturally distinct from the ecologies of their parents. The generational status of parents and children contributes to variations in the ecologies of families that have implications for child rearing (Buriel, 1993b). The importance of generational status to diversity in family ecologies is illustrated with an example using Mexican Americans.

### *Generational Differences in Family Ecologies*

The first generation includes those persons born in Mexico who later immigrated to the United States. Some immigrate as single young adults or as married couples, whereas others are brought to this country as young children by their parents. Some parents immigrate with only some of their children, leaving the other children in Mexico under the care of relatives. As the parents' economic condition improves, children are brought to the United States. These children often experience multiple socializing influences in both Mexico and the United States. This transnational socialization experience may also give rise to a dual frame of reference for these parents and children (Perez, 2004; Valenzuela, 1999) that shapes how they perceive opportunities in the United States. At the time of immigration, adults have usually completed the extent of their formal education in Mexico, 7 years on average (Bean, Chapa, Berg, & Sowards, 1994), which is 1 year over compulsory education in Mexico. School-age immigrant children have usually begun their schooling in Mexico and then continue it in this country. Children with prior schooling in Mexico often achieve higher academic levels in U.S. schools relative to native-born Mexican Americans (Padilla & Gonzalez, 2001; Valenzuela, 1999). Preschool immigrant children begin and complete their schooling in the United States. Because these children's formative years are spent in the United States, they are often referred to as the "one and a half" generation. Family income is typically low in the first generation due to parents' lower education and limited knowledge of English. In the first 6 to 8 years after immigration, it is not uncommon for immigrants to live with families of relatives or friends (Blank, 1993; Chavez, 1990) who assist parents with child care. After 8 years, the rate of immigrant families living in single family households is about 75%, which is the same as for U.S. Mexican Americans (Blank, 1993). First-generation children are socialized

in home environments influenced by immigrant Mexican culture, which includes elements of Mexican culture, as well as the adaptive strategies of parents associated with the immigrant experience that parents convert into socialization goals (Buriel, 1993b; Delgado-Gaitan, 1994; Valdes, 1996). Elements of Mexican cultural socialization include familism, respect for adults, and interdependence among family and ethnic group members (Delgado-Gaitan, 1994; Rueschenberg & Buriel, 1989). Socialization goals related to the immigrant experience are self-reliance, productive use of time (Buriel, 1993b), and biculturalism (Buriel, 1993a). Immigrant parents and their children both prefer a Mexican ethnic identity (Buriel & Cardoza, 1993), and use Spanish as their primary home language. The parents' and other family members' exposure to English often comes through children's participation in the U.S. schooling system. As a result, many immigrant children serve as interpreters or "cultural brokers" for their parents, which means they are often given adultlike responsibility when acting as the family's representative to the outside English-speaking world. Child cultural brokers play an important role in helping immigrant families adapt and survive in a new environment.

The second generation represents the U.S. born children of immigrant parents. The family environments of these children are in many ways similar to those of their first-generation peers owing to the foreign-born status of their parents. There are some important differences between the two generations that are reflected in the sociocultural characteristics of the family. In some cases, the immigrant parents of second-generation children came to the United States as single young adults who later became partners in generationally endogamous marriages (Murguia, 1982). As a result, they have lived longer in the United States. In those cases where these parents came from Mexico as young children, they may have attended U.S. schools for some or all of their education. Cultural synergisms are most apparent in the families of second-generation children. Thus, although Spanish is usually the native language of second-generation children, English becomes their dominant language after the onset of schooling. However, Spanish continues as the primary language of parents, which creates a strong motivation for the development of bilingualism. Parents strongly encourage the learning of English (Esposito, 2004) but also stress the retention of Spanish as it is the language used to demonstrate respect to adults. Retention of Spanish may help to preserve parental au-

thority during the more rapid acculturation of children. Socialization of first- and second-generation children is similar, particularly in areas such as respect for adults, *personalismo* (Valdes, 1996), and family obligation (Fuligni et al., 1999). The academic achievement of the second generation is often higher than the third generation (Rodriguez, 2002). The second generation's life-long exposure to European American culture impacts on their child-rearing practices as adults. For example, the longer families live in the United States, the more socialization practices and child behavior shift in an individualistic direction, particularly in the area of critical thinking (Delgado-Gaitan, 1994). In the area of ethnic identity, foreign-born parents prefer a Mexican identity, whereas their second-generation children prefer either a Mexican American or Chicano identity (Buriel & Cardoza, 1993). Individuals calling themselves Chicano are more likely to be aware of prejudice against Mexican Americans, and to work through political avenues to improve the status of their group.

The third generation refers collectively to all persons of Mexican descent whose parents were born in the United States. This includes persons in the fourth and subsequent generations whose grandparents and great grandparents were born in this country. Due to immigration and birth rate differences between generations, third-generation children are in the minority in the Mexican American population (Edmonston & Passel, 1994). The third generation is distinguished from previous generations by the absence of any direct parental links to Mexico involving immigration. Consequently, socialization goals derived from immigrant adaptation strategies are not a direct part of the socialization experiences of these children (Buriel, 1993b). Nevertheless, because many members of this generation live in ethnic neighborhoods (*barrios*) populated by immigrants, socialization practices retain some immigrant influences. For example, familism, or the expectation of support from family members, continues as a socialization goal into later generations (Keefe & Padilla, 1987) even after controlling for SES (Sabogal et al., 1987). Persons in this generation are also socialized in homes where all family members are U.S. citizens, where English is the primary language (Lopez, 1982), where parental schooling has taken place exclusively in the United States, and where children and parents express a Mexican American ethnic identity (Buriel & Cardoza, 1993). Laosa (1982) theorizes that U.S. schooling alters the child-rearing practices of Mexican American parents. Mothers with

less education, who are likely to be immigrants, use more modeling to instruct children, whereas mothers with more schooling, who are likely to be native born, use more inquiry and praise to instruct children. This shift in teaching style occurs because more highly schooled mothers adopt the teaching style of school, which emphasizes inquiry and praise. Buriel (1993b) also found that among parents of third-generation children, parental schooling was associated with a child-rearing style involving more support, control, and equality. Divorce is more common among parents of third-generation children, which has implications for child socialization (Buriel, 1993b; Oropesa & Landale, 1995). Teacher ratings of Mexican American children indicate more school maladjustment in boys from single-parent (mothers only) homes than in boys from two-parent homes or in girls of either family type (LeCorgne & Laosa, 1976). Although family incomes are higher in the third generation, schooling outcomes are often lower than in the previous generation. Second-generation children complete more years of schooling and have higher educational aspirations than their third-generation peers (Buriel, 1987, 1994; Valenzuela, 1999).

**Acculturation.** Researchers have focused on the construct of acculturation in an effort to unpackage the cultural components of generational status that account for within-group diversity. Acculturation is the process of learning a new culture and is typically measured by increasing English proficiency, English media preferences, and European American friendships (Cuellar, Arnold, & Maldonado, 1995). Recently, the measurement of acculturation has included culturally related values, attitudes, and identity in acknowledgment of the multidimensional nature of this construct (Felix-Ortiz de la Garza, Newcomb, & Meyers, 1995). Multidimensional measures can provide information about the cultural processes associated with behavioral changes in immigrant groups, both within and across generations. The relative predictive power of generation and acculturation varies with the constructs under investigation. For example, acculturation may be a better predictor of ethnic identity than generation (Cuellar, Nyberg, Maldonado, & Roberts, 1997), whereas generation is a better predictor of students' academic achievement (Fuligni, 1997; Padilla & Gonzalez, 2001).

The developmental and socialization outcomes associated with generation and acculturation also have relevance for other U.S. ethnic/racial groups not typically

included in the category of immigrants. Landrine and Klonoff (1996) suggested that acculturation is useful for deconstructing race and reviving culture among African Americans, and have developed an African American acculturation scale. In addition, African American families moving from the ghetto into a predominately European American neighborhood may describe their experiences as having to adapt or acculturate to an all-White environment. The same set of experiences may also hold true for American Indian families moving off the reservation to live in a mostly non-Indian environment or for American Indian children attending government boarding schools off their reservation (Garcia Coll, Meyer, & Brillion, 1995).

Acculturation across generations is not a uniform process. In each generation, there is considerable diversity in individuals' involvement with both native and European American culture. In addition, acculturation is not a unidirectional process such that movement toward European American culture is necessarily associated with a corresponding loss of the native culture. Ecological variables such as degree of societal discrimination, educational and employment opportunities, and opportunities to participate in the native culture can all contribute to variations in both the rate and direction of acculturation across generations.

### *Bicultural Adaptation*

For Mexican Americans, the proximity of Mexico and the fact that the southwestern United States was once a part of Mexico create many opportunities for members of this group to participate in their native culture. For Latinos and Asian Americans, a high rate of immigration resulting in densely populated ethnic communities also creates powerful environmental influences for retention of many aspects of the native cultures. Finally, for all ethnic/racial minorities, a non-European phenotype triggers many societal stereotypes and prejudices that limit access to the larger society (Buriel, 1994). Padilla and Perez (2003) argue that a darker phenotype stigmatizes individuals, making it harder and even less desirable for them to acculturate. The combination of these environmental and ethnic/racial group influences differentially operate within and between groups, giving rise to adaptation strategies that do not conform to the assimilationist orientation of European immigrants. Instead, many ethnic/racial minority group members strive for a bicultural orientation that allows for selective acculturation to European American culture while

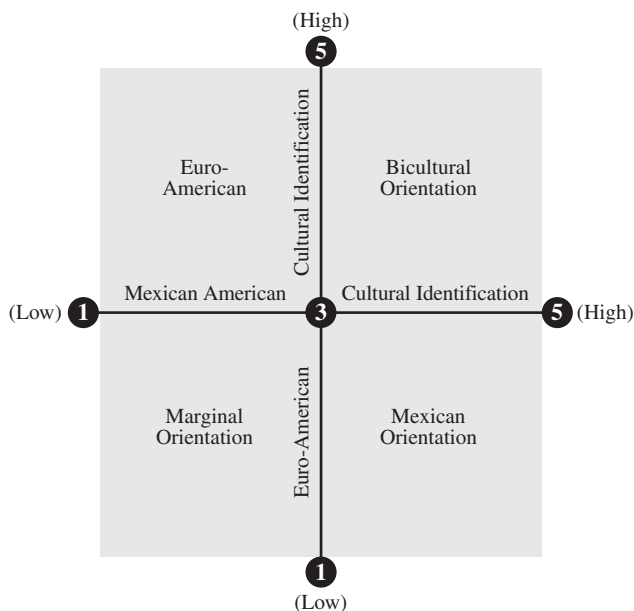

simultaneously retaining aspects of the native culture. This bidirectional adaptation strategy permits individuals to meet the dual cultural expectations that characterize the lives of ethnic/racial minorities as they move in and out of minority and majority cultural environments. The bicultural person learns to function optimally in more than one cultural context and to switch repertoires of behavior appropriately and adaptively as called for by the situation (Harrison et al., 1990). Although all ethnic/racial minority groups have expressed biculturalism in some form as an adaptive strategy (Harrison et al., 1990), most research has focused on immigrant groups, especially Mexican Americans (Chun & Akutsu, 2003; Chun, Balls Organista, & Marin, 2003).

Using Mexican Americans as an example, Figure 8.5 illustrates a bidirectional model of cultural adaptation. This bidirectional model posits four acculturation adaptation styles for Mexican immigrants and their descendants, depending on their involvement with both Mexican immigrant culture and European American culture. The four acculturation styles are: (1) the bicultural orientation, (2) the Mexican orientation, (3) the marginal orientation, and (4) the European American orientation. Ramirez (1983) has defined biculturalism as the simultaneous adoption of the language, values, and social competencies of two cultures. Because culture is multidimensional in nature, involvement in either culture can vary along different dimensions and at dif-

ferent rates. Cultural involvement is represented on a scale of 1 to 5. Thus, persons expressing a bicultural orientation are those above 3 in both Mexican and European American culture. The Mexican orientation is characterized by those individuals who are primarily involved in Mexican culture. This category usually includes many adult recent immigrants, as well as a few later-generation persons living in rural areas.

Also included in this category are the elderly parents of immigrants who are brought to this country to live with the families of their adult children after the children become financially stable. For the elderly, a Mexican orientation seems well suited to their life experiences, which at their stage in life, revolves around family and community rather than schooling and the workplace. The marginal orientation includes a minority of individuals who have become “deculturated” (Berry, 1980) from their ancestral culture and simultaneously alienated from European American society. Deculturation arises from society’s denigration of the ethnic/racial group and the internalization of society’s stereotypes of the group (Buriel, 1984). Ogbu’s (1987) description of Mexican Americans (as well as American Indians and African Americans) as caste-like minorities is probably accurate only for the minority of individuals who adopt a marginal orientation. For example, Vigil (1988) has described hard-core Mexican American gang members in terms characteristic of the marginal orientation. Non-gang members are described as expressing either a traditional or bicultural orientation. Individuals in the European American quadrant of the bidirectional model are those who are primarily involved and identified with European American culture; their preference for friends, language, and social activities are those characteristic of European American culture.

To date, most empirical research on acculturation and biculturalism has been done with adult and adolescent samples. More research is needed with young children to better understand the developmental pathways to bicultural competency (Buriel, 1993a). Some research indicates that ethnic/racial minorities who develop bicultural competencies have better physical and psychological health than those who do not (Buriel & Saenz, 1980; Chun et al., 2003; LaFromboise, Coleman, & Gerton, 1993). Gutierrez and Sameroff (1990) found that mothers’ biculturalism is positively associated with the complexity of their concepts about children’s development and that more acculturated and more bicultural mothers scored higher in their concepts of development.

**Figure 8.5** Bicultural model of acculturation.

Mothers who were the most bicultural had the highest concept of development scores when compared to the other Mexican American mothers and a sample of highly acculturated European American mothers. They concluded that bicultural mothers have insights into two cultures and realize that child development beliefs associated with each culture are appropriate in different contexts in the same society. LaFromboise et al. (1993) connect biculturalism to self-efficacy theory (Bandura, 1977) by using the term *bicultural efficacy* to describe the belief, or confidence, that one can live effectively, and in a satisfying manner, in two cultural groups without compromising one's sense of identity.

### ***Emic Developmental Research Issues***

Immigrants and their children face many sociocultural adaptation challenges that have implications for parenting and child development. Psychology's interest in immigrant groups has generally been threefold. First, to document between-group differences in constructs and measures developed on European American populations (Ramirez, 1983). These studies often erroneously equate race/ethnicity with culture, and conclude that differences are due to culture. A second research line attempts to extend theories, also developed on European Americans, to immigrant groups and their descendents (Parke et al., 2004). The goal is to understand how culture affects the hypothesized pattern of relationships between variables for the different groups and to adjust the theories accordingly. A third area involves identification of emic or unique aspects of a group's behavior arising from the immigrant experience itself. Three experiences common to immigrant families and children include language and cultural brokering, children as family workers, and dual frames of reference.

**Language and Cultural Brokers.** It is estimated that approximately one in every five children in the United States comes from a home where at least one parent is of foreign birth (Federal Interagency Forum on Child and Family Statistics, 2002). Most of these children are the first members of their families to learn English and attend U.S. schools. As a result, these children are often delegated adultlike responsibilities by their parents, such as interpreting and making decisions with English-speaking agents that affect the whole family (Chao, 2001; DeMent, Buriel, & Villanueva, 2005; Orellana, Dorner, & Pulido, 2003; Tse, 1995, 1996;

Valdes, 2003). "With responsibility as interpreters of the new culture and language, immigrant children are often in a position with no one to translate or interpret for them. Traditional intergenerational authority relationships change and the child also becomes very involved in the worries and concerns of the family, such as hassles with landlords, arranging for medical care, and dealing with the legal system" (Olsen & Chen, 1988, p. 31). Children who serve as interpreters for their non-English speaking parents are referred to as "language brokers." Because these children of immigrants represent the link between their parents' culture and European American society, they can also be considered "cultural brokers."

Child cultural brokers are unique because in addition to the stress related to their own acculturation, they experience additional stressors arising from their role as mediators between their parents and U.S. society. In public, child cultural brokers act with adult authority on behalf of their parents, but at home they are expected to behave as children and show deference and respect to parents. These conflicting expectations and responsibilities represent a form of role strain that may raise children's anxiety to debilitating levels and lower their general well-being. The stress connected to language brokering may be particularly pronounced among young children because their cognitive and social capacities are still in the early stages of development (Weisskirch & Alva-Alatorre, 2002). However, among adolescents, there is little evidence that language brokering is associated with psychological distress (Buriel, Love, & DeMent, in press), particularly among girls. In some groups, such as Mexican Americans, language brokering seems to be associated more with the gender role responsibilities of girls (Buriel et al., in press). In addition, a strong affective parent-child bond buffers adolescents against stress connected to language brokering (Buriel et al., in press).

Language brokers act as adults in interactions with their parents, which often gives rise to role reversals involving the transmission of information. Language brokers must sometimes teach parents things about the new culture while still demonstrating deference and respect consistent with their status as children. Child language brokers must assume a higher-status teaching role without causing parents to lose face in public or in the family. The instructional demands inherent in brokering are thus likely to promote instructional strategies by chil-

dren that achieve the transmission of information to adults without causing embarrassment to parents. Based on her in-depth study, Valdes (2003) concluded that parent and child act as a team in a language brokering situation "to present the impression of the parent that will be most effective in a given context and that will evoke positive responses from majority individuals" (p. 96). Drawing on Gardner's theory of multiple intelligences, Valdes (2003) argues that competent language brokers exhibit multiple types of cognitive, social, and interpersonal intelligences and should therefore be considered "gifted." Buriel et al. (1998) found that among Latino adolescents, more language brokering was associated with greater biculturalism and more social self-efficacy. Children who broker in diverse settings such as stores, banks, hospitals, and schools have more opportunities to develop accelerated linguistic, cognitive, and interpersonal skills and have higher school grades.

Tse (1995) notes that unlike formal translators, language brokers sometime influence the content and nature of the messages they convey between adult parties. They sometimes favorably paraphrase messages between teachers and their parents. In addition, given their greater knowledge of U.S. culture, language brokers are often assigned responsibility for making decisions with English-speaking agents that affect the entire family (DeMent et al., 2005; Olsen & Chen, 1988). Thus, as a result of the language-brokering role, there is the potential for the modification of traditional intergenerational authority relationships in immigrant families. However, the strong sense of family obligation in immigrant families (Fuligni, Tseng, & Lam, 1999) may mitigate the threat to authority relationships. Rather than threatening parental authority, greater language brokering is associated with a stronger parent-child bond (Buriel et al., in press).

**Children as Family Workers.** Family obligation and duty to family are strong values among immigrant children from collectivist cultures (Fuligni et al., 1999). The operationalization of these values often takes the form of young children devoting time assisting parents in their occupations. This assistance, however, is viewed not so much as helping parents as much as contributing to the welfare of the entire family. These work-related situations involve shared parent-child activities that can influence children's perceptions and values about work, family relations, and gender roles.

In addition to household chores, children in immigrant families often assume adultlike responsibilities as workers whose labor is beneficial, and sometimes essential, to the financial well-being of the family (Orellana, 2001). Many immigrants work in manual and service labor occupations where it is not unusual to "bring children along" to help with the work and make extra money. In the past, when Mexican immigrants were involved mostly in agricultural labor, children often worked in the fields with their parents. This situation still exists today, especially during summers, but at a lesser scale due to child labor laws. More typical today, however, is the situation of children working with parents in service and manual labor sectors in jobs such as masonry, gardening and landscaping, painting, construction, cleaning, restaurants, street vending, auto shops, and cottage industries pertaining to garment work and food preparation.

The constructs of parent involvement, family cohesion, and parent-child bonding are typically examined in the context of routine domestic activities and recreation experiences. However, for many immigrant families, economic survival creates roles for children that may promote parental involvement and contribute to family cohesion and parent-child bonding in work-related settings. From a social learning perspective, children in family worker roles may have more opportunities to develop personal responsibility, autonomy, and self-efficacy by observing and modeling their parents in work-related activities. The topic of children as family workers is an area arising from the immigrant experience that deserves further attention.

**Dual Frames of Reference.** The immigrant adaptation experience may give rise to a dual frame of reference that allows immigrant children to compare their socioeconomic and cultural status in the United States to their past situation in their country of origin. A dual frame of reference has been discussed in various contexts as an enabling quality that gives foreign-born children higher expectations and feelings of positive self-worth relative to their native-born counterparts (Ogbu, 1991; Suarez-Orozco & Suarez-Orozco, 1995). Although economically poor by U.S. standards, the families of immigrant children experience an immediate increase in their SES on arriving in this country, leading to a relative interpretation of their deprivation. This can bolster the family's sense of optimism and

expectations for the future. For example, many immigrant children are frequently exhorted by their parents to take advantage of the opportunities in this country, including education (Perez, 2004; Valenzuela, 1999), and constantly reminded of the hard economic conditions they left behind in their native country. A dual frame of reference may buffer children against the psychologically damaging effects of societal prejudice and discrimination. By having been raised in a culturally supportive environment in their native country, immigrant children have a frame of reference to counter the often negative stereotypes ascribed to many immigrant groups in this country (Buriel & Vasquez, 1982; Perez, 2004). A dual frame of reference represents a useful psychological mechanism for understanding generational differences in school achievement, motivation, and feelings of self-worth.

### *Socialization Concerns in Ethnic Minority Families*

**African American Families.** Today, approximately 96% of all African Americans are descendants of enslaved people (Reed, 1982) who exhibited extraordinary resiliency to survive in this country without benefit of any human rights. The socially disruptive effects of slavery were felt in all spheres of life, including family formation and functioning. According to M. Wilson (1992), the focus on African American family research has shifted from a pathological/disorganizational model to a strength/resilient model. This shift is characterized by (a) an examination of African Americans in an African American sociocultural context, (b) a consideration of the role of grandmothers and other extended family members in child-rearing activities, and (c) an analysis of the presence of fathers rather than their absence in the family. To this list can be added the role of grandfathers in the transmission of family values and beliefs (McWright, 2002).

"The African American family is a term used to characterize a group of people who are biologically and spiritually bonded or connected and whose members' relations to each other and the outside world are governed by a particular set of cultural beliefs, historical experiences and behavioral practices" (Nobles, Goddard, Caviel, & George, 1987, p. 22). Sudarkasa (1993) notes that to understand African American families, households, and children, it is important to understand that these groupings evolved from an African family structure where coresidential families were the norm. The type and quality of adaptations to enslave-

ment and life in America were perhaps facilitated by the West African heritage of African Americans. From her studies of West African culture, she contends that African extended-family traditions may have proved useful in preserving family ties and for the socialization of children in the face of the disruptive aspects of slavery and its aftermath. Characteristics of African American extended-kin systems include: (a) a high degree of geographical propinquity; (b) a strong sense of family and familial obligations; (c) fluidity of household boundaries, with great willingness to absorb relatives, both real and fictive; (d) frequent interaction with relatives; (e) frequent extended-family get-togethers for special occasions and holidays; and (f) a system of mutual aid (Harrison et al., 1990; Hatchett & Jackson, 1993). Some may surmise that extended-kin behavior among African Americans is a response to poverty rather than an authentic cultural characteristic of the group. However, higher-SES African Americans have greater activity within-kin networks than their lower-SES counterparts (H. McAdoo, 1978). This suggests that higher-SES African Americans continue to derive physical and psychological benefits from these behaviors. Boykin (1983; Boykin & Toms, 1985) has noted similarities between the West African traditions of spirituality, harmony, affect, and communalism and African American culture.

The influence of the extended family among African Americans is important because of the large number of female-headed households that require child-rearing assistance and economic support (M. Wilson, 1992). The proportion of African American households with elderly heads that have young family members is also high, numbering about one in three families (Pearson, Hunter, Ensminger, & Kellam, 1990). When coupled with the fact that many African American grandparents live in close proximity to their married children and families, African American grandparents have many opportunities to influence the development of their grandchildren. Pearson et al. (1990) found that in multigenerational households, mothers were the primary caregivers, followed by grandmothers and then fathers. Grandmothers also showed more supportive behaviors in mother-grandmother families than in mother-father-grandmother families. In mother-absent families, grandmothers were more involved in control and punishment of children. Tolson and Wilson (1990) found that the presence of grandmothers in African American families

increases the moral-religious emphasis in the household. Nobles et al. (1987) note that such religious emphasis helps to sustain the African American family and reinforce the sense of family and family solidarity. Although some research suggests that children are better adjusted in grandmother households (Staples & Johnson, 1993), other research suggests that intergenerational conflict may offset the positive effects of grandmother presence. Using systematic observation measures, Wakschlag, Chase-Lansdale, and Brooks-Gunn (1996), found that mothers whose interactions with their *own* mothers were characterized by an open, flexible, and autonomous style, provided their children with more competent parenting. In addition, grandmother directness (e.g., nonconfrontational or assertive maturity demands) was positively related to problem parenting, whereas grandmother emotional closeness was negatively associated with problematic parenting. These results were strongest when the mother and grandmother were not living together, suggesting that intergenerational modeling effects of parenting may occur more readily from a distance. In a compensatory situation where mothers must live with grandmothers, shared child rearing may contribute to tensions between the two adults, which may have negative implications for children. In situations where fathers live with mothers and grandmothers, paternal involvement with caregiving activities is associated with positive relationships with mothers and grandmothers (Krishnakumar & Black, 2003). When grandmothers reported a positive relationship with both mother and father, the mother reported a positive relationship with the father, leading the authors to suggest that grandmothers may play a gatekeeping role in these intergenerational families (Krishnakumar & Black, 2003).

The role of grandfathers has also begun to receive attention. Given that two-parent households were the plurality in the African American community before 1980, many grandfathers are currently involved in the socialization of grandchildren. In a study of the transmission of family values through the use of proverbs, McWright (2002) found that grandfathers' influence was greatest in the area of family connectedness.

Male-present households were the norm in poor African American communities in the period between 1880 and 1925 (Staples & Johnson, 1993). Until the 1980s, most African American families included two parents; today, approximately 35% of all African

American children live in two-parent families (U.S. Census Bureau, 1998). According to R. Hill (1988), this decline occurred as the result of economic recessions in the 1970s, which were experienced as depressions in the African American community. Despite the statistical norm of two-parent families until recently, most research on African American fathers focused either on fathers' absence or their maladaptive responses to familial roles (Bowman, 1993). More research is beginning to focus on African American husband/fathers who remain with their families and document their high level of involvement in child rearing, family decision making, as well as the economic provider. J. McAdoo (1993) notes that African American spouses share equally in the major decisions in the family. From an exchange theory perspective, cooperation in decision making has been essential because in most families both spouses have had to work to overcome the lower wages earned by the husband (J. McAdoo, 1993.).

Previous research suggests that persistent economic marginality among African American fathers may lessen their perceptions of the quality of family life and contribute to their separation from their families (Farley & Allen, 1987; W. Wilson, 1987). Bowman (1993) has adopted a role strain model to investigate how African American males perceive economic marginality and how cultural resources facilitate adaptive coping. Subjective cultural strengths, which are transmitted across generations, appear to reduce harmful effects of provider role barriers among husband-fathers and to facilitate coping. African American husband/fathers were much more likely to have jobs (75%) than unmarried fathers (58%); joblessness is a major factor distinguishing unmarried fathers from traditional husband/fathers. Education and employment opportunities are increasing the population of middle-income African American families. However, research with such families is lagging. Due to discrimination, middle-income African American parents face difficulties not encountered by affluent parents of some other racial groups. According to Strom and colleagues (2000), affluent fathers who grew up in low-income areas teach children to distinguish between right and wrong and to expect punishment for breaking rules. As a result, adolescents saw their fathers as overly strict and seldom or never patient. Interestingly, fathers agreed with their children's assessment. Smetana and Chuang (2001) also found that middle-class parents rated limiting adolescents' behavior as more important

than encouraging independence, suggesting that parents view firm limits necessary to maintain social order given their particular social ecology.

Working-class African American fathers use more physical than verbal discipline and deliver it in accordance to the transgression's consequences rather than the child's intent (Staples & Johnson, 1993). Although these parents use physical discipline, they rarely couple this with withdrawal of love from children, which may eliminate some of the anxiety and resentment associated with this method. Because African American socialization stresses obedience to adults and physical discipline, parents have often been described as harsh, rigid, and strict (P. Portes, Dunham, & Williams, 1986). The disciplinary style of African American parents is sometimes referred to as being parent centered rather than child centered because it does not focus on the desires of the child (Kelley, Power, & Wimbush, 1992). These descriptions fail to take into account the settings in which parents raise children and the adaptive value of this approach to child rearing. Growing up in dangerous neighborhoods brings with it greater risks for involvement in antisocial behavior. Under these circumstances, strict obedience to parental authority is an adaptive strategy that parents may endeavor to maintain through physical discipline (Dodge, McLoyd, & Lansford, 2005; Kelley et al., 1992). This disciplinary method may also serve to impress on children the importance of following rules in society and the consequences incurred from breaking those rules when one is a member of an ethnic/racial group that is unfairly stereotyped as violent (Willis, 1992). There is considerable diversity in the disciplinary methods used by African American parents. Younger mothers raising their children alone use more physical discipline. Mothers with less education use more restrictive disciplinary practices that include insensitivity, inflexibility, and inconsistent parental behavior. Mothers who are more involved in organized religion also express more child-oriented disciplinary attitudes (Kelley et al., 1992). According to Whaley (2000), African American parents' use of spanking is more a consequence rather than a cause of problem behaviors, unlike European American families where the positive association between spanking and child behavior problems is bidirectional.

An important socialization goal of many ethnic minority parents is fostering a sense of ethnic/racial pride in children (Harrison et al., 1990). Some parents believe that for their children to successfully confront the hos-

tile social environment they will encounter as African Americans, it is necessary to teach them to be comfortable with their Blackness (Harrison, 1985; Peters, 1985). Bowman and Howard's (1985) study of a national sample of African American three-generational families indicated that the manner in which parents oriented their children toward racial barriers was a significant element in children's motivation, achievement, and prospects for upward mobility. Parents of successful children emphasized ethnic pride, self-development, awareness of racial barriers, and egalitarianism in their socialization practices. Using a national sample, Thornton, Chatters, Taylor, and Allen (1990) also report that two out of three African American parents indicate that they either spoke or acted in a manner intended to racially socialize children. African American parents envisioned racial socialization as involving messages regarding their experiences as minority group members, themes emphasizing individual character and goals, and information related to African American cultural heritage. In addition, Thornton et al. (1990), found that (a) older parents were more likely than younger parents to view racial socialization information as a necessary element of socialization; (b) that mothers were more likely than fathers to educate children about race; (c) that never-married parents both women and men, were less likely than their married counterparts to racially socialize their children; (d) that fathers in the Northeast were more likely than those in the South to racially socialize children; and (e) that mothers living in racially integrated neighborhoods were more likely to socialize their children to racial matters than were mothers living in all-African American communities. Murray and Mandara (2002) found that African American youth exposed to race empowerment strategies were higher in racial identity and self-concept than those exposed to a race-defensiveness strategy, which taught dislike of other groups and the usefulness of acting White. They conclude that, "a proactive racial socialization agenda buffers and prepares African American children to face the challenges of racial discrimination" (p. 89).

**American Indian Families.** In the recent past, American Indians were known as the "Vanishing Americans." Since 1940, however, the American Indian population has increased at every census count. The Indian population was 345,000 in 1940, but in 2000 numbered over 2,400,000 American Indians and Alaskan Natives (U.S. Census Bureau, 2002). American Indians are a so-

cioculturally diverse group consisting of over 450 distinct tribal units who speak over 100 different languages (Trimble & Medicine, 1993). Typically, American Indians prefer their tribal designation over American Indian (Burgess, 1980). The Navajo of New Mexico and Arizona are the largest tribe, with more than 170,000 members. Other large tribes include the Cherokee, the Sioux, the Chippewa, the Aleuts, and the Eskimos.

Today, approximately 70% of American Indians live off reservations (Banks, 1991), mostly in urban areas, although most research on American Indians focuses on those living on reservations. Due to cultural differences and discrimination, many American Indians have a difficult time adjusting to life in urban areas. For this reason, many reservation American Indians who migrate to urban areas tend to settle in cities and towns near reservations and to maintain contact with their family on the reservation (Banks, 1991). Such living arrangements close to the reservation are more conducive to the development of biculturalism than when Indians live in large urban areas removed from reservations. Contact with European Americans and other cultural groups, such as Latinos, has introduced changes in traditional Indian values and behaviors. Consequently, it is necessary to consider level of acculturation in research involving American Indians even though most studies with American Indians describe the tribe (e.g., Navajo or Sioux) without reference to the study participants' level of acculturation.

American Indian families may be characterized as a collective cooperative social network that extends from the mother and father union to the extended family and, ultimately, the community and tribe (Burgess, 1980). American Indian tribes are resilient in that they have withstood attempts at extermination, removal from their traditional lands, extreme poverty, removal of their children to boarding schools, loss of self-governance, and assimilationist policies aimed at destroying Indian languages, traditions, dress, religions, and occupations (Harjo, 1993). A strong extended-family system and tribal identity characterizes many urban and rural American Indian families (Harrison et al. 1990). American Indian patterns of extended family include several households representing significant relatives that give rise to village-like characteristics even in urban areas. In such families, grandparents retain an official symbolic leadership role. Children seek daily contact with grandparents, who monitor children's behavior and have a voice in child rearing (Lum, 1986). Despite the many

social problems faced by these families (e.g., poverty, alcoholism, accidents, and adolescent suicide) the majority are two-parent families. In 1990, nearly 7 out of 10 American Indian families included married couples living together (U.S. Census Bureau, 1995).

Although there are variations among tribes in their value orientations, some common themes can be characterized as traditional American Indian values. These include (a) present-time orientation—a primary concern for the present and acceptance of time as fluid and not segmented; (b) respect for elders—with age comes experience that is transmitted as knowledge that is essential for group survival and harmony in life; (c) identity with group—self-awareness has meaning only in the context of the family and tribe so that the interests of the family and tribe are the same as one's own self-interest; (d) cooperation and partnership—among the Pueblo Indians a common saying is "Help each other so the burden won't be so heavy" (Suina & Smolkin, 1994, p. 121); (e) the concept of partnership is stressed as the desirable way of conducting most activities; and (f) living in harmony with nature—nature, like time, is indivisible, and the person is an integral part of the flow of nature and time.

Traditional American Indian values constitute a worldview that is fundamentally different from Western assumptions about the "proper" relationships among people, the environment, and time. Trimble and Medicine (1993) argue that in its present form, psychology cannot properly describe and explain traditional-oriented American Indian affective and behavioral patterns. A traditional-oriented American Indian worldview represents an "indigenous psychology" (U. Kim & Berry, 1993; Ramirez, 1983) that can only be understood when examined from ecological and sociohistorical perspectives that do not assume the superiority of a Western worldview. For example, in the Iroquoian language, uncles and aunts are called fathers and mothers, respectively. This naming practice implies that parenting is spread across several extended family members. Thus, the parents' primary role in tribal culture is to give children affection and support, whereas supervision and discipline are usually provided by aunts and uncles (Machamer & Gruber, 1998). This may lead to the misperception that parenting is permissive when viewed from a nuclear family perspective. When viewed from an extended family perspective, however, parenting involves both affection and the setting of limits. According to Machamer and Gruber (1998), "the loss of extended family by American Indian

adolescents as a result of out-migration (from reservations) signifies the loss of a principal mechanism through which values are transmitted and accountability is learned and enforced" (p. 367). Differences in world-views represent important theoretical, conceptual, and methodological challenges facing researchers studying American Indian populations (see Table 8.1). Methodological and ethical considerations are beginning to receive attention in the literature (Hudson & Taylor-Henley, 2001; Stubben, 2001).

In traditional-oriented Indian culture, the uses of knowledge and learning are prescribed to help individuals live fulfilling lives as fully integrated members of the family and tribe. For example, among the Navajo, knowledge is organized around three life goals. First, there is knowledge that lasts throughout one's lifetime and concerns language, kinship, religion, customs, values, beliefs, and the purpose of life (Joe, 1994). This kind of knowledge is usually taught informally and using a variety of sources. Among the Pueblo Indians, teaching and learning at this stage is thought to be the responsibility of all Pueblo members (Suina & Smolkin, 1994). The sec-

ond area of knowledge involves learning an occupation or the means to making a living. This learning often requires an apprenticeship and involves a narrower range of teaching experts such as herders, weavers, and hunters. Learning is through listening, watching, and doing, with a strong emphasis placed on modeling and private practicing of the emerging skill (Suina & Smolkin, 1994). At this stage, children learn the appropriate context for the use of their knowledge. The person learns how knowledge is enmeshed with the history, culture, and survival goals of the tribe. The third category of knowledge is the most restrictive because it is reserved for those interested in becoming healers and religious leaders (Joe, 1994). These are lifetime commitments involving specialized instruction that is usually in addition to learning other means of livelihood.

Differences in the uses and value of knowledge and education have implications for the relative effectiveness of tribal schools versus public schools. Because tribal schools are embedded in a supportive cultural context, they may ameliorate the cultural conflicts in classrooms that can arise when children attend public schools

**TABLE 8.1 American Indian Culture versus Dominant Culture Values**

American Indian Culture	Dominant Culture
Support of large extended family	Support of, and from, immediate family
Slower, softer speech	Louder, faster speech
Avoids speaker and listener with little or no eye contact	Addressed listener directly, often by name
Interjects less	Interrupts frequently
Deep sense of humor	Light humor
Allows time for thought	Gives instant answers to questions
Nonverbal communication prized	Verbal skills highly prized
Cooperation	Competition
Group needs are most important	Personal goals are most important
Harmony with nature	Power and control of nature
Control of self not others	Control of self and others
Sharing, keep only what one needs	Material things are important
Time is here, be patient	Time is very important, get things done
Noninterference	Need to control all
Patient, allows others to go first	Aggressive and competitive
Talk about good things before criticizing	Criticism is immediate, blunt, to the point
Group-centered society; group emphasis	Individual-centered society, self-emphasis

where they are exposed to societal values and prejudices. Wall and Madak (1991) found that students attending tribal schools felt that their parents and favorite teacher held higher educational aspirations for them than their peers in public schools. The greater family connectedness found on reservations is also positively associated with more favorable attitudes toward school and less risk-taking behavior among adolescents (Machamer & Gruber, 1998). Public schools may subscribe to academic expectations and practices that are at variance with American Indian learning styles, which can contribute to poorer achievement and lower motivation. Delpit (1995) notes that the American Indian prohibition against speaking for others makes tasks such as writing summaries or book reports difficult for some American Indian children. When given such assignments, American Indian children often prefer to write about their own experiences (Delpit, 1995) and their families' experiences, especially those of their grandparents.

The establishment of boarding schools for American Indian children, far removed from the reservation, was an attempt to destroy traditional child-rearing practices (Harjo, 1993). Between 1890 and 1920, children were forcibly removed from their families for up to 12 years, and parents and relatives were not allowed to visit children during the school year (Harjo, 1993). From 1920 to the 1970s, boarding schools were still a usual part of the childhood and adolescent experience of most American Indian children. Among the many deleterious effects of boarding schools was the deprivation of children from adult parenting models and an undermining of parental authority. Several boarding schools currently exist, although attendance is voluntary. Today, many American Indian grandparents and parents are products of government boarding schools, which impacts on the quality of their parenting. Having been deprived of a parent-child relationship during their childhood, many American Indian parents now experience problems in relations with their own children. Child abuse, particularly in the form of neglect, is cited as a major reason for the removal of Indian children from their families and tribes. American Indian children are placed out of homes at a rate five times higher than other children (Harjo, 1993; Spicer, 1998).

Two major concerns of some tribes are infant health and the child-rearing abilities of adolescents, which are critical for the tribes' survival (Berlin, 1987). American Indian teens are nearly two and a half times more likely to become pregnant before reaching their 18th birthday.

Although infant death at birth is among the lowest of any racial/ethnic group, the rate of sudden infant death syndrome (SIDS) is three times the national average. In addition, due to high rates of alcoholism, American Indian children have a 500% greater chance of being born with Fetal Alcohol Syndrome (Fuller, 2004). Indian Health Services and greater tribal self-determination in the areas of education (the Indian Self-Determination and Education Assistance Act of 1975), family life (The Indian Child Welfare Act of 1978), and culture (The American Indian Religious Freedom Act of 1978) have made it possible for some tribes to sustain healthy families and to recover traditional child-rearing practices. The role of fathers in the socialization of children, especially boys, has special implications for the survival of tribal cultural traditions. An exploratory study with Ojibwa families found a positive association between the amount of time fathers spent as primary caregivers and their sons' academic performance and social development (Williams, Radin, & Coggins, 1996). In addition, fathers with more paternal involvement also had fathers who participated more in their own upbringing. The significance of father involvement for cultural survival may arise from the expectation that as boys grow into adulthood they will assume gender-prescribed leadership roles and therefore need appropriate role models. Leadership expectations for their sons may promote greater father participation in child rearing because fathers are more involved in community leadership activities (Williams et al., 1996).

Zimmerman, Ramirez, Washienko, Walter, and Dyer (1998) have proposed an "enculturation hypothesis" to explain how involvement with American Indian culture buffers children from the negative effects of acculturation, which is associated with alcohol and substance abuse. They developed an empirically derived measure of enculturation that included, (a) cultural affinity, (b) family activities, and (c) Native American identity. In their research with Odawa and Ojibwa tribal members, they found that cultural affinity positively predicted youths' self-esteem. Youth with the highest levels of self-esteem and cultural identity had the lowest levels of alcohol and substance abuse, which was consistent with the enculturation hypothesis. Zimmerman et al. (1998) concluded that enculturation is an important protective factor for American Indian youth. The findings also have implications for preventing depression and reducing suicide, which is three times the national average among American Indian youth (Fuller, 2004).

**Asian American Families.** The Asian American population includes people from 28 Asian countries or ethnic groups. It is a very diverse group in terms of languages, cultures, number of generations in the United States, and reasons for immigrating to the United States. The first Asian immigrants came from China in the 1840s. However, due to discriminatory immigration policies against Asians, the number of Asian Americans remained low until recently. The growth of the Asian American population in recent years has been accompanied by shifts in ethnicity and national origin. Before 1970, Japanese Americans were the largest Asian ethnic group (41%), followed by Chinese (30%), and Filipinos (24%). Today, the largest groups, in millions, are Chinese Americans (2.7), Filipino Americans (2.4), Asian Indians (1.9), Vietnamese Americans (1.2), Korean Americans (1.2), and Japanese Americans (1.1; U.S. Census Bureau, 2002).

Historically, Japanese, Chinese, and Filipino immigrants came to the United States primarily to improve their economic status. However, Indo-Chinese have arrived primarily as political immigrants or refugees. At the end of the Vietnam War in 1975, 130,000 refugees found asylum in the United States. Beginning in 1978, a massive flow of Indo-Chinese refugees (boat people or second wave) occurred, abruptly ending in 1992 (Rumbaut, 1995). Refugees may suffer more psychological problems and have a more difficult time adjusting to life in the United States than economic immigrants. They tend to experience more undesirable change in the process of acculturation, a greater threat of danger, and a decreasing sense of control over their lives (Rumbaut, 1991).

Little research exists on the structure and process of Asian American families. Most studies have sampled from Chinese and Japanese American populations. Often, examination of Asian American families' socialization processes is for the purpose of identifying the family characteristics that contribute to children's academic performance (Huntsinger & Jose, 1995; Huntsinger, Jose, & Larson, 1998). Of late, research on the adaptive strategies and socialization goals of Asian American parents that bears on the socioemotional development of children has received more attention (see Okagaki & Bojczyk, 2002, for a review). Discussions of Asian American families usually invoke Confucian principles to explain family structure and roles. Confucius developed a hierarchy defining a person's roles, duties, and moral obligations in the state. This hierarchical

structure is also applied to the family, and each member's role is dictated by age and gender. Typically, Asian American families are seen as patriarchal, with the father maintaining authority and emotional distance from other members (Ho, 1986; Wong, 1988, 1995). Traditionally, the family exerts control over family members, who are taught to place family needs before individual needs. Children show obedience and loyalty to their parents and, especially for male children, are expected to take care of elderly parents (filial piety). In many Asian countries, subjugation of personal will to elders is an indicator of maturity and persists in intergenerational relationships among Asian American adolescents (Ying, Coombs, & Lee, 1999). Confucian influences on family life are stronger in some Asian American populations (e.g., Chinese and Vietnamese) than others (e.g., Japanese) due to differences in immigration patterns and degree of Westernization of the country of origin. Length of U.S. residence and acculturation also contribute to extensive within-group differences in family structure and roles. Kibria (1993) found that large Vietnamese families varying in age and gender fared better economically than smaller nuclear families. The larger extended family enabled households to connect to a variety of social and economic resources. In Vietnamese families, the kin group is seen as more important than the individual. This perspective has its source in Confucian principles, especially ancestor worship (Kibria, 1993). Ancestor worship for Vietnamese Americans consists of devotion in caring for an altar containing pictures of deceased family members and praying at ritually prescribed times (Chao, 1992). This act affirms the sacredness, unity, and timelessness of the kin group.

Aspects of traditional Asian child-rearing practices appear to be continued by Asian American families (Uba, 1994). Studies tend to be focused primarily on characteristics of parental control. Chiu (1987) compared the child-rearing attitudes of Chinese, Chinese American, and European American mothers. Chinese mothers endorsed restrictive and controlling behavior more than Chinese American and European American mothers, and Chinese American mothers were more restrictive and controlling in their child-rearing attitudes than European American mothers. The intermediate position of Chinese American mothers suggests that their child-rearing attitudes are shifting toward European American norms due to acculturation.

Chao (1994) has argued that the traditional view of Chinese parents as authoritarian, restrictive, and con-

trolling is misleading because these parenting behaviors do not have cross-cultural equivalence for European Americans and Chinese: these child-rearing concepts are rooted in European American culture and are not relevant for describing the socialization styles and goals of Chinese parents. "The 'authoritarian' concept has evolved from American culture and psychology that is rooted in both evangelical and Puritan religious influences" (Chao, 1994, p. 1116). Instead, Chinese parenting should be viewed from the concepts of *chiao shun* and *guan*. *Chiao shun* means "training" or "teaching in appropriate behaviors." Parents and teachers are responsible for training children by exposing them to examples of proper behavior and limiting their view of undesirable behaviors. However, training in the European American sense is conceptualized as strict discipline. This is not the case for Chinese, for whom training is accomplished in the context of a supportive and concerned parent or teacher. The word *guan* means "to govern," "to care for or to love," and parental care and involvement is seen as an aspect of *guan*. Thus, control and governance have positive connotations for the Chinese. Chao (1994) compared European American and immigrant Chinese American mothers on standard measures of control and authoritarian parenting, as well as measures of *chiao shun* and *guan*. Chinese American mothers scored higher on standard measures of parental control and authoritarian parenting. However, they also scored higher on measure reflecting the concepts of *chiao shun* and *guan*. Thus, although Chinese American mothers scored high on the European American concepts of parental control and authoritarian parenting, their parenting style could not be described using European American concepts. Instead, the style of parenting used by the Chinese American mothers is conceptualized as a type of training performed by parents who are deeply concerned and involved in the lives of their children.

The value of this approach is that it helps resolve paradoxes in the literature. In studies on ethnicity achievement, Steinberg, Dornbusch, and Brown (1992) found that Asian American students rated their parents higher on authoritarian parenting than European American and Hispanic groups. Although their parents were lower on the optimal parental style of authoritativeness, Asian students had the highest achievement scores (Steinberg et al., 1992). Chao's (1994) study suggests that confusion between "authoritarian" and "training" child-rearing concepts among Chinese respondents may account for the paradox. Chinese parents may have a different set of

child-rearing values and styles that are distinct from the conventional U.S. child-rearing schemes. The same can be said about the construct of parent-child closeness. Immigrant Chinese American parents express closeness through behaviors emphasizing family harmony, whereas European American families express closeness through romantic themes that include more parent-child physical contact (Rothbaum, Morelli, Pott, & Liu-Constant, 2000).

Future research with Asian American families should take into account within-group difference in child-rearing practices due to generation and acculturation. Studies have found that larger acculturation gaps between Asian immigrant parents and their children are associated with more parental difficulties and communication problems and lower parenting satisfaction (Buki, Ma, Strom, & Strom, 2003; Tseng & Fuligni, 2000).

**Latino Families.** The term *Latino* is used here to describe those persons often referred to as Hispanics. *Hispanic* is a word coined by the Department of Commerce to enumerate persons in the United States whose ancestry derives from the Spanish-speaking countries and peoples of the Americas. Many people in this group prefer Latino over Hispanic because Latino is the Spanish word for describing this group, whereas Hispanic is an English word imposed on the group. The Latino population consists primarily of Mestizo peoples born of the Spanish conquest of the Americas. They are descendants of Spanish fathers and American Indian women. Although the language of Mestizos is Spanish, much of their culture is a hybrid of Spanish and American Indian influences. Child rearing, in particular, is heavily influenced by American Indian cultures because it was the American Indian women who bore the children of the Spanish conquistadores and raised them in their extended families. As these children grew, they formed unions with other Mestizos and American Indians and extended the predominately American Indian child-rearing practices across generations through their children.

Latinos are now the largest "minority" group in the nation. Mexican Americans make up the vast majority of Latinos (67%), followed by Central and South Americans (14%), Puerto Ricans (9%), and Cuban Americans (4%; U.S. Census Bureau, 2002). It is estimated that if current immigration trends continue, more than half the Latino population for the next 50 years will be made up of immigrants and their children (Edmonston & Passel, 1994). The Latino population will be characterized by sociocultural diversity and change as new immigrants

and their children adapt to life in the United States. The direction and nature of this change will be influenced by the sociocultural ecology of the United States, which itself is being gradually transformed by the growing numbers of Latinos and Asians of immigrant families. For many Latinos, especially Mexican Americans, retention of their ethnic and cultural identity is fostered by several factors that include: (a) proximity to the United States-Mexican border, (b) the former historical status of the United States Southwest as a part of Mexico, (c) the continuing growth of the Latino population, (d) mass media and communication between the United States and Latin America, and (e) a non-European phenotype that marks Latinos in this country as *others* (Buriel, 1994).

Ramirez and Castaneda (1974) have described the cultural values of Latinos by four conceptual categories: (1) identification with family, community, and ethnic group; (2) personalization of interpersonal relationships; (3) status and roles based on age and gender; and (4) Latino Catholic ideology. The following discussion of these values recognizes that there are important subgroup variations (e.g., Cuban American, Mexican American, Puerto Rican, and Central and South American) and variations due to acculturation, generation, and social class.

*Identification with Family, Community, and Ethnic Group.* Latino child-rearing practices encourage the development of a self-identity embedded firmly in the context of the *familia* (family). One's individual identity is therefore part of a larger identity with the familia. For many Latinos, the word family refers to a combination of nuclear and extended family members, including fictive kin such as godparents.

The desire to be close to the familia often results in many members of the same familia living in the same community. The familia network extends further into the community through kinships formed by intermarriage among familias and *el compadrazco*, which is the cultural practice of having special friends become godparents of children in baptisms. Adults united through *el compadrazco*, called *compadres* and *comadres*, have mutual obligations to each other similar to those of brothers and sisters. Vidal (1988) found that Puerto Rican godparents served as role models and social supports for their godchildren and regarded themselves as potential surrogate parents in the event of the parents' death. Extended familia ties in the community give rise to a sense of identity with one's community.

The worldview of many Latinos includes a sense of identity with *La Raza* (the Race), which is a sense of

peoplehood shared by persons of the Americas who are of Mestizo ancestry. The concept of *La Raza* suggests that many Latinos have a more flexible definition of race than the rigid categories typically used in the United States and by the Census Bureau. The Census Bureau and demographers consider Latinos an ethnic group belonging to the White race. However, when responding to the question on race in the 2000 census, 48% of Latinos reported only White, whereas approximately 42% reported only "Some Other Race" (U.S. Census Bureau, 2001a). In contrast, only 0.2% of the total non-Latino population reported "Some Other Race." These data point toward the need for a critical re-examination of how ethnic and racial identity are conceptualized and measured among Latinos.

*Personalization of Interpersonal Relationships.* Latino culture places a heavy emphasis on sensitivity to the social domain of the human experience. Individuals are socialized to be sensitive to the feelings and needs of others and to personalize interpersonal relationships (*personalismo*). This socialization goal encourages the development of cooperative social motives while discouraging individual competitive behaviors that set apart the individual from the group (Kagan, 1984).

The importance of the social domain for Latinos is reflected in the term *bien educado*, which means "well educated." In Latino culture, however, the term is used to refer not only to someone with a good formal education but also to a person who can function successfully in any interpersonal situation without being disrespectful. Okagaki and Sternberg (1993) found that Mexican immigrant parents emphasized social skills as equal to or as more important than cognitive skills in defining an "intelligent" child. Children in particular are expected to be *bien educados* in their relations with adults (Valdes, 1996). Addressing adults in Spanish with the formal "you" (*usted*) rather than the informal "you" (*tu*) is an example of being *bien educado*. Thus, if children lose Spanish and cannot communicate with Spanish monolingual adults, they may be unable to achieve the status of being *bien educado* in their community.

*Status and Roles Based on Age and Gender.* Latino culture has clearly defined norms of behavior governing an individual's actions in the familia and the community. Age and gender are important determinants of status and respect. Children are expected to be obedient and respectful toward their parents, even after they are grown and have children of their own. An authoritarian

parenting style has been reported among Latinos (Dornbusch, Ritter, Leiderman, Roberts, & Fraleigh, 1987; Schumm et al., 1988). Yet, as Chao (1994) has shown, in the context of non-Western cultures, this parenting style may be experienced as parental support and concern. Grandparents, and older persons in general, receive respect and have considerable status owing to their knowledge of life. Consequently, children are taught to model themselves after adults; as a result, modeling becomes a preferred teaching style (Laosa, 1980).

Gender also influences a person's role in the familia and community. Males are expected to have more knowledge about politics and business, whereas females are expected to know more about child rearing, health care, and education. Because politics and business expose males more to the outside world, they are often perceived as the dominant figures in the familia. However, decision-making studies in the United States reveal that Latino husbands and wives most often share responsibility for major family decisions (Cooney, Rogler, Hurrell, & Ortiz, 1982; Zavella, 1987).

*Latino Catholic Ideology.* Religion strongly influences the lives of Latinos because Latino Catholicism reinforces and supports cultural values. Latino Catholicism is a synthesis of Spanish European Catholicism and indigenous religious beliefs and practices. Identity with family and community is facilitated through religious practices, such as weddings and *el compadrazco*, which help extend family networks. Identity with the ethnic group is reinforced by the common Catholic religion shared by more than 80% of La Raza. Religious symbols are often used as markers of ethnic identity. For example, the image of the Virgin of Guadalupe, the Mestizo equivalent of the Virgin Mary, is both a religious symbol and a symbol for La Raza. The cultural emphasis on respect, group harmony, and cooperation in interpersonal relations is in line with the religious themes of peace, community, and self-denial. Many cultural celebrations and developmental milestones are celebrated in religious contexts, such as a *quinceañera*,—a coming-of-age celebration for a young girl on her fifteenth birthday that marks the beginning of adulthood.

### ***The Role of Family in Latino Adaptation***

Latino families have 3.71 members on average compared to 2.97 for European American and 3.31 for African American families. Puerto Rican women tend to have their first child before marriage, whereas Mexican American and Cuban American mothers usually

have their first child after marriage. Female-headed households are twice as common among Puerto Ricans relative to Mexican Americans and Cuban Americans (see Caucé & Domenech-Rodriguez, 2002, for a summary of family characteristics between Latino subgroups).

The longer immigrants live in the United States, the more their family networks expand. Family networks grow through marriage and birth and from continued immigration of family members. Thus, even as individual family members become acculturated, their local extended family becomes larger (Keefe & Padilla, 1987). Second- and third-generation Mexican Americans have larger and more integrated extended families than immigrants (Keefe & Padilla, 1987). Griffith and Villavicencio (1985) report that for Mexican Americans education and income are the best predictors of increased contact and support from family members.

Buriel (1993b) found that early assumption of responsibility was a dominant socialization goal of Mexican immigrant parents that persists into adolescence. He also found greater similarity in socialization styles among immigrant mothers and fathers than among native-born mothers and fathers. Consensus in socialization styles may reflect an area of domestic interdependence conditioned by the immigrant experience. Because immigrants lack extended kinship networks, parents may depend more on each other for socialization of children, which encourages agreement in parents' socialization styles.

Family research has often focused on how immigration and acculturation affect the adaptation of individual family members. However, the family can be viewed as an adapting entity with its own developmental processes. The family unit undergoes its own development, which transcends the development of its individual members. From a systems perspective (Minuchin, 2002), the Mexican American family can be thought of as an open system with both internal and external aspects of functioning. Internal aspects include the family's patterns of relationships and interactions and also the structure of the family. External aspects include the family's interactions with outside social systems including social institutions and the larger context of U.S. society. Rueschenberg and Buriel (1989) have shown that the Mexican American family is capable of adapting to U.S. social systems while retaining many of its internal characteristics that are cultural in nature.

Research is beginning to examine how traditional theories of parenting and socialization "fit" with family relations and child outcomes in Latino families. N. Hill,

Bush, and Roosa (2003) studied Mexican American and European American mothers and their children to map the relationship between harsh parenting and negative child outcomes. For both groups, families with low levels of conflict and hostile control had children with fewer conduct problems and depressive symptoms. In addition, in the Mexican American sample, lower acculturation, as measured by Spanish/English usage, was associated with a stronger negative relationship between maternal acceptance and child conduct problems. Moreover, among Spanish-speaking parents, hostile control co-occurred with acceptance, which is generally inconsistent with the traditional European American model of parenting. The combination of hostile control and acceptance may represent an adaptive parenting strategy for families living in culturally unfamiliar environments involving high levels of acculturative stress.

Parke et al. (2004), in a longitudinal study examining a family stress model involving economic hardship, family relations, and child outcomes, found that for both Mexican American and European American families, feelings of economic hardship were positively related to depression for both parents. In addition, paternal hostile parenting was related to higher levels of children's internalizing and externalizing behaviors in both European American and Mexican American families. However, among Mexican American families, maternal acculturation was associated with higher levels of marital problems and lower levels of both maternal and paternal hostile parenting. Although higher maternal acculturation may disrupt traditional male-centered authority patterns in the family, it may also serve as the catalyst for altering parenting styles in a less hostile direction.

A widely misunderstood and understudied area in Latino family research involves the role of fathers in parenting and socialization. The stereotype of machismo has led to the belief that Latino fathers are neither caring nor involved with their spouses and children. However, less acculturated Mexican American men supervise and engage their children in conventionally feminine activities more than their more acculturated counterparts (Coltrane, Parke, & Adams, 2004). Paternal participation in family rituals, which are often cultural in nature, is positively associated with monitoring and interacting with children in these families (Coltrane et al., 2004). Father involvement may represent an important dimension of familism, which is the most important value in Latino culture. This is supported by a study with Puerto Rican fathers, which found that fathers' assessments of their commitment to the fam-

ily and their competence in family matters were positively related to their involvement with their preschool-age children (Roopnarine & Ahmeduzzaman, 1993).

In addition to the role of fathers, research on grandparent involvement, particularly grandmothers, has begun. Owing to the values of familism and status and respect based on age and gender, grandmothers are often the symbolic heads of extended families and are sought after for advice and support in child rearing (Ramos-McKay, Comas-Diaz, & Rivera, 1988). The cultural diversity in the Latino population suggests that the impact of grandmother support may vary as a function of acculturation. Using a Puerto Rican sample, Contreras, Lopez, Rivera-Mosqueda, Raymond-Smith, and Rothstein (1999), examined how acculturation affected relations between grandmother involvement and adolescent mothers' adjustment. Greater grandmother support was related to less symptomatology and parenting stress among less acculturated mothers. When mothers were more unidirectionally acculturated, greater grandmother support was associated with more symptomatology and parenting distress. This research, like the work with fathers, underscores the importance of the moderating role of acculturation in family relationships with Latinos.

### *Perspectives on Ethnic Influences on Family Socialization*

Research on ethnic minority families in the United States has not kept pace with their rapid rate of growth. Until recently, ethnic/racial minority families were lumped together under the category of "minority," which overlooked important differences among ethnic/racial groups and significant diversity in individual groups. Most often, research with ethnic/racial families has compared them against European American families to identify group differences. An implicit assumption in two-group studies is that ethnic/racial minority families are not yet like European American families and that this developmental lag is responsible for the problems besetting ethnic/racial minority families. Recently, some researchers have begun to eschew two-group studies in favor of single-group studies that examine variations in ethnic/racial minority families and their relation to child outcomes. This research is guided by either an ecological or systems perspective that seeks to understand how parents adapt to the challenges they face as ethnic/racial minorities in U.S. society and how these experiences contribute to socialization goals they hold for their children.

The value of the concepts of collectivism and individualism that have been used to distinguish European American families from ethnic minority families (Greenfield & Cocking, 1994; Okagaki & Divecha, 1993) is being questioned as well (Scott-Jones, Lewis, & Shirley, 1996). As our review has indicated, both individualism and collectivism are important elements in the socialization of *both* European American and ethnic minority families and to continue to draw sharp contrasts using these terms serves only to promote stereotypes that are no longer valid. Scott-Jones et al. (1996) have suggested the adoption of Sampson's (1988) notion of ensembled individualism, which "reflects the importance of both individual development and commitment to family as complementary, intertwined elements in the socialization goals of ethnic families" (Scott-Jones et al., 1996, p. 8). Although the precise terminology that is best suited to capture the complexity of ethnic family socialization is still evolving, it is clear that *both* individual and collectivist features will continue to be recognized as important in describing ethnic families.

At present, and for the foreseeable future, the growth of minority families will be due primarily to immigration from Latin America and Asia. Research with families of these groups needs to take into account the acculturation level and generational status of parents and children and the effects these factors have on family processes and child outcomes. Together with acculturation, recognition of biculturalism as both an adaptation strategy and socialization goal should guide future research. The effects of prejudice and discrimination on ethnic minorities, in such areas as social and emotional development, ethnic/racial identity, and achievement motivation, deserve more attention. Language development research should also give greater attention to second-language acquisition (usually English) and bilingualism and their relation to cognitive development and school achievement. More attention must be given to the role of fathers, grandparents, and extended family members in the socialization of children. Finally, observational studies with ethnic/racial minority families have the potential for yielding a contextual richness about the family environments of ethnic/racial minorities that can lead to more culturally relevant insights and theories about their socialization experiences.

## REMAINING ISSUES AND FUTURE TRENDS

A number of issues remain to be examined in future research if we are to describe fully the complexities, spec-

ify the determinants and processes, and outline the consequences of family-child relationships. These include the choice of the unit of analysis, the effects of family variation, types of developmental change, the role of historical change, methodological, and contextual issues.

### Unit of Analysis

Current work is recognizing the importance of considering parents from a family systems perspective. However, our conceptual analysis of dyadic and triadic units of analysis is still limited (Dickstein, Seifer, et al., 1998; Parke, 1988). Considerable progress has been made in describing the behavior of individual interactants (e.g., mother, father, or child) in dyadic and to a lesser extent triadic settings, but less progress has been achieved in developing a language for describing interaction in dyadic and triadic terms. Even if such terms as *reciprocal* or *synchronous* hold promise, there remains little real advance in this regard. In addition, greater attention needs to be paid to the family as a unit of analysis. A number of researchers have offered differing taxonomies of family types or typologies that move us to this level of analysis (Cook, 2001), but, to date, little effort has been made to apply these notions systematically to family relationships in childhood.

### Parenting and Family Variation

One of the clear advances of the past decade is recognition of the importance of individual differences in children; one of the next advances will be the recognition of individual differences among families. Recognition of individual variability across families implies the necessity of expanding sampling procedures. Despite demands for a greater awareness of family diversity, the range of family types that are studied is still relatively narrow. Although progress has been made in describing interaction patterns of parents and children in different cultures (Rogoff, 2003) and in different ethnic groups in the United States (Contreras, Kerns, & Neal-Barnett, 2002; McLoyd, Hill, & Dodge, 2005; McLoyd & Steinberg, 1998), this work represents only a beginning. Particularly critical is an extension of earlier work on parent-child relationships in other ethnic groups to other subsystems such as the marital, sibling, and family systems. Evaluation of family systems notions in families with different ethnic backgrounds, organizations, and structure will provide an opportunity to test the generality of this theoretical

perspective. Finally, recent work on gay and lesbian families (Patterson, 2002) and the effects of growing up in these alternative family arrangements on children is raising important questions about the necessity of male-female family arrangements for the rearing of children (Parke, 2002).

### Types of Developmental Change

Developmental issues need to be addressed more fully to include children at a wider range of ages. Despite Maccoby's (1984) plea, we still are only beginning to map developmental changes in parental socialization strategies. Moreover, we need to move beyond childhood and examine more closely parental relationships with their adult children—if we are to achieve a life-span view of family socialization. Although development traditionally has marked change in the individual child, it is evident from this review that this perspective is too limited and parents, as well as children, continue to develop across time (Elder, 1998; Parke, 1988). Parents' management of a variety of life-course tasks, such as marriage, work, and personal identity, will clearly determine how they will execute parental tasks; in turn, these differences may find expression in measures of parent-child interaction. Because developmental shifts in children's perceptual, cognitive, and social development may alter parental attitudes and behaviors and/or the nature of the adults' own developmentally relevant choices, such as work or career commitment, this clearly argues for the recognition of two developmental trajectories—a child developmental course and an adult developmental sequence. The description of the interplay between these two types of developmental curves is necessary to capture adequately the nature of developmental changes in a families' role in the socialization process.

### Monitoring Secular Trends

There is a continuing need to monitor secular trends and to describe their impact on family relationships (Modell & Elder, 2002). Secular change is complex and clearly does not affect all individuals equally or all behavior patterns to the same extent. It is a serious oversimplification to assume that general societal trends can isomorphically be applied across all individual children, parents, and families. Moreover, better guidelines are necessary to illuminate which particular processes in families are most likely to be altered by historical events

and which processes are less amenable to change (Parke, 2004a). For example, the structural dynamics of early interaction (Stern, 1977) and some qualitative aspects of early parent-infant interactive style may be insulated from the influence of secular shifts. Are fathers biologically prepared to interact in a more physical way, and mothers in a more verbal mode? If this assumption about differences in parental play style is true, rates of interactions would be more likely to change than style when employment opportunities for men and women become more equal. Alternatively, the restraints may be more solely environmental, and as opportunities for adult male and female participation in child care and child rearing equalize, some maternal-paternal stylistic differences may diminish.

### Methodological and Design Issues

It is likely that not a single methodological strategy will suffice to understand the development of family socialization. Instead, a wide range of designs and data collection and data analysis strategies is necessary. To date, there is still a paucity of information concerning interrelations across molar and molecular levels of analysis. However, it is becoming increasingly clear that a micro-analytic strategy is not always more profitable in describing relationships among interactive partners; in some cases, ratings may be a more useful approach. A set of guidelines concerning the appropriate level of analysis for different questions would be helpful.

Parents' own reports are increasingly being recognized as important sources that can aid in interpretation of observed patterns (Goodnow, 2002; Parke, 1978). Types of self-reports other than structured interviews and questionnaires need to be more frequently employed. Focus groups are commonly used in other disciplines but are used less often by psychologists. A focus group is a type of group interview, which relies on an emergent process of interaction between group members to produce data and insights that would not be found without such interaction. Focus groups are excellent forums in which to explore microlevel experiences of families and examine similarities and differences across different genders, socioeconomic classes, and ethnic groups. These provide a unique opportunity for parents and children to articulate their concerns, values, and goals in a context that is less constrained than the usual interview format. This technique is of particular value in the early stages of research with understudied

populations (see Gomel et al., 1998, and Parke et al., 2003, for illustrations of the use of focus groups with African American and Hispanic American groups). As Rutter (2002) has argued, qualitative and quantitative approaches are not incompatible. Quantitative analytic strategies have recently become available for use with the type of qualitative verbal reports generated by focus groups (Richards & Richards, 1991). Recent computer programs (e.g., Nudist, Nonnumerical Unstructured Data Indexing, or Searching and Theory Building) allow the researcher to explore patterns in the data that aid in grounded theory construction, while simultaneously allowing for the application of a coding scheme to the transcript text and then converting the coded text into quantitative information. Recently, Gomel et al. (1998) successfully utilized this program in a focus group study of the impact of economic downturn on ethnic minority families. Ethnographic methodologies can play an important role in family research as well, particularly to gain a better understanding of contextual factors that affect parental functioning (see Burton, & Price-Spratlen, 1999).

Reliance on nonexperimental strategies may be insufficient to address the important issue of direction of effects in work on the impact of parents on children and families. Experimental strategies have been underutilized in studies of families. By experimentally modifying either the type of parental behavior or level of involvement, firmer conclusions concerning the direct causative role that parents play in modifying their children's and their spouse's development will be possible. As Cowan and Cowan (2002) recently argued, intervention studies provide the "gold standard" for testing causal hypotheses. Intervention studies (e.g., Fagan & Hawkins, 2001; Parke, Hymel, Power, & Tinsley, 1980) aimed at modifying fathering behavior provide models for this type of work and, by extending these studies to include measures of child, mother, and father development, they could provide evidence of the impact of changes in parenting behavior on developmental outcomes. Moreover, these experimentally based interventions have clear policy implications by exploring the degree of plasticity of parenting behavior. Similarly, studies in which child behavior is either experimentally modified (Bell & Chapman, 1986) or children with known characteristics (e.g., hyperactivity, conduct disorder) are paired with parental surrogates (Anderson, Lytton, & Romney, 1986) are needed to capture the bidirectionality of family influence effects. By expand-

ing the range of family members or subsystems that are measured, to include nontargeted individuals and subsystems, the impact of modifying the behavior of one family member on other parts of the family system could be evaluated. These interventions can serve as a vehicle for evaluation of alternative theoretical views of parenthood and socialization. In addition to intervention designs, natural experiments continue to be a useful tool for aiding us in sorting out causal issues (Rutter, 2002). For example, recent work on adopted Romanian children has shown that the length of institutionalization is a major predictor of later functioning (Rutter, Pickles, Murray, & Eaves, 2001).

More recognition of the utility of combined sampling strategies is needed. Recently, researchers have begun to use multistage sampling strategies in which survey level information on a national representative sample is secured in combination with the selection of a subsample for purposes of more intensive analyses such as in-depth interviews or observations (Reiss, Neiderhiser, Hetherington, & Plomin, 2000). Together, this strategy ensures greater confidence in the generalizability of the findings and permits access to process-level variables.

For research designs, under the influence of the behavior geneticists (Plomin, 1994), there has been an increased focus on the value of nonshared environmental designs, which allow measurement of the differential impact of families on different children in the same family. Although some have argued for the decreased use of traditional between-family designs that still form the foundation of most of our knowledge of family effects (Plomin, 1994), others (e.g., Hoffman, 1991) have argued for the continued utility of both types of designs with the goal of discovering "what environmental conditions might lead to sibling similarity and dissimilarity" (Hoffman, 1991, p. 199). More conceptual work is needed to provide guidelines concerning the value of within- and between-family designs for different variables and issues.

The field has progressed beyond the simple environment-gene partitioning argument (Harris, 1998) toward a more complex conceptual framework that reframes the debate as gene x environment interactions. According to this view (Reiss, 2003), family processes mediate genetic influence in children's outcomes, and the future challenge is to determine how this gene x environment family model plays out across development. Several designs, including cross-fostering studies with nonhuman primates (Suomi, 2000), modified sibling designs

(Reiss et al., 2000), and prospective adoption designs (Reiss, 2003) are promising new approaches for addressing this issue.

### Contextual Issues

Greater attention needs to be paid to the role of context in determining family relationships. How do parent-child interaction patterns shift between home and lab settings and across different types of interaction contexts such as play, teaching, and caregiving? Moreover, it is important to consider the social as well as the physical context. Recognition of the embeddedness of parents in family contexts is critical, and conceptualizing families as embedded in a variety of extrafamilial social settings is important for understanding variation in family functioning. In this regard, it is necessary to recognize that variations in family structure and in ethnicity and social class will modify significantly the ways in which social networks are organized and utilized. For example, the role of the extended family is much more prominent in some groups, such as African American, than in other groups (Gadsen, 1999; McLoyd, Hill, & Dodge, 2005). Similarly, single-parent families may be more directly embedded in a community-based social network than two-parent families. Descriptions of these variations are necessary for an adequate understanding of the role of extrafamilial networks on parent and family functioning.

### Locating Families in a Network of Socialization Influences

One of the major challenges is to determine the unique contribution of families to socialization outcomes and the limits of family effects (Harris, 1998). As Maccoby and Martin (1983) argued in their review of the relations between parental functioning and characteristics of children, "in most cases the relationships that have appeared are not large, if one thinks in terms of the amount of variance accounted for" (p. 82). Their conclusion is still valid, if we assume a narrow view of family influence as the direct impact of parents on their children. However, our increased recognition of the family as a *partner* with other institutions, such as peers, schools, media, religious institutions, and government policy-makers that together influence children's development, has significantly expanded our view of the family's role in the socialization process and suggests that the family—directly and indirectly—may have a larger impact

on children's outcomes than previously thought. As we have argued, families serve not just as direct influences on children but as indirect influences as well in their roles as managers, modifiers, and negotiators on behalf of children in relation to these social institutions. However, our understanding of the ways in which families influence their children's socialization through their links with other institutions is still poorly understood. Moreover, these agents and institutions (e.g., schools, or peers) play a direct as well as indirect role through the family in the socialization process. Several issues need to be addressed. What are the unique roles that families play in socialization? Are some kinds of outcomes specifically in the family purview such as the development of early social attachments? Are other outcomes influenced largely by other groups (e.g., tastes in music and fashion)? How does the relative role of family and other agents shift across development? Perhaps the most interesting question concerns the ways in which families coordinate their socialization roles with other agents and institutions. Successful socialization requires a gradual sharing of responsibility for socialization with other groups, but we know relatively little about this process of coordination and mutual sharing across socialization agents. It is unhelpful to continue to posit linear models of decreasing family influence across development. Instead, we need models that help us understand the changing nature of family influence relative to other groups and the mechanisms that maintain family values and orientation after direct influence has subsided. Recent work on the intergenerational transmission of working models of relationships (Bretherton & Munholland, 1999) testifies to the prolonged influence of childhood socialization on later adult parenting roles. This work anticipates one of the major themes of future research: the impact of childhood socialization patterns on later adult development—not just in parenting but in other types of adult relationships, including marital, friendship, and work relationships. Closely related is the issue of how families and other institutions are linked. Earlier work has focused on family peer linkages (Parke et al., 2003), family-work ties (Perry-Jenkins, Repetti, & Crouter, 2000), and family-school relationships (Epstein & Sanders, 2002). More recently, there is emerging evidence that the prior neglect of family links with other institutions such as the legal system (Parke & Clarke-Stewart, 2003), religious institutions (Mahoney et al., 2001), social service systems (Olds et al., 1999), and health delivery organizations (Tinsley,

2003) is being corrected. More work on these cross-context relationships is needed. Nor are the processes that promote or constrain family involvement with other institutions well understood. Finally, the bidirectional nature of the linkage needs more attention so that we understand the dynamic and mutual influence of families on other institutions and vice versa.

## A Final Word

Families continue to play a central role in the socialization process but their role has undergone dramatic change during the past several decades. To maintain our understanding, it is critical to monitor how changing ecologies of families of different ethnic backgrounds are modifying the socialization of families. Only by a better understanding of these changes will we be able to offer meaningful assistance and support for families. And only by achieving these goals will we be able to fulfill our goal of providing optimal conditions for promoting children's development.

### CONCLUSIONS 561

### REFERENCES 561

Interest in self-processes has recently burgeoned in many branches of psychology. Cognitive-developmentalists of a neo-Piagetian persuasion have addressed normative changes in the emergence of a sense of self (e.g., Case, 1992; Fischer, 1980; Harter, 1997; Higgins, 1991). Developmentalists interested in memory processes have described how the self is crafted through the construction of narratives that provide the basis for autobiographical memory (see Fivush, 1987; Nelson, 1993; Snow, 1990). Contemporary attachment theorists, building on the earlier efforts of Ainsworth (1979) and Bowlby (1980), have provided new insights into how interactions with caregivers shape the representations of self and others that young children come to construct (see Bretherton, 1991, 1993; Cassidy, 1990; Cicchetti, 1993; Cicchetti & Beeghly, 1990; Cicchetti & Cohen, 1995; Cicchetti & Rogosch, 1996; Pipp, 1990; Rutter & Sroufe, 2000; Sameroff, 2000; Sroufe, 1990). Clinicians in the psychodynamic tradition have also contributed to

our understanding of how early socialization experiences come to shape the structure and content of self-evaluations and contribute to psychopathology (Blatt, 1995; Bleiberg, 1984; Kernberg, 1975; Kohut, 1977; Winnicott, 1965). Moreover, social and personality theorists have devoted considerable attention to those processes that produce individual differences in perceptions of self, particularly among adults (see Baumeister, 1987, 1993; Epstein, 1991; Kihlstrom, 1993; Markus & Wurf, 1987; Steele, 1988).

Although there is a new look to many of these contemporary formulations, the field has also witnessed a return to many of the classic issues that captured the attention of historical scholars of the self. For example, new life has been breathed into James's (1890, 1892) distinction between the I-self as subject, agent, knower and the Me-self as object, as known. In addition, James's analysis of the causes of self-esteem is alive and well. There has also been a resurgence of interest in

symbolic interactionists, such as Baldwin (1897), Cooley (1902), and Mead (1934), who placed heavy emphasis on how interactive processes with caregivers shape the developing self.

In this chapter, the emphasis is on self-representations, beginning with toddlers and very early childhood, through late adolescence, where most of recent work on self-development has been conducted. The critical period of the development of the self in infancy was covered in detail in the previous handbook volume (see Harter, 1998; also Thompson, Chapter 2, this *Handbook*, this volume) where there continues to be agreement on the basic processes that govern the period of infancy. More recent treatments (see Fonagy, 2002; Mascolo, Fischer, & Neimeyer, 1999; Rochat & Striano, 2002) echo and refine the role of interactional experiences embedded in the crucible of the primary parent-infant relationship, where sensitive caregiving is critical to healthy self-development. These recent treatments also focus on the importance of the differentiation of the self from caregivers as a foundation for later self-concept development and on intentionality in early social relationships. These acquisitions help motivate the infant to realize that he or she constitutes a self, both independent of, but dependent on, caregivers that supports self-definition.

The first part of this chapter deals with six stages of self-development. Specifically, the focus is on changes in self-understanding and self-evaluation during three periods of childhood, very early, middle, and late childhood, and three periods of adolescence, early, middle, and late adolescence. In each of these six periods, three issues are covered. First, the *normative-developmental features of self-description and self-evaluation* are presented. Features include the salient content of the self, the structure or organization of self-constructs, the valence and accuracy of self-representations, the nature of social comparisons in forming self-judgments, and sensitivity to others as sources of information that may be relevant to self-representations.

Second, the *normative-developmental liabilities* that mark the emergence to each period or stage are described. The very fabric of development involves advances to new stages that may bring with them normative liabilities that should *not* be interpreted as pathological, liabilities that will dissipate as more advanced developments and skills are acquired. Movement to a new stage of cognitive development inevitably leads to liabilities given that the individual lacks “cognitive control” (see Fischer, 1980) over emerging new skills.

Because the self is not only a cognitive construction but also a social construction (Harter, 1999) crafted in the crucible of interactions with significant others, normative-developmental manifestations of the self will necessarily be affected by socialization at the hands of parents and peers, two key influences.

Third, I indicate how at each developmental period there are *individual differences*, against a normative backdrop, the causes of which can lead to healthy forms of self-development. Alternatively, self-development can be seriously derailed due to socialization influences that can result in maladaptive outcomes. These are to be distinguished from normative-developmental liabilities in their severity and the extent to which they compromise the functioning of the child or adolescent.

Before describing each of these three issues at six stages of development during childhood and adolescence, several general themes need to be presented as background: (a) the antecedents of the self as a cognitive and social construction, (b) distinctions between the I-self and the Me-self, (c) recent perspectives on the differentiation of the self and the creation of multiple selves during adolescence, (d) historical formulations and contemporary perspectives, and (e) recent genetic positions on the heritability of self-esteem.

After reviewing the normative-developmental changes in the self, the normative liabilities, and the roots of individual differences leading to healthy versus more maladaptive self-development at each of the six stages, the following issues are explored, drawing on considerable recent research. These themes include (a) the stability of self-esteem, (b) gender differences and the special impact of perceived appearance on self-esteem, (c) cross-cultural differences, and (d) ethnic differences in self-perceptions. For those interested in implications for intervention, the reader is referred to Harter (1999).

## ANTECEDENTS OF THE SELF AS A COGNITIVE AND SOCIAL CONSTRUCTION

In examining self-development, this chapter focuses on the antecedents of self-representations as well as on their consequences. With regard to antecedents, the self is a cognitive *and* a social construction—two major themes around which the material to be presented is or-

ganized. From a cognitive-developmental perspective, changes in self-representations are inevitable. As neo-Piagetians (e.g., Case, 1992; Fischer, 1980) and self theorists (e.g., Epstein, 1981, 1991; Greenwald, 1980; Kelly, 1955; Markus, 1980; Sarbin, 1962) have forcefully argued, our species has been designed to actively create theories about our world, to make meaning of our experiences, including the construction of a theory of self. Thus, the self is, first and foremost, a cognitive construction.

As a result, the self will develop over time as cognitive processes undergo normative-developmental change. Thus, because the self is a cognitive construction, the particular cognitive abilities and limitations of each developmental period will dictate the features of the self-system or how self-representations are conceptually organized. As such, emphasis is given to the processes responsible for those normative-developmental changes that result in *similarities* in self-representations at a given developmental level.

Previous ontogenetic accounts highlighted major qualitative differences in the nature of self-descriptions associated with broad stages of development. Observers were initially struck by the dramatic differences that defined the stage models of the day (e.g., Piaget, 1960). More recent treatments of self-development fill in the gaps by providing a more detailed account of the progression of the substages of self-understanding. As a result, we have necessarily had to alter our views about whether self-development is best viewed as a discontinuous or continuous process. Employing frameworks of the past, self-development was viewed as largely discontinuous, with an emphasis on the conceptual leaps from one broadly defined stage to another. Thus, theorists highlighted the dramatic differences between the self-descriptions and evaluations of young children, older children, and adolescents. However, there has been a shift in emphasis. The development of self-representations is now viewed as more continuous, in that investigators specify more ministeps or substages that occur, including how such levels build on, and transform, one another.

In focusing on normative-developmental changes, we see how cognitive development impacts two general characteristics of the self-structure, both the *differentiation* and the *integration* that an individual can bring to bear on the postulates in his or her self-theory. With regard to differentiation, emerging cognitive abilities allow the individual to create self-evaluations that differ

across various domains of experience. Moreover, they permit the older child to distinguish between real and ideal self-concepts that can then be compared to one another, creating potential discrepancies that have consequences for the self. During adolescence, newfound cognitive capabilities support the creation of multiple selves in different relational contexts.

With regard to integration, cognitive abilities that emerge across development allow the individual to construct higher-order generalizations about the self in the form of trait labels (e.g., demonstrated skills in math, science, and language arts are subsumed under the self-concept of "smart"). Abilities that emerge in middle childhood also permit the individual to construct a concept of his or her worth as a person, an evaluation of his or her global self-esteem. Further cognitive advances in adolescence allow one to successfully intercoordinate seemingly contradictory self-attributes (e.g., "How can I be both cheerful and depressed?") into meaningful abstractions about the self (e.g., "I'm a moody person"). Each of these themes is addressed.

In addition to an exploration of the cognitive-developmental antecedents of the self, emphasis is placed on the self as a social construction. Thus, attention is devoted to how socialization experiences in children's interactions with caregivers, peers, teachers, and in the wider sociocultural context will influence the particular *content* and *valence* of their self-representations. Those building on the symbolic interactionist perspective (Baldwin, 1897; Cooley, 1902; Mead, 1934), as well as those of an attachment theory persuasion (Bretherton & Munholland, 1999), have focused on how socialization experiences with caregivers produce individual differences in the content of self-representations, including whether self-evaluations are favorable or unfavorable. The reactions of significant others determine whether the child comes to view the self as competent versus incapable, as lovable versus undeserving of others' affection and esteem. Although cognitive-developmentalists emphasize the fact that children are active agents in their own development, including the construction of self, the symbolic interactionist and attachment perspectives alert us to the fact that children are also at the mercy of the particular caregiving hand they have been dealt.

To summarize, with regard to antecedents, the self is both a cognitive and a social construction. In examining the self as a cognitive construction, attention focuses on those cognitive-developmental processes that result in changes in the structure of the self-system, namely,

how self-representations are organized. This approach provides an account of normative, developmental change, and emphasizes the similarities among individuals at a given stage of development. In treating the self as a social construction, attention turns to those socialization processes that reflect how children are treated by caregivers, interactions that primarily impact the evaluative content of self-representations. Child-rearing practices do impact normative-developmental changes; however, they are also the major causes of individual differences in whether judgments about the self are favorable or unfavorable.

### The I-Self and the Me-Self

In addressing these themes, we can draw on a distinction in the literature between the I-self and the Me-self. The majority of scholars who have devoted thoughtful attention to the self have come to a similar conclusion: Two distinct but intimately intertwined aspects of self can be meaningfully identified: (1) self as subject (the I-self) and (2) self as object (the Me-self). William James (1890) introduced this distinction defining the I-self as the actor or knower, whereas the Me-self was the object of one's knowledge, "an empirical aggregate of things objectively known" (p. 197). James also identified particular features or components of both the I-self and the Me-self. Components of the I-self included (a) self-awareness, an appreciation for one's internal states, needs, thoughts, and emotions; (b) self-agency, the sense of the authorship over one's thoughts, and actions; (c) self-continuity, the sense that one remains the same person over time; and (d) self-coherence, a stable sense of the self as a single, coherent, bounded entity. Components of the Me-self included the "material me," the "social me," and the "spiritual me." In contemporary models, this translates into new domains of the self-concept and supports the current multidimensional approaches to the self (see Harter, 1999).

The distinction between the I-self and the Me-self has proved amazingly viable and is a recurrent theme in many theoretical treatments of the self. While more recent scholars have employed somewhat different terminology, the essence of the distinction has been retained. Dickstein (1977), for example, contrasted the "dynamic" self that possesses a sense of personal agency to the self as the object of one's knowledge. Lewis and Brooks-Gunn (1979) initially defined this duality as the existential self and the categorical self. The task of the

developing I-self, the self as subject, is to develop the realization that it is "existential" in that it exists as separate from others. The Me-self, the self as object, is referred to as "categorical" in that the developing child must construct categories by which to define the self (e.g., age and gender labels). Wylie (1979, 1989) has summarized the essence of the distinctions that have been drawn by numerous theorists. The I-self is the active observer, whereas the Me-self is the observed, the product of the observing process when attention is focused on the self.

More recently, Lewis (1994) has adopted new terminology. He now refers to the I-self as the "machinery of the self," the basic biological, perceptual, and cognitive processes that allow for the construction of the Me-self as the "idea of me." Such cognitive representations of the self begin to emerge in rudimentary form in the second half of the 2nd year. Both the "machinery of the self" as well as the "idea of me" undergo considerable change during the course of development.

Historically, major attention has been devoted to the Me-self (to the study of the self as an object of one's knowledge and evaluation) as evidenced by the myriad number of studies on self-concept and self-esteem (see Harter, 1983; Wylie, 1979, 1989). More recently, the I-self, which James himself regarded as an elusive if not incorrigible construct, has become more prominent in accounts of self-development. As we come to appreciate, both the structure and content of the Me-self at any given developmental level depend on the particular I-self capabilities (those cognitive processes that define the knower). Thus, cognitive-developmental changes in I-self processes will directly influence the nature of the self-theory that the child is constructing.

Most scholars conceptualize the self as a theory that must be cognitively constructed. Those theorists in the tradition of adult personality and social psychology have suggested that the self-theory should possess the characteristics of any formal theory, defined as a hypothetico-deductive system. Such a personal epistemology should, therefore, meet those criteria by which any good theory is evaluated: that it is parsimonious, empirically valid, internally consistent, coherently organized, testable, and useful. From a developmental perspective, however, the self-theories created by children cannot meet these criteria, given numerous cognitive limitations that have been identified in Piagetian (1960) and neo-Piagetian formulations (e.g., Case, 1992; Fischer, 1980). The I-self in its role as constructor of the Me-self

does not, in childhood, possess the capacities to create a hierarchically organized system of postulates that are internally consistent, coherently organized, testable, or empirically valid. It is not until late adolescence or early adulthood that the cognitive abilities to construct a self-portrait meeting the criteria of a good formal theory potentially emerge. Therefore, it is essential to examine how the changing characteristics of the I-self processes that define each developmental stage directly impact the Me-self (the self-theory that is being constructed).

### Global versus Domain-Specific Evaluations

The increasing ability with development to differentiate self-domains, as well to integrate self-perceptions into a larger global concept of self, has led contemporary scholars to separate domain-specific perceptions from a global concept of a person's worth or self-esteem. Thus, it has become increasingly important to distinguish between self-evaluations that represent global characteristics of the individual (e.g., "I am a worthwhile person") from those that reflect the individual's sense of adequacy across particular domains such as their cognitive competence (e.g., "I am smart"), social competence (e.g., "I am well liked by peers"), athletic competence (e.g., "I am good at sports"), and so forth (see Bracken, 1996; Epstein, 1991; Harter, 1986b, 1998; Marsh, 1986, 1987; Rosenberg, 1979). Conceptualizations and instruments that aggregate domain-specific self-evaluations into a single score (e.g., Coopersmith, 1967) have been found wanting in that they mask meaningful distinctions between an individual's sense of adequacy across domains. Moreover, the separation of the evaluation of an individual's global worth as a person from more domain-specific attributes has allowed investigators to construct hierarchical models of the relationship among these self-constructs.

With regard to terminology, global self-evaluations have typically been referred to as *self-esteem* (Rosenberg, 1979), *self-worth* (Harter, 1983, 1999) or *general self-concept* (Marsh, 1986, 1987). In each case, the focus is on the overall evaluation of one's worth or value as a person. In this chapter, the terms *self-esteem* and *self-worth* are employed interchangeably. It is important to appreciate that this general evaluation is tapped by a separate set of items that explicitly tap one's perceived worth as a person (e.g., "I feel that I am a worthwhile person"). It is not a summary statement of self-evaluations across specific domains.

In this chapter, the term *self-concept* is primarily reserved for evaluative judgments of attributes in discrete domains, such as cognitive competence, social acceptance, physical appearance, and so forth, or "domain-specific self-evaluations." Such a focus allows the investigator to construct a profile of self-evaluations across domains for individuals or for particular subgroups of interest. Moreover, the separation of global self-esteem or self-worth from domain-specific evaluations allows us to address the issue of whether evaluations in some domains are more predictive of global self-esteem than are others.

Developmental advances allowing older children and adolescent to differentiate self-domains also extend to the development of "multiple selves" that become highly salient in early adolescence (Harter, 1999). Thus, an individual comes to develop a self with each parent, a best friend, a romantic other, and classmates of each gender—selves that often are defined by very different self-descriptors. Although cognitive-developmental processes contribute to the ability to construct multiple selves, social forces, including the pressure to be a particular self in each relational context, also contribute to this differentiation.

### Historical Perspectives

These contemporary themes find their roots in the writings of historical scholars of the self. William James clearly contributed with regard to his formulations regarding the origins of our self-esteem, to the differentiation of domains of the self, and to what he labeled the "conflict of the different Me's" across differing relational constructs. The symbolic interactionists, such as Cooley (1902), Baldwin (1895), and Mead (1934), clearly articulated the role of social processes in constructing the self.

The field has witnessed a return to classic issues that captured the attention of historical scholars of the self. Thus, it behooves us to briefly review the scripts of the major actors in this drama as a conceptual backdrop against which more contemporary issues can be examined. The history of interest in the self can be traced back to ancient Greek philosophy, as revealed in the injunction to "know thyself." However, contemporary scholars of the self-concept typically pay major intellectual homage to James (1890, 1892) and to the previously listed symbolic interactionists such as Cooley, Mead, and Baldwin. The reader interested in the history of the

self prior to the turn of the twentieth century is referred to excellent treatments by Baumeister (1987), Broughton (1987), and Logan (1987).

### *The Legacy of William James*

The contributions of James (1890, 1892) were legion. Of paramount importance was his distinction between two fundamental aspects of the self, the I-self as subject or knower and the Me-self as object or known. It is the Me-self that took center stage as the major focus of empirical attention. Those interested in individual differences in the self-concept focused primarily on the correlates of favorable versus unfavorable self-evaluations (see Wylie, 1979). In developmental psychology, earlier attempts to identify age-related changes in self-representations concentrated exclusively on the Me-self (see Harter, 1983, 1999). Thus, the data consisted of the differing self-descriptions produced by children at different age levels, with little analysis of what accounted for such shifts (see Montemayor & Eisen, 1977). However, contemporary developmentalists have afforded the I-self a far greater role as the architect of the Me-self. It has become apparent that an appreciation for developmental changes in I-self processes is critical to understand how and why the structure and content of the Me-self changes with age (see Damon & Hart, 1988; Harter, 1983, 1999).

In differentiating various aspects of the self, including the multiplicity of social selves, James (1890) noted that these multiple selves may not all speak with the same voice. For example, James observed that “many a youth who is demure enough before his parents and teachers, swears and swaggers like a pirate among his tough young friends” (p. 169). James further noted that this multiplicity can be harmonious; for example, when an individual is tender to his children but stern to the soldiers under his command. Alternatively, there may be a “discordant splitting” if one’s different selves are experienced as contradictory.

The conflict of the different Me’s could also be observed in the incompatibility of potential adult roles. James, himself, fantasized about his own desires to be handsome, athletic, rich, and witty, a bon vivant, lady-killer, philosopher, philanthropist, statesman, warrior, African explorer, as well as a tone-poet and a saint. He knowingly concluded that because all of these roles could not possibly coexist, it was necessary to selectively choose, suppressing the alternatives. Thus, “the seeker of his truest, strongest, deepest self must review

the list carefully, and pick out the one on which to stake his salvation” (1890, p. 14).

The repudiation of particular attributes or roles was not, for James (1890), necessarily damaging to the individual’s overall sense of worth, the “average tone of self-feeling which each one of us carries about” (p. 171). Thus, his own deficiency at Greek led to no sense of humiliation because he made no pretensions to be proficient at Greek. The role of pretensions became paramount in James’s formulation of the causes of self-esteem. Self-esteem could not simply be reduced to the aggregate of perceived successes but rather represented a ratio of successes to one’s pretensions. If perceived successes were equal to or greater than one’s pretensions or aspirations for success, high self-esteem would result. Conversely, if pretensions exceeded successes (if an individual were unsuccessful in domains deemed important), he or she would experience low self-esteem. Critical to this formulation is the assumption that lack of success in an area in which one does not have pretensions (e.g., Greek for James) will not erode self-esteem because it can be discounted. Thus, both the presence and absence of pretensions figured heavily in James’s theorizing. He argued that abandoning certain pretensions can be as much a relief as striving to meet goals: “How pleasant is the day when we give up striving to be young” (p. 201).

For James, therefore, we find many themes that anticipate contemporary issues about the self. First and foremost is the distinction between “I” and “Me” selves. James’s multidimensional view of the Me-self has been modernized in recent treatments of the self-structure, where investigators have sought to examine the particular relationships among global and domain-specific self-evaluations. Moreover, the potential conflict between different Me-selves that James observed has served as a springboard to contemporary interest in the construction of multiple selves. As we come to see, differing attributes across role-related selves that appear contradictory (e.g., depressed with parents but cheerful with friends) usher in the potential for conflict. Finally, James’s formulation concerning the causes of self-esteem has been revived, leading to empirical investigations of its viability.

### *The Contribution of the Symbolic Interactionists*

In contrast to James, the symbolic interactionists placed primary emphasis on how social interactions with others profoundly shaped the self. For Cooley (1902), Mead (1934), and Baldwin (1897), the self is viewed as a so-

cial construction, crafted through linguistic exchanges (symbolic interactions) with others. Several themes have found their way into contemporary theorizing. For example, beginning in childhood, the child (a) engages in the imitation of significant others' behaviors, attitudes, and values or standards; (b) adjusts his or her behavior to garner the approval of salient socializing agents; (c) comes to adopt the opinions that significant others are perceived to hold toward them (these reflected appraisals come to define one's self as a person). The fact that these processes occur in multiple social contexts adds to the complexity of the construction of a self that can be experienced as coherent, as integrated, and as authentic.

Charles Horton Cooley was perhaps the most influential. His formulation was the most metaphorical, given his postulation of the "looking glass self." In his now-famous couplet, he observed that:

Each to each a looking glass  
Reflects the other that doth pass

For Cooley, significant others constituted a social mirror into which the individual gazes to detect their opinions toward the self. These opinions, in turn, are incorporated into one's sense of self. Cooley contended that what becomes the self is what we imagine that others think of us, including our appearance, motives, deeds, character, and so on: We come to own these reflected appraisals. Such a "self-idea" was comprised of three components: (1) the imagination of our appearance to the other person; (2) the imagination of that person's judgment of that appearance; and (3) some sort of self-feeling—an affective reaction to these reflected appraisals. These components gradually become psychologically removed from their initial social sources through an implied internalization process. Cooley writes that the adult is "not immediately dependent on what others think; he has worked over his reflected self in his mind until it is a steadfast portion of his thought, an idea and conviction apart, in some measure, from its external origin. Hence this sentiment requires time for its development and flourishes in mature age rather than in the open and growing period of youth" (1902, p. 199).

Cooley's views on the internalization of others' opinions about the self paved the way for a more developmental perspective on how the opinions of others are incorporated into the self. Moreover, his looking glass self-perspective provides an alternative to James's con-

tentions regarding the determinants of global self-esteem. James focused largely on those cognitive processes in which an individual actively compares particular aspirations to perceived successes in corresponding domains. For Cooley, the antecedents were far more social in nature, and less consciously driven, in that children inevitably internalized the opinions that they believed significant others held toward the self. Cooley also spoke more directly to developmental changes, including the consequences of the internalization process for adults. He contended that the more mature sense of self is not buffered about by potentially transient or disparate views of significant others. As Cooley (1902) observed, the person with "balanced self-respect has stable ways of thinking about the image of self that cannot be upset by passing phases of praise or blame" (p. 201). His thesis anticipates contemporary interest in whether self-concepts are malleable versus resistant to change.

In George Herbert Mead (1925), we find an elaboration of the themes identified by Cooley, with an even greater insistence on the role of social interaction. For Mead, "We appear as selves in our conduct insofar as we ourselves take the attitude that others take toward us. We take the role of what may be called the 'generalized' other" (p. 270). Mead spoke to the origins of these attitudes in childhood. He postulated a two-stage developmental process through which the child adopted the attitudes of others toward the self, labeling these stages as the play and the game. The *play* involved the imitation of adult roles, which Mead documented in his description of the young child "continually acting as a parent, a teacher, a preacher, a grocery man, a policeman, a pirate, or an Indian" (p. 270). In the subsequent stage of *games*, there are proscribed procedures and rules:

The child must not only take the role of the other, as he does in the play, but he must assume the various roles of all the participants in the game and govern his actions accordingly. If he plays first base, it is as the one to whom the ball will be thrown from the field or from the catcher. Their organized reaction becomes what I have called the "generalized other" that accompanies and controls his conduct. And it is this generalized other in his experience which provides him with a self. (p. 271)

For Mead, the individual adopts the generalized perspective of a group of significant others that shares a particular perspective on the self. In predicting global judgments of self, Mead's formulation implies a process through which the evaluations of significant others are

somehow psychologically weighted to produce an overall sense of self-worth as a person. However, Mead was not explicit on precisely how other's judgments were combined. Contemporary researchers have begun to address these processes more directly.

For Cooley and Mead, several themes have found their way into contemporary treatments of the self. Paramount is the role of the opinions of others in shaping the self-concept through social interaction. Cooley hinted at a developmental internalization process that has implications for the stability of the self-concept in which the reflected appraisals of specific others become incorporated into relatively enduring attitudes about the self. For Mead, a more generalized sense of self was internalized, although just how the opinions of various others are psychologically homogenized into a collective sense of self remains elusive. Finally, Cooley's observation that self-judgments are accompanied by self-feelings highlighted the role of affective processes in self-concept development, particularly self-conscious emotions such as pride and shame (see Harter, 1999).

### *Self-Psychology in the Second Half of the Twentieth Century*

During the eras of James, Cooley, and later Mead, inquiry into topics concerning the self and psyche flourished. However, with the emergence of radical behaviorism, such constructs were excised from the scientific vocabularies of many theorists and the writings of James and the symbolic interactionists gathered dust on the shelf. It is of interest to ask why the self became an unwelcome guest at the behaviorists' table. Why did constructs such as self, including self-esteem, ego strength, sense of omnipotence, narcissistic injury, and so on, do little to whet the behaviorists' appetite? Several reasons appear responsible.

The very origins of the behaviorist movement rested on the identification of observables. Thus, hypothetical constructs were both conceptually and methodologically unpalatable. Cognitions, in general, and self-representations, in particular, could not be operationalized as observable behaviors. Moreover, self-report measures designed to tap self-constructs were not included on the methodological menu, because people were assumed to be very inaccurate judges of their own behavior. Those more accepting of introspective methodologies found the existing measures of self-concept ungratifying because their content was overly vague. Finally, self-constructs were not satisfying to the behaviorist's palate because their functions were not

clearly specified. The very cornerstone of behavioral approaches rested on a functional analysis of behavior. In contrast, approaches to the self did little more than implicate self-representations as correlates of behavior, affording them little explanatory power as causes or mediators of behavior.

Several shifts in emphasis, later in the twentieth century, allowed self-constructs to become more palatable. Hypothetical constructs, in general, gained favor as parsimonious predictors of behavior, often far more economical in theoretical models than a multitude of discrete observables. Moreover, we witnessed a cognitive revolution in both child and adult psychology (Bruner, 1990). For developmentalists, Piagetian and neo-Piagetian models came to the forefront. For experimental and social psychologists, numerous cognitive models found favor. In this revolution, self theorists jumped on the bandwagon, resurrecting the self as a cognitive construction, as a mental representation that constitute a theory of self (e.g., Brim, 1976; Case, 1985; Epstein, 1973, 1981; Fischer, 1980; Greenwald, 1980; Kelly, 1955; Markus, 1980; Sarbin, 1962). Finally, self representations gained increased legitimacy as behaviorally oriented therapists were forced to acknowledge that the spontaneous self-evaluative statements of their clients seemed powerfully implicated in their pathology.

### **POSSIBLE GENETIC INFLUENCES ON SELF-ESTEEM**

The discussion thus far has focused on psychological mechanisms that account for a child's level of self-esteem, describing the contribution of cognitive-developmental and social determinants. For many years, these have been the prevailing approaches. Recently, neurological and genetic models have come to the forefront, the 1990's were declared the decade of the brain, and it became obvious that our splintered subfields needed to be integrated if we are truly to understand development and human behavior. Thus, how might such a genetic perspective be applied to differences in levels of self-esteem in children? Several investigators have recently presented statistical findings (from twin studies) that suggest the heritability of self-esteem. The empirical findings cannot be disputed (see McGuire et al., 1999; Neiss, Sedikides, & Stevenson, 2002).

However, does this mean that there is a self-esteem gene? I think not. Might there be heritability, yes. What might be a thoughtful explanation? We know a great deal

about heritability from many compelling studies of intelligence, temperament, athleticism, and creativity to name but a few characteristics. There are also considerable data demonstrating the heritability of conditions such as various learning disabilities, autism, and attention-deficit/hyperactivity disorder (ADHD; see Pennington, 2002). These studies can be linked to the issue of the heritability of self-esteem. If the genetic throw of the dice causes a child to be intellectually competent, athletically competent, or attractive by current societal standards, and if these domains are deemed important, then according to James (and our own findings), this child is on the path to high self-esteem. Conversely, genetically driven negative attributes, where success is viewed as important, will lead to low self-esteem.

A behavioral-genetic twin study by Hur, McGue, and Iacono (1998) comes to a similar conclusion. Findings revealed that 30% of individual differences in the self-concept subscales on the Piers-Harris instrument (Piers, 1976) were associated with genetic factors. The authors suggest two possible mechanisms by which genetic factors could affect self-concept. They first note that the genetic influence could reflect the well-documented genetic influence on actual abilities, personality traits, and physical make-up. Alternatively, they note that genetic factors might affect various dimensions of the self-concept by predisposing identical twins to psychologically evaluate themselves similarly, if they form a close emotional bond. They indicate that sorting out these interpretations will require further research.

Moreover, if children are genetically blessed with a sociable temperament and are rewarded for their sociability by parents, peers, teachers, extended family, and others, from a looking glass self-perspective, this positive feedback will enhance their self-esteem. Thus, it would seem that the constructs identified by James (1892) and Cooley (1902), and documented in our own research (Harter, 1999), are likely to be the mediators of genetic influences, rather than that there exists a direct connection between genes and self-esteem.

## DEVELOPMENTAL DIFFERENCES IN SELF-REPRESENTATIONS DURING CHILDHOOD

In the sections to follow, we examine the nature of self-representations and self-evaluations at three periods of childhood: (1) toddlerhood to very early childhood, (2) early to middle childhood, and (3) middle to late childhood. For each period, there is a prototypical

self-descriptive cameo that reflects the cardinal features of the content and structure of the self at that developmental level. Discussion will focus on (a) the normative-developmental changes that are critical as a backdrop and against which we can judge whether a child's self-representations are age-appropriate; (b) the normative-developmental liabilities for the self at this period; and (c) what cognitive and social factors at each period lead to individual differences in self-development, producing positive adjustment outcomes for some versus deviations that can be considered more maladaptive for others.

### Toddlerhood to Early Childhood: Verbal Cameo of Normative Self-Representations and Self-Evaluations

I'm almost 3 years old and I live in a big house with my mother and father and my brother, Jason, and my sister, Lisa. I have blue eyes and a kitty that is orange and a television in my own room. I know all of my ABCs, listen: A, B, C, D, E, F, G, H, J, L, K, O, P, Q, R, X, Y, Z. I can run real fast. I like pizza and I have a nice teacher at preschool. I can count up to 100, want to hear me? I love my dog Skipper. I can climb to the top of the jungle gym, I'm not scared! I'm never scared! I'm always happy. I have brown hair and I go to preschool. I'm really strong. I can lift this chair, watch me! (adapted from Harter, 1999)

Such descriptions will typically be observed in 3- to 4-year-olds. Noteworthy is the nature of the attributes selected to portray the self. Theory and evidence (see Fischer, 1980; Fischer & Canfield, 1986; S. Griffin, 1992; Harter, 1998, 1999; Higgins, 1991; Watson, 1990) indicate that the young child can only construct concrete cognitive representations of observable features of the self (e.g., "I know my ABC's," "I can count," "I live in a big house"). Damon and Hart (1988) label these as categorical identifications; the young child understands the self only as separate, taxonomic attributes that are physical (e.g., "I have blue eyes"), active (e.g., "I can run real fast, climb to the top"), social (e.g., "I have a brother, Jason, and a sister, Lisa"), or psychological (e.g., "I am happy"). Particular skills are touted (running, climbing) rather than generalizations about being athletic or good at sports. Moreover, often these behavioral descriptions will spill over into actual demonstrations of one's abilities ("I'm really strong. I can lift this chair, watch me!"), suggesting that these emerging self-representations are still directly tied to behavior. From a cognitive-developmental perspective, they do not

represent higher-order conceptual categories through which the self is defined. In addition to concrete descriptions of behaviors, the young child defines the self by preferences (e.g., "I like pizza; I love my dog Skipper") and possessions ("I have an orange kitty and a television in my own room"). With regard to possessions, Fasig (2000) has specifically studied toddlers' basic understanding of ownership as a facet of the extended self. Those with rudimentary ownership understanding provided richer self-representations than those who did not possess such knowledge. On balance, as Rosenberg (1979) cogently observes, the young child acts as a demographer or radical behaviorist in that his or her self-descriptions are limited to characteristics that are potentially observable by others.

From the standpoint of organization, the self-representations of this period are highly differentiated or isolated from one another. The young child is incapable of integrating these compartmentalized representations of self, and thus self-descriptive accounts appear quite disjointed. This lack of coherence is a general cognitive characteristic that pervades the young child's thinking across a variety of domains (Fischer, 1980; Harter, 1999). As Piaget (1960) observed, young children's thinking is transductive in that they reason from particular to particular in no logical order.

Neo-Piagetians have elaborated on these processes. Case (1992) refers to this level as "Interrelational," in that young children can forge rudimentary links in the form of discrete structures that are defined by physical dimensions, behavioral events, or habitual activities. However, they cannot coordinate two such structures (see also S. Griffin, 1992), in part, because of working memory constraints that prevent young children from holding several features in mind simultaneously. Fischer's (1980) formulation is very similar. He labels these initial structures "Single Representations." Such structures are highly differentiated from one another because the cognitive limitations at this stage render the child incapable of integrating single representations into a coherent self-portrait.

Moreover, self-evaluations during this period are typically unrealistically positive (e.g., "I know all of my ABCs"—which he or she doesn't) because young children have difficulty distinguishing between their desired and their actual competence, which is a confusion initially observed by both S. Freud (1952) and Piaget (1932). Thus, young children cannot yet formulate an ideal self-concept that is differentiated from a real self-

concept. Rather, their descriptions represent a litany of talents that may transcend reality (Harter & Pike, 1984). For contemporary cognitive-developmentalists, such overstated virtuosity stems from another cognitive limitation of this period: The inability of young children to bring social comparison information to bear meaningfully on their perceived competencies (Frey & Ruble, 1990; Ruble & Dweck, 1995). The ability to use social comparison toward the goals of self-evaluation requires that the child be able to relate one concept (e.g., his or her own performance) to another (e.g., someone else's performance), a skill that is not sufficiently developed in the young child. Thus, self-descriptions typically represent an overestimation of personal abilities. It is important to appreciate, however, that these apparent distortions are normative in that they reflect cognitive limitations rather than conscious efforts to deceive the listener.

Another manifestation of the self-structure of very young children is their inability to acknowledge that they can possess attributes of opposing valence, for example, good and bad or nice and mean (Fischer, Hand, Watson, Van Parys, & Tucker, 1984). This all-or-none thinking can be observed in the cameo, in that all of the attributes appear to be positive. Self-representations may also include emotion descriptors (e.g., "I'm always happy"). However, children at this age do not acknowledge that they can experience both positive and negative emotions, particularly at the same time. The majority will deny that they have negative emotions (e.g., "I'm never scared!") as salient features of their descriptive self-portrait. Other procedures reveal that they do have rudimentary concepts of such single negative emotions as mad, sad, and scared (see Bretherton & Beeghly, 1982; Dunn, 1988; Harter & Whitesell, 1989). Evidence now indicates that young children report that they cannot experience seemingly opposing emotional reactions simultaneously (Carroll & Steward, 1984; Donaldson & Westerman, 1986; Gnepp, McKee, & Domanic, 1987; P. Harris, 1983; Harter & Buddin, 1987; Reissland, 1985; Selman, 1980). For Fischer and colleagues (e.g., Fischer & Ayoub, 1994), this dichotomous thinking represents the natural fractionation of the mind. Such "affecting splitting" constitutes a normative form of dissociation that is the hallmark of very young children's thinking about both self and other.

Cognitive limitations of this period extend to the inability of young children to create a concept of their overall worth as a person: a representation of their

global self-esteem (Harter, 1990b). This self-representation requires a higher-order integration of domain-specific attributes that have first been differentiated. Young children do describe themselves in terms of concrete cognitive or physical abilities, how they behave, how they look, and the friendships they have formed (Harter, 1990b, 1999). However, these domains are not clearly differentiated from one another, as revealed through factor-analytic procedures (Harter, 1998; Harter & Pike, 1984).

### ***Behaviorally-Presented Self-Esteem in Young Children***

The fact that young children cannot cognitively or verbally formulate a general concept of their worth as a person does not dictate that they lack the experience of self-esteem. Rather, our findings (see Harter, 1990a, 1999) indicate that young children manifest self-esteem in their behavior. In examining the construct of "behaviorally presented self-esteem," we first invoked the aid of experienced nursery school and kindergarten teachers. We found that for early childhood educators, self-esteem is a very meaningful concept that distinguishes children from one another. Teachers first provided prototypic descriptors of the high and low self-esteem child, as well as attributes that did not discriminate the two groups. A second group of teachers performed a Q-sort procedure on 84 behavioral descriptors, indicating which described the high self-esteem child, the low self-esteem child, and those that were not relevant to self-esteem.

There were two classes of behaviors that were viewed as characteristic of the high self-esteem child:

1. Active displays of confidence, curiosity, initiative, and independence that included: trusts his or her own ideas, approaches challenge, initiates activities confidently, takes initiative, sets goals independently, is curious, explores and questions, is eager to try doing new things, describes self in positive terms, and shows pride in his or her work.
2. Adaptive reaction to change or stress that included: able to adjust to changes, comfortable with transitions, tolerates frustration and perseveres, and able to handle criticism and teasing.

Similar categories describing the low self-esteem child representing the converse of these two sets of items emerged:

1. Failure to display confidence, curiosity, initiative, and independence that included: doesn't trust his or her own ideas, lacks confidence to initiate, lacks confidence to approach challenge, is not curious, does not explore, hangs back, watches only, withdraws and sits apart, describes self in negative terms, and does not show pride in his or her work.
2. Difficulty in reacting to change or stress that included: gives up easily when frustrated, reacts to stress with immature behavior, and reacts inappropriately to accidents.

Of particular interest are the categories of behaviors that do not seem to discriminate, according to teachers, between high and low self-esteem children. Most noteworthy was the fact that *competence* was not viewed by teachers as indicative of self-esteem in young children. It would appear that confidence, as a behavioral style, is not synonymous with competence, at least at this age level. This is illuminating because it suggests that the origin of a sense of confidence during early childhood does not necessarily reside in the display of skills, more objectively defined. During later childhood, the link between confidence in the self and level of competence apparently becomes stronger. As becomes apparent in describing the antecedents of self-esteem that emerge in middle childhood, competence becomes a much more critical factor. We would argue that, in bridging these two developmental periods, socialization practices that reward displays of confidence will lead the child to engage in behaviors that would allow him or her to develop skills and competencies that will subsequently become a defining predictor of self-esteem.

### ***Additional Functions of the Socializing Environment***

Higgins (1991), building on the efforts of Case (1985), Fischer (1980), and Selman (1980), focuses on how self-development during this period involves the interaction between the young child's cognitive capacities and the role of socializing agents. He provides evidence for the contention that at Case's stage of "interrelational development" and Fischer's stage of "single representations," the very young child can place him- or herself in the same category as the parent who shares his or her gender, forming an initial basis for identification with that parent. Thus, the young boy can evaluate his overt behavior with regard to the question: "Am I doing what Daddy is doing?" Similarly, the young girl evaluates her

behavior, asking “Am I doing what Mommy is doing?” Attempts to match that behavior impact which attributes become incorporated into the young child’s self-definition. Thus, these processes represent one way in which socializing agents impact the self.

Higgins (1991) observes that at the interrelational stage, young children can also form structures allowing them to detect the fact that their behavior evokes a reaction in others, notably parents, which causes psychological reactions in the self (see Thompson, Chapter 2, this *Handbook*, this volume). These experiences shape the self to the extent that the young child chooses to engage in behaviors designed to please the parents. Stipek, Recchia, and McClintic (1992) have provided empirical evidence for this observation, demonstrating that slightly before the age of 2, children begin to anticipate adult reactions, seeking positive responses to their successes and attempting to avoid negative responses to failure. At this age, they also find that young children show a rudimentary appreciation for adult standards, for example, by turning away from adults in seeming distress and hunching their shoulder in the face of failures (see also Kagan, 1984). For Mascolo and Fischer (1995), such reactions constitute rudimentary forms of shame. Shame at this period, like self-esteem, can only be *behaviorally* manifest. Children do not understand the concept at a verbal level (see Harter, 1999). Moreover, although young children are beginning to recognize that their behavior has an impact on others, their perspective-taking skills are extremely limited (see Harter, 1999; Selman, 1980). Thus, they are unable to incorporate others’ opinions of the self into a realistic self-evaluation that can be verbalized.

### *The Role of Narrative in the Co-Construction of the Self*

Another arena in which parental figures, in particular, impact children’s self-development involves the role of narratives in promoting the young child’s autobiographic memory: a rudimentary story of the self. The infantile amnesia that one observes before the age of approximately 2 can only be overcome by learning from adults how to formulate their own memories as *narratives*. Initially, parents recount to the child stories about his or her past and present experiences. With increasing language facility, children come to take on a more active role in that parent and child co-construct the memory of a shared experience (Eisenberg, 1985; Hudson, 1990a, 1990b; Nelson, 1990, 1993; Rogoff, 1990; Snow, 1990).

However, for the young child, such narratives are still highly scaffolded by the parents, who reinforce aspects of experience that they feel are important to codify and remember (Fivush, Gray, & Fromhoff, 1987; Fivush & Hudson, 1990; Nelson, 1989). Through these interactions, an autobiographic account of the self is created. Of further interest are findings demonstrating individual differences in maternal styles of narrative construction (see Bretherton, 1993; Nelson, 1990, 1993). For example, Tessler (1991) has distinguished between an elaborative style (where mothers present an embellished narrative) and a pragmatic style (focusing more on useful information). Elaborative mothers were more effective in establishing and eliciting memories with their young children.

More recently, Nelson (2003) has introduced the concept of a social-cultural-linguistic self that arises from autobiographical memory and a narrative self, between the ages of 2 and 5. The transition to a “cultural self” is dependent on social-linguistic exchanges and exposure to cultural messages that are meaningful to the self. It requires the child’s social and cognitive awareness and the capacity for new levels of mental representations that develop during this period. For Nelson, this is a gradual process eventuating in a culturally saturated concept of self, an autobiographical self with both a specific self-history, and an imagined future self that reflects the values and expectations of the culture in which one is embedded. Bem’s (1985) gender schema theory is quite consistent with this conceptualization in that she describes how the initial labeling of one’s gender leads the young child to look to the culture where they learn that gender distinctions are very important, causing them to attend to the content of gender roles for males and females. Learning that boys are expected to be strong, brave, and assertive but girls are expected to be good, nice, and quiet, boys and girls acquire gender schemas, adopting the characteristics that the culture deems appropriate for their gender.

For most developmental memory researchers, language is the critical acquisition allowing one to establish a personal narrative and to overcome infantile amnesia (Budwig, 2000; Fivush & Hammond, 1990; Hudson, 1990a; Nelson, 1990, 2003; Pillemer & White, 1989). The mastery of language, in general, and of personal pronouns, in particular, enables young children to think and talk about the I-self and to expand their categorical knowledge of the Me-self (Bates, 1990; P. Miller, Potts, Fung, Hoogstra, & Mintz, 1990). Moreover, representa-

tions of the self in language are further facilitated by acquisition of the past tense, which occurs toward the latter half of the 3rd year.

Howe (2003) and Howe and Courage (1993) argue, however, that the emergence of language is not sufficient to explain the demise of infantile amnesia and the emergence of an ability to create autobiographical memories. Self-knowledge is also required, in that an appreciation for the self as an independent entity with actions, attributes, affects, and thoughts that are distinct from those of others is necessary for the development of autobiographical memory. Without the recognition of an independent I-self and Me-self, there can be no referent around which personally experienced events can be organized. Thus, for Howe and Courage, the emergence of the toddler's sense of self is the cornerstone in the development of autobiographical memory that further shapes and solidifies one's self definition.

Linguistic interactions with parents also impact the developing child's representation of self in semantic memory (Bowlby, 1969, 1973; Nelson, 1993; Snow, 1990). As Bowlby first noted, early semantic memory is conferred by caregivers. Parents convey considerable descriptive and evaluative information about the child, including labels to distinguish one from others (e.g., "You're a big boy"), evaluative descriptors of the self (e.g., "You are so smart"; "You're a good girl"), as well as rules and standards and the extent to which the child has met parental expectations ("Big boys don't cry"). Consistent with Cooley's (1902) model of the looking glass self, children incorporate these labels and evaluations into their self-definition in the form of general trait knowledge (represented in semantic memory). Thus, the linguistic construction of the self is a highly interpersonal process, with caregivers making a major contribution to its representation in both autobiographical and semantic memory.

More recently, experts on infant memory development have suggested additional processes that may account for childhood amnesia (see Hayne, 2004). Reviewing numerous studies of infant memory, Hayne concludes that there are three developmental processes that may add to our understanding of the infant's failure to retain autobiographical content. The large corpus of research first reveals that the *speed* with which infants encode information increases as a function of age. Secondly, the *retention* interval also dramatically increases as a function of age during infancy. Third, the *flexibility* of memory retrieval also improves during infancy,

meaning that memories are not as bound by specific contextual or proximal cues, whereas changes in such cues can disrupt or preclude memory retrieval in younger infants. Older infants have been found to gradually utilize more or different retrieval cues allowing them to access memories in a wider range of situations. These newer explanations are not incompatible with earlier theories of the function of language and self-development but rather provide additional explanations for the phenomenon of infantile amnesia.

### *Normative Liabilities for Self-Development during Very Early Childhood*

Infantile amnesia precludes a conscious sense of self for the toddler. Even once very young children are able to verbally describe the self, their self-representations are still limited in that they reflect concrete descriptions of behaviors, abilities, emotions, possessions, and preferences that are potentially observable by others. These attributes are also highly differentiated or isolated from one another, leading to rather disjointed accounts, because at this age, young children lack the ability to integrate such characteristics. For some, this lack of a logical self-theory may be cause for concern if not consternation. However, these features are normative in that the I-self processes (i.e., the cognitive structures available at this developmental period) preclude a more logical rendering of the Me-self.

Self-representations are also likely to be unrealistically *positive* for several reasons (see Harter, 1999). First, they lack the cognitive ability to engage in social comparison, for the purpose of self-evaluation. From a cognitive-developmental perspective, this skill, like many of the abilities that are unavailable to the preoperational child as Piaget (1960) revealed, requires that one be able to simultaneously hold two dimensions in mind to compare them (cf. conservation tasks). We apply this analysis to the inability to hold in mind an evaluation of one's own attributes while simultaneously thinking about another's attributes and comparing them.

Second, and for similar reasons, the very young child is unable to distinguish between their *actual* self-attributes and their *ideal* self-attributes. This requires making a discrimination between the two, holding each in mind simultaneously, and comparing the two judgments, a cognitive ability that the very young child lacks. As a result, self-evaluations are unrealistically positive because the fusion of the two favors the ideal or desirable self-concept. When we are dealing with older

children, we might interpret such a tendency to reflect socially desirable responding (i.e., the conscious distortion of one's self-evaluation) to be favorable. Cognitive-developmental interpretations lead to a different conclusion: that the very young child's positive evaluations reflect cognitive limitations rather than a conscious attempt to deceive.

Third, young children lack the perspective-taking ability to understand and therefore incorporate the perceived opinions of significant others toward the self (Harter, 1999; Selman, 1980). As becomes evident in the discussion of middle childhood, the ability to appreciate others' evaluations of the self becomes a powerful determinant of a child's sense of worth as he or she emerges in middle childhood.

Cognitive limitations also lead to young children's inability to acknowledge that they can possess both positive and negative self-attributes. The all-or-none, black-and-white thinking that is characteristic of the preoperational child extends to his or her conceptualizations of self: One must be one or the other. To the extent that the majority of socializing agents are relatively benevolent and supportive, the psychological scale will tip toward the imbalance of positive self-attributes. Thus, the young child will bask in the glow of overall virtuosity (even if it is unrealistic).

The inability to possess a verbalizable concept of self-esteem can also be explained by the cognitive limitations of this period. As is documented, the subsequent ability to compare one's actual self-attributes with one's ideal self-attributes will become an important determinant of one's level of self-esteem. Perspective-taking abilities will also become critical given that the internalization of the opinions of significant others becomes a powerful predictor of a child's overall sense of personal worth. It was noted that *behavioral* manifestations of self-esteem do emerge during early childhood, as has been documented. However, it is an interesting empirical question as to whether level of self-esteem as so displayed parallels or predicts the concept of a child's self-esteem that will emerge in middle childhood.

The description of the normative liabilities that impact conceptions and manifestations of the self during early childhood follow from normative cognitive limitations. One may question, however, the extent to which these reflect *psychological* liabilities. Many of the cognitive limitations of this period may serve as *protective* factors, to the extent that the very young child maintains

very positive perceptions of self, even if potentially unrealistic. Positive self-views may serve as motivating factors and emotional buffers, contributing to the young child's development. They may propel the child toward growth-building mastery attempts, they may instill a sense of confidence, and they may lead the child to rebuff perceptions of inadequacy, all of which may foster positive future development. From an evolutionary perspective, such "liabilities" may represent critical strengths, at this developmental level. This issue is revisited as we move up the ontogenetic ladder of representations and evaluations of the self.

### ***Individual Differences: Adaptive and Maladaptive Outcomes during Toddlerhood and Early Childhood***

In the previous two sections on the period of toddlerhood to early childhood, the focus was on *normative* self development, including normative liabilities. It is also critical to identify the causes of individual differences in self-development at each period. Individual differences will reflect a combination of the competencies, attributes, and temperament that the child brings into the world. They will also be heavily dependent on the role of socializing agents in the child's life. Thus, we explore what facilitates positive self-evaluations and what compromises the self in terms of negative evaluations. An important goal of this chapter is to distinguish between normative liabilities in the formation of the self and more maladaptive or pathological processes and outcomes at each developmental level.

Findings from the socialization literature in general (see Bugenthal & Goodnow, 1998; Thompson, 1998, and Chapter 2, this *Handbook*, this volume), and attachment theory, in particular (see Bretherton & Munholland, 1999) highlight the critical role of care, sensitivity, and feedback from socializing agents. Theory, going back to Winnicott's (1965) concept of "good enough mothering," suggests that sensitive responding to the infant's and toddler's needs sets the stage for positive self-development (see also Stern, 1985). Soothing, positive affect, interest in the infant's activities, support for mastery attempts, praise, and (nonintrusive) encouragement all lay the groundwork for a healthy sense of self during toddlerhood and early childhood.

Attachment theory (see Bretherton and Munholland, 1999) focuses on the development of working models of self and other, constructed in the crucible of early care-

giving experiences. For securely attached infants, a working model of self as valued, loved, and competent will emerge in the context of a working model of parents as emotionally available, loving, sensitive, and supportive of mastery attempts. Conversely, a working model of the self as devalued and incompetent is the counterpart of a working model of parents as rejecting or ignoring of attachment bids and interfering with exploration and mastery attempts.

Moreover, during toddlerhood to very early childhood, other factors could serve to seriously derail normative self-development, leading to outcomes that would seriously compromise a very young child's psychological development. Typically, the causes of severe maladjustment involve an interaction between the child's level of cognitive development and chronic, negative treatment at the hands of caregivers.

**The Effects of Abuse.** It is not uncommon for children who experience severe and chronic sexual abuse to have also been subjected to other types of maltreatment, including verbal, physical, and emotional abuse (see Cicchetti, 2004; Harter, 1999; Rossman & Rosenberg, 1998). The normative penchant for very young children to engage in all-or-none thinking (e.g., all good versus all bad) will lead abused children to view the Me-self as *all bad*. As noted earlier, the more typical pattern for children who are socialized by benevolent, supportive parents is to view the self as all good. Abuse, as well as severe neglect (Bowlby, 1980), can lead to early forms of depression in which the very young child eventually becomes listless, unconnected to caregivers, and, eventually numb, emotionally.

Abuse or maltreatment can also affect I-self functions, for example, self-awareness—one of the basic functions of the I-self as originally described by James (1892). Briere (1992) points to a feature of abusive relationships that interfere with the victim's lack of awareness of self. The fact that the child must direct sustained attention to external threats draws energy and focus away from the developmental task of self-awareness. Thus, the hyper-vigilance to others' reactions, what Briere (1989) terms *other directedness*, interferes with the ability to attend to the child's own needs, thoughts, and desires.

Research findings with children support these contentions. Cicchetti (1989) and colleagues (Cicchetti & Rogosch, 2001) found that maltreated children (ages 30

to 36 months) report less internal-state language, particularly negative internal feeling and physiological reactions than do their nonmaltreated, securely attached counterparts (see also Beeghly & Cicchetti, 1994). Similar findings by Beeghly, Carlson, and Cicchetti (1986); Coster, Gersten, Beeghly, and Cicchetti (1989) have also reported that maltreated toddlers use less descriptive speech, particularly about their own feelings and actions. Gralinski, Feshbach, Powell, and Derrington (1993) have also observed that older, maltreated children report fewer descriptions of inner states and feelings than children with no known history of abuse. Thus, there is a growing body of evidence that the defensive processes that are mobilized by maltreated children interfere with one of the primary tasks of the I-self namely awareness of inner thoughts and feelings. Lack of self-awareness should also interfere with the ability to develop autobiographical memory.

Attachment theorists have also contributed to our understanding of how maltreatment in early childhood can adversely influence self-development. There is considerable consensus that the vast majority of maltreated children form insecure attachments with their primary caregivers (Cicchetti & Rogosch, 2001; Crittenden & Ainsworth, 1989; Erickson, Egeland, & Pianta, 1989; Schneider-Rosen, Braunwald, Carlson, & Cicchetti, 1985; Westen, 1993). Findings have documented that maltreated infants are more likely to develop disorganized-disoriented type D attachment relationships (Barnett, Ganiban, & Cicchetti, 1999; Carlson, Cicchetti, & Barnett, 1989). Thus, the effects of early sexual and/or physical abuse, coupled with other forms of parental insensitivity, disrupt the attachment bond, which interferes with the development of positive working models of self and others. The foundation of attachment theory rests on the premise that if the caregiver has fairly consistently responded to the infant's needs and signals, and has respected the infant's need for independent exploration of the environment, the child will develop an internal working model of self as valued, competent, and self-reliant. Conversely, if the parent is insensitive to the infant's needs and signals, inconsistent, and rejecting of the infant's bid for comfort and exploration, the child will develop an internal working model of the self as unworthy, ineffective, and incompetent (Ainsworth, 1979; Bowlby, 1973; Bretherton, 1991, 1993; Crittenden & Ainsworth, 1989; Sroufe & Fleeson, 1986). The parental practices that have been associated

with child abuse represent precisely the kind of treatment that would lead children to develop insecure attachments and a concept of self as unlovable and lacking in competence.

As noted earlier, one critical function of parenting is to assist the child in creating a narrative of the self, an autobiographical account that includes the perceptions of self and other (see Hudson, 1990a, 1990b; Nelson, 1986, 2003; Snow, 1990). Initially, these narratives are highly scaffolded by parents, who reinforce aspects of experience that they, the parents, feel are important to codify and to remember or to forget (Fivush & Hudson, 1990; Hudson, 1990a; Nelson, 1986, 1990, 1993; Rogoff, 1990; Snow, 1990). Findings have indicated that the narratives of maltreated children contain more negative self-representations and more negative maternal representations compared to nonmaltreated children (Toth, Cicchetti, Macfie, Maughan, & Vanmeenen, 2000). Moreover, such narratives show less coherence; that is, the self that is represented is less coherent (Crittenden, 1994; Macfie, Cicchetti, & Toth, 2001). These findings document greater signs of dissociative symptoms that reflect disruptions in the integration of memories and perceptions about the self. Thus, maltreatment severely disrupts normative self-development, which leads to associated pathological symptoms, where it has been found that conflictual themes in young children's narratives predict externalizing problems. Moreover, severe, chronic abuse has been associated with disorders, such as borderline personality, where symptoms emerge later in development during adulthood (Putnam, 1993; Westen, 1993).

**Language and False-Self Behavior.** Language clearly promotes heightened levels of relatedness and allows for the creation of a personal narrative. Stern (1985) also alerts us to the liabilities of language. He argues that language can drive a wedge between two simultaneous forms of interpersonal experience: as it is lived and as it is verbally represented. The very capacity for objectifying the self through verbal representations allows us to transcend, and potentially distort, our immediate experience and to create a fantasized construction of the self. As noted earlier, there is the potential for incorporating the biases of caregivers' perspectives on the self, because initially, adults dictate the content of narratives incorporated in autobiographical memory (Bowlby, 1980; Bretherton, 1987; Crittenden, 1994; Pipp, 1990). Children may receive subtle signals that

certain episodes should not be retold or are best forgotten (Dunn, Brown, & Beardsall, 1991). Bretherton describes another manifestation (defensive exclusion) in which negative information about the self or the other is not incorporated because it is too psychologically threatening (see also Cassidy & Kobak, 1988). Wolf (1990) further describes several mechanisms, such as deceit and fantasy, whereby the young child, as author of the self, can select, edit, or change the facts in the service of personal goals, hopes, or wishes (see also Dunn, 1988).

Such distortions may well contribute to the formation of a self that is perceived as unauthentic if a person accepts the falsified version of experience. Winnicott's (1958) observations alert us to the fact that intrusive or overinvolved mothers, in their desire to comply with maternal demands and expectations, lead infants to present a false outer self that does not represent their own inner experiences. Moreover, such parents may reject the infant's "felt self," approving only of the falsely presented self (Crittenden, 1994). As Stern (1985) notes, the display of false-self, incurs the risk of alienating a person from those inner experiences that represent their true self (see also Main & Solomon, 1990). Thus, linguistic abilities not only allow a person to share his or her experiences with others but also to withhold them as well.

**The Impoverished Self.** As noted in the discussion of normative-development during early childhood, an important function of parenting is to scaffold the child's construction of autobiographical memory in the form of a narrative of one's nascent life story. However, clinicians observe that maltreatment and neglect sow the seeds for children, beginning in early to middle childhood, to develop what we (Marold & Harter in Harter, 1999) have come to call an "impoverished self," which has its roots in the early socialization practices of caregivers who fail to assist the child in the co-construction of a positive, rich, and coherent self narrative. Research (Tessler, 1991) has revealed individual differences among mothers in that some help to construct an embellished narrative, whereas others focus on a more restricted narrative that focuses on useful information leading to fewer autobiographical memories. Clinical observations reveal that there is another group of parents who, because of their own dysfunction (e.g., depression) and parental inadequacies, do little to nothing in the way of co-constructing with the child a self-narrative. The seeds of an impoverished self, therefore, begin in early childhood and con-

tinue into middle childhood and beyond if such children do not receive therapeutic intervention.

When these children come to the attention of family therapists, they lack a vocabulary to define the self, in that there is little in the way of autobiographical memory and descriptive or evaluative concepts about the self. An impoverished self represents a liability in that the individual has few personal referents or self-concepts around which to organize present experiences. As a result, the behavior of such children will often appear to be disorganized. Moreover, to the extent that a richly defined self promotes motivational functions in terms of guides to regulate behavior and to set future goals, such children may appear aimless, with no clear pursuits. A clinical colleague of mine, Donna Marold, has astutely observed that these children do not have dreams for the future, whereas most children do have future aspirations (Marold, personal communication, August 1998). For example, the prototypical child in early to middle childhood indicates that he or she is going to be on a team someday. Marold notes that the families of such children typically do not create or construct the type of narratives that provide a basis for autobiographical memory and a sense of self. Nor do such parents provide the type of personal labels or feedback that would lead to the development of semantic memory for self-attributes. Often, these are parents who do not take photographs of the children or the family, nor do they engage in such activities as posting the child's artwork or school papers on the refrigerator door. Marold has also observed that such parents do not have special rituals such as cooking the child's favorite food or reading (and rereading) cherished bedtime stories.

What type of therapeutic interventions might be applicable, and how can they be guided by developmental theory and research? Therapists (myself included) have learned through trial and error that one cannot, with older children, simply try to instill, teach, or scaffold the self-structures appropriate for their age level; namely, trait labels that represent generalizations that integrate behavioral or taxonomic self-attributes. With such children, there are few attributes to build on. Thus, we must begin at the beginning, utilizing techniques that help the child create the missing narratives, the autobiographical memory, and the self-labels. Marold has successfully employed a number of very basic techniques to achieve this goal, techniques that necessarily enlist the aid of parents. She suggests that the parent and child create a scrapbook in which whatever materials that

might be available (the scant photograph, perhaps from the school picture; a child's drawing; anything that may make a memory more salient) are collected and talked about. Where such materials are not available, Marold suggests cutting pictures out of magazines that represent the child's favorite possessions, activities, preferences, the very features that define the young child's sense of self. If there have been no routines that help to solidify the child's sense of self, Marold recommends that parents be counseled to establish routines, for example, establishing some family rituals (e.g., Friday night pizza) around a child's favorite food. Obviously, these techniques require collaboration with the parents and depend on their ability to recreate their child's past experiences, something that not all parents may be equipped to do. Here, the therapist can serve as an important role model. From the standpoint of our developmental analysis, the prevention of an impoverished self requires this type of support in early childhood. In the absence of such support, such impoverishment will continue into later childhood.

### **Early to Middle Childhood: Verbal Cameo of Normative Self-Representations and Self-Evaluations**

I have a lot of friends, in my neighborhood, at school, and at my church. I'm good at schoolwork, I know my words, and letters, and my numbers. I can run fast, and I can climb high, a lot higher than I could when I was little and I can run faster, too. I can also throw a ball real far, I'm going to be on some kind of team when I am older. I can do lots of stuff real good. Lots! If you are good at things you can't be bad at things, at least not at the same time. I know some other kids who are bad at things but not me! My parents are real proud of me when I do good at things. It makes me really happy and excited when they watch me! (adapted from Harter, 1999)

Such self-descriptions are typical of children ages 5 to 7. Some of the features of the previous stage persist in that self-representations are still typically very positive, and the child continues to overestimate his or her virtuosity. References to various competencies, for example, social skills, cognitive abilities, and athletic talents are common self-descriptors. With regard to the advances of this age period, children begin to display a rudimentary ability to intercoordinate concepts that were previously compartmentalized (Case, 1985; Fischer, 1980; Harter, 1999). For example, they can form a category or

representational set that combines a number of their competencies (e.g., good at running, jumping, school-work, having friends in the neighborhood, at school, and at church). However, all-or-none thinking persists. In Case's (1985) model and its application to the self (S. Griffin, 1992), this stage is labeled "unidimensional" thinking. Such black-and-white thinking is supported by another new cognitive process that emerges at this stage. The novel acquisition is the child's ability to link or relate representational sets to one another, to "map" representations onto one another, to use Fischer's (1980) terminology. Of particular interest to self-development is one type of representational mapping that is extremely common in the thinking of young children—a link in the form of opposites. For example, in the domain of physical concepts, young children can oppose up versus down, tall versus short, and thin versus wide or fat.

Opposites can also be observed in the realm of the descriptions of self and others, where the child's ability to oppose "good" to "bad" is especially relevant. As observed earlier, the child develops a rudimentary concept of the self as good at a number of skills. Given that good is defined as the opposite of bad, this cognitive construction typically precludes the young child from being "bad," at least at the same time. Thus, the oppositional mapping takes the necessary form of "I'm good and therefore I can't be bad." However, other people may be perceived as bad at these skills, as the cameo description reveals ("I know other kids who are bad at things but not me!"). Therefore, the structure of such mappings typically leads the child to overdifferentiate favorable and unfavorable attributes, as demonstrated by findings revealing young children's inability to integrate attributes such as nice and mean (Fisher et al., 1984) or smart and dumb (Harter, 1986a). Moreover, the mapping structure leads to the persistence of self-descriptions laden with virtuosity.

These principles also apply to children's understanding of their emotions, in that they cannot integrate emotions of opposing valence such as happy and sad (Harter & Buddin, 1987). There is an advance over the previous period in that children come to appreciate the fact that they can have two emotions of the same valence (e.g., "I'm happy and excited when my parents watch me"). However, the representational set for positive emotions is cognitive separate from negative emotions (e.g., sad, mad, or scared). Thus, children at this stage cannot yet integrate the sets of positive and negative emotions sets that are viewed as conceptually opposites and therefore

incompatible. The inability to acknowledge that a person can possess both favorable and unfavorable attributes, or experience both positive and negative emotions, represents a cognitive liability that is a hallmark of this period of development. Unlike the previous period, the child is now, due to greater cognitive and linguistic abilities, able to verbally express his or her staunch conviction that a person cannot possess both positive and negative characteristics at the same time. As one 5-year-old vehemently put it, "Nope, there is no way you could be smart and dumb at the same time. You only have one mind!"

### *The Role of the Socializing Environment*

Socializing agents also have an impact on self-development, in interaction with cognitive acquisitions. Thus, children acquire an increasing cognitive appreciation for the perspective of others that influences self-development. The child at this level comes to realize that socializing agents have a particular viewpoint (not merely a reaction) toward them and their behavior (Higgins, 1991). As Selman (1980) also observes, the improved perspective-taking skills at this age permit children to realize that others are actively evaluating the self (although children have not yet internalized these evaluations sufficiently to make independent judgments about their attributes.) Higgins observes that the viewpoints of others begin to function as "self-guides" as the child comes to further identify with what he or she perceives socializing agents expect of the self. These self-guides also function to aid the child in the regulation of his or her behavior. However, at this age level, cognitive-developmental limitations preclude the internalization of others' standards and opinions about the self, which will, with later advances, allow the child to personally come to own such standards and opinions.

As Higgins (1991) and Selman (1980) have pointed out, although children at this age do become aware that others are critically evaluating their attributes, they lack the type of self-awareness that would allow them to be critical of their own behavior. In I-self/Me-self terminology, the child's I-self is aware that significant others are making judgments about the Me-self, yet the I-self cannot directly turn the evaluative beacon on the Me-self. These processes will only emerge when the child becomes capable of internalizing the evaluative judgments of others for the purpose of self-evaluation. As a result, children at this age period will show little interest in scrutinizing the self. As Anna Freud (1965)

has cogently observed, young children do not naturally take themselves as the object of their own observation. They are much more likely to direct their inquisitiveness toward the outside world of events rather than the inner world of intrapsychic experiences.

There are additional forms of interaction between cognitive-developmental level and the socializing environment that affect the self, including certain advances in the ability to utilize social comparison information. Frey and Ruble (1985, 1990) as well as Suls and Sanders (1982) provide evidence that at this stage children first focus on temporal comparisons (how I am performing now, compared to when I was younger) and age norms rather than individual difference comparisons with age-mates. As our prototypical subject tells us, "I can climb a lot higher than when I was little and I can run faster, too." Suls and Sanders observe that such temporal comparisons are particularly gratifying to young children given the rapid skill development at this age level. As a result, such comparisons contribute to the highly positive self-evaluations that typically persist at this age level.

Evidence (reviewed in Ruble & Frey, 1991) now reveals that younger children do engage in certain rudimentary forms of social comparison; however, it is directed toward different goals than for older children. For example, young children use such information to determine if they have received their fair share of rewards, rather than for purposes of self-evaluation. Findings also indicate that young children show an interest in others' performance to obtain information about the task demands that can facilitate their understanding of mastery goals and improve their learning (Frey & Ruble, 1985; Ruble & Dweck, 1995). However, they cannot yet utilize such information for the purposes of self-evaluation, in large part due to the cognitive limitations of this period; thus, their evaluations continue to be unrealistic.

#### ***Normative Liabilities for Self-Development between Early to Middle Childhood***

Many of the features of the previous stage persist, in that self-representations are typically very positive, and the child continues to overestimate his or her abilities. Moreover, the child at this period still lacks the ability to develop an overall concept of his or her worth as a person. With regard to advances, children do begin to display a rudimentary ability to intercoordinate self-concepts that were previously compartmentalized; for example, they can construct a representational set that

combines a number of their competencies (e.g., good at running, jumping, and schoolwork). However, all-or-none thinking persists due to a new cognitive acquisition in which different valence attributes are verbally conceptualized as opposites (e.g., good versus bad or nice versus mean). Typically this all-or-none structure leads to self-attributes that are all positive, these beliefs are even more intractable than in the previous period given cognitive and linguistic advances that bring such beliefs into consciousness to the extent that the socializing environment supports such positivity.

Rudimentary processes allow the child to appreciate the fact that others are evaluating the self, although cognitive-developmental limitations preclude the child from internalizing these evaluations. Advances include the ability to make temporal comparisons between one's past performance. Given the rapid skill development during these years, such comparisons contribute to the highly positive self-evaluations that typically persist at this age level. The failure to use social comparison information for the purpose of self-evaluation, however, contributes to the persistence of unrealistically favorable self-attributes. As noted in describing the previous period, children at this stage are not consciously distorting their self-perceptions. Rather, they have not yet acquired the cognitive skills to develop more realistic self-perceptions.

#### ***Individual Differences: Adaptive and Maladaptive Outcomes during Early to Middle Childhood***

A major source of individual differences in self-representations and self-evaluations continues to derive from the caregiving of significant others. During this particular developmental period, rudimentary beginnings of looking glass self-processes emerge (Cooley, 1902), namely, some appreciation for the opinions of significant others that will come to shape opinions of oneself. However, the capacities to engage in looking glass self-processes, as well as to construct working models of self, do not emerge at one particular point in development but evolve gradually over the course of childhood. Children begin, toward middle childhood, to introject parental values and to realize (through rudimentary perspective-taking skills) that not only do parents have standards that they expect will be met, but also that parents form an evaluative opinion about the child (Higgins, 1991; Leahy & Shirk, 1985; Oosterwegel & Oppenheimer, 1993; Selman, 1980). In I-self/Me-self terms, the I-self of the child can realize

that others are forming evaluative opinions about one's Me-self. The I-self has not yet *internalized* or come to own the parental evaluations and therefore the I-self cannot yet directly evaluate the Me-self—a process that requires such internalizations. Further advances that allow children to fully engage in Cooley's looking glass self-processes will emerge in the subsequent period of middle to late childhood.

The ability to engage in even the rudimentary processes that emerge during early to middle childhood point to the importance of early socialization in the family as a source of individual differences in children's self-representations. There is considerable evidence from different theoretical perspectives that the quality of caregiving has a tremendous impact on the nature of the child's self-representations; for example, how favorably one evaluates the self (the *content* of one's self image) as well as how features of the self are *organized*. Thus, in general, parents who are nurturant, sensitive, responsive, and approving in the context of demanding realistically high standards will produce children with positive self-evaluations.

Traditional psychodynamic theorists such as Sullivan (1953) and Winnicott (1958) placed heavy emphasis on how the quality of mother-infant interactions impacted self-development, a theme amplified in more contemporary treats of the self (see Stern, 1985). For example, Winnicott described a pattern of "good-enough" mothering that would promote healthy self-development. The good-enough mother responds promptly and appropriately to the infant and toddler's demands, thereby initially promoting feelings of "omnipotence" or power, which certain theorists consider to be a critical precursor of positive feelings about the self (see also Erikson, 1959; Kohut, 1977). The good-enough mother also responds positively to mastery attempts. During periods when the young child's basic needs are met, such a mother retreats, supporting the capacity for her child to play alone, which Winnicott considered essential to the development of a stable and positive sense of self to emerge in early to middle childhood. Small failures in parental responsiveness at this period will lead to some disappointment for the child and less exaggerated feelings of omnipotence. However, according to both Winnicott and Kohut, these experiences play a vital role in self-other differentiation, allowing the children to both separate from the parent and to become more reality-oriented (see also Mahler, 1967).

Similarly, from an attachment theory perspective, a working model of self emerges in the crucible of the caregiver-infant relationship, a process that continues through childhood: Internal working models are believed to reflect experienced interaction patterns between the child and his or her attachment figures, and therefore the developmental working models of self and of the attachment figures are necessarily complementary. Thus, as Bowlby (1969) initially contended, the children who experiences parents as emotionally available, sensitive to his or her needs, loving, and supportive of his or her mastery attempts will construct a working model of the self as lovable and competent—the pattern for securely attached children (see also Bretherton, 1993). Conversely, a working model of self as devalued and incompetent is associated with a working model of parents as rejecting or ignoring of attachment behavior, including interference with exploration.

Although these themes were introduced in describing the earlier period of development, they continue to be relevant during early to middle childhood, from an attachment perspective. Classic models of attachment (e.g., Bowlby, 1969) implied more of a one-time "inoculation" process in which early experiences of maternal sensitivity, emotional availability, love, and support for mastery and exploration would lead, during the critical period of infancy and toddlerhood, to positive self-representations that would carry a person through childhood, adolescence, and beyond. The precursors of a secure attachment relationship leading to positive self-development are necessarily revisited at subsequent stages, given revisions of this earlier model (see Cassidy & Shaver, 1999). These neo-attachment theorists would argue that a person's attachment style and resulting working models or representations of self and others will only remain consistent *to the extent that* the same caregiving pattern continues in subsequent developmental periods. Thus, a more appropriate framework involves a "booster shot model" in which consistency will only be observed if the same pattern of parenting continues, be it contributing to secure or insecure attachment styles and their associated working models (see Thompson, 1998).

**Patterns That Are More Maladaptive.** In the attachment literature (see Bretherton, 1991; Bretherton & Munholland, 1999; Cassidy & Shaver, 1999; Crittenden, 1990; Main, 1995), there have been further dis-

tinctions between less than optimal parenting styles that are associated with three patterns of insecurely attached children, which have implications for the self-development of children described as (1) having an avoidance attachment style, (2) being ambivalently attached, and (3) being disorganized (a more recent style identified by Main).

The (anxious) avoidant style leads the young child to perceive that the mother is unavailable, nonnurturing, and not sharing positive affect. She is viewed as non-soothing in times of need, as turning away when the child is distressed, and sometimes angry. Not feeling loved, the child cuts the self off from emotionally threatening situations. Given this working model of the mother, the working model of the self follows directly. Thus, the child does not feel lovable, nor does he or she feel capable of getting people to meet his or her needs. Sensitivity to being rebuffed leads to occasional periods of anger and hostility. Moreover, the precursors of this style lead the child to eventually feel ineffective in the social domain with peers.

The (anxious) ambivalent child, also labeled as "resistant" by some, perceives the mother to be inconsistently available, sometimes there, sometimes not, leading to the inability to predict and therefore to trust whether she will meet basic and psychological needs. Therefore, distress is expressed in the absence of assurance, leading to a sense that one is not loved and that the mother is not there to support the mastery of new skills. Sometimes, when the mother is present, the child feels good. When she is not available, fussiness and resistance are expressed.

The most recent category describes disorganized-disoriented infants (Main, 1995). This type of child has even more severe doubts about his or her caregiver's ability to adequately provide comfort or reassurance when needed. The caregiver is experienced as highly inconsistent, disorganized, and perhaps neglectful or abusive. Cicchetti's findings (see Cicchetti, Beegley, Carlson, & Toth, 1990) reveal that maltreated, abused infants are more likely to exhibit this D style. Some (see Crittenden, 1990) have suggested that such children manifest a maladaptive combination of child rearing that leads to both avoidant and ambivalent tendencies, including contradictory patterns of behaviors, signs of fear and confusion, crying, depression, freezing, and numbing that reflect more severe disturbances, negativity, and inconsistencies in self-development.

Much of what has been addressed earlier documents negativity in the *content* of self-evaluations. However, of further interest are findings revealing that interactions with caregivers also impact the structure or the *organization* of working models (Bretherton, 1991; Bretherton and Munholland, 1999). Insensitive caregivers who ignore the child's signals will produce insecurely attached children whose working models are less coherently organized from the outset and are less likely to become well integrated. Parental underattunement leads to impoverished working models because it undermines the infant's ability to attend to and subsequently label his or her affective states and thereby incorporate them into a self-portrait (Crittenden, 1994). The child may defensively exclude painful experiences at the hands of insensitive caregivers. At the other extreme, Stern (1985) observes that parental overattunement (or intrusiveness) represents a form of emotional theft in which the parent accentuates how the infant *should* feel rather than how the child actually does feel. Thus, actual feeling states and related perceptions are not shared but become isolated, contributing to fragmentation or a lack of self-coherence.

Crittenden (1994) further distinguishes between securely attached and two types of insecurely attached individuals. Her findings reveal that those with a history of secure attachment can access and integrate the various memory systems, can view themselves from several perspectives, and can accept both their desirable and undesirable features. As a result, they evaluate the self more realistically, including the narrative that they construct of the self. For example, Cassidy (1988) found that securely attached 6-year-olds described themselves in generally positive terms, but they were also able to point out negative attributes, revealing a self-portrait in which they envisage themselves as imperfect.

Those with an *avoidant* attachment history, whom Crittenden labels as "defended" and Bartholomew and Horowitz (1991) identify as "dismissing," have less access to their various memory systems given that some features of the true self have been held out of awareness, whereas others have been defensively "corrected." Those with an ambivalent attachment history, which she (1994) labels as "coercive," also have more fragmented and distorted working models. Their tendency to blame others for their misbehavior robs them of the opportunity to integrate certain behavioral aspects of the self into their working model. Moreover, the inconsistent

parenting that they have experienced prevents them from developing an organized or coherent set of internal representations.

The potentials for maladaptive self-development that were identified for very early childhood exist for this subsequent period of development, therefore particularly if the caregiving of socializing agents remains consistently negative. However, the effects may become more evident because the child is more able, given linguistic and cognitive advances, to better verbalize negative self-evaluations.

Abuse at the hands of socializing agents can also continue to derail the self-system. In chronic and severe abuse, the major coping strategy is “dissociation” in which the individual attempts to cognitively split off the traumatic event from consciousness—to detach the self from the traumatic event (Herman, 1992; Putnam, 1993; Terr, 1991). When such abuse occurs at this period of childhood, it conspires with the natural or normative penchant for cognitive dissociation, splitting, or fragmentation (Fischer & Ayoub, 1994). Moreover, the very construction of cognitive structures that consciously lead the child of this age to think in opposites, one must be all good or all bad, lead to a painful awareness that one must be *all bad* or that the self is totally flawed. This can lead to compromising symptoms of depression.

Briere (1992), based on clinical cases, provides a complementary analysis of the sequential “logic” that governs the abused child’s attempt to make meaning of his or her experiences. Given maltreatment at the hands of a parent or family member, the child first surmises that either “I am bad or my parents are bad.” However, the assumption of young children that parents or adult authority figures are always right leads to the conclusion that parental maltreatment must be due to the fact that they, as children, are bad (that the acts were their fault), and that therefore they deserve to be punished. When children are repeatedly assaulted, they come to conclude that they must be “very bad” contributing to the sense of fundamental badness at their core.

From a cognitive-developmental perspective, the young child who is abused will readily blame the self (Herman, 1992; Piaget, 1932; Watson & Fischer, 1993; Westen, 1993): Given young children’s natural egocentrism, they will take responsibility for events they did not cause and cannot control. Moreover, as Piaget demonstrated, young children focus on the deed (e.g., the abusive act) rather than on the intention (e.g., the

motives of the perpetrator). As Herman points out, the child must construct some version of reality that justifies continued abuse and therefore inevitably concludes that his or her innate badness is the cause.

Finally, the preceding section on very early childhood described the rudimentary antecedents of the impoverished self that reside in the fact that caregivers do not adequately support the child’s construction of an autobiographical narrative of the child’s sense of self. The effects of such lack of scaffolding should become more evident as children move into middle childhood and should be able to verbally express his or her autobiographical sense of self—a narrative of one’s past life story, with implications for the future. However, the failure to express dreams for the future, to positively describe one’s capabilities, to express pride in one’s accomplishments all reflect maladaptive if not pathological distortions of self-development. These symptoms should represent serious red flags that require clinical intervention.

### **Middle to Late Childhood: Verbal Cameo of Normative Self-Representations and Self-Evaluations**

I’m in fourth grade this year, and I’m pretty popular, at least with my girl friends. That’s because I’m nice to people and helpful and can keep secrets. Mostly I am nice to my friends, although if I get in a bad mood I sometimes say something that can be a little mean. I try to control my temper, but when I don’t, I’m ashamed of myself. I’m usually happy when I’m with my friends, but I get sad if there is no one to do things with. At school, I’m feeling pretty smart in certain subjects like language arts and social studies. I got As in these subjects on my last report card and was really proud of myself. But I’m feeling pretty dumb in math and science, especially when I see how well a lot of the other kids are doing. Even though I’m not doing well in those subjects, I still like myself as a person, because math and science just aren’t that important to me. How I look and how popular I am are more important. I also like myself because I know my parents like me and so do other kids. That helps you like yourself. (adapted from Hartner, 1999)

Such self-descriptions are typically observed in children ages 8 to 11. In contrast to the more concrete self-representations of younger children, older children are much more likely to describe the self in terms such as *popular, nice, helpful, mean, smart, and dumb*. Children moving into late childhood continue to describe them-

selves in terms of their competencies (e.g., “smart,” “dumb”). However, self-attributes become increasingly interpersonal as relations with others, particularly peers, become an increasingly salient dimension of the self (see also Damon & Hart, 1988; Rosenberg, 1979).

From the standpoint of emerging cognitive-developmental (I-self) processes, these attributes represent traits in the form of higher-order generalizations, integrating more specific behavioral features of the self (see Fischer, 1980; Siegler, 1991). Thus, in the cameo, the higher-order generalization that she is “smart” is based on the integration of scholastic success in both language arts and social studies. That she also feels “dumb” represents a higher-order construction based on her math and science performance. “Popular” also combines several behaviors: being nice, helpful, and keeping secrets.

This developmental analysis has focused primarily on advances in the ability to conceptualize self-attributes. However, these processes can also be applied to emotion concepts. Thus, the child develops a representational system in which positive emotions (e.g., “I’m usually happy with my friends”) are integrated with negative emotional representations (e.g., “I get sad if there is no one to do things with”), as a growing number of empirical studies reveal (Carroll & Steward, 1984; Donaldson & Westerman, 1986; Fischer, Shaver, & Carnochan, 1990; Gnepp et al., 1987; P. Harris, 1983; P. Harris, Olthof, & Meerum-Terwogt, 1981; Harter, 1986b; Harter & Buddin, 1987; Reissland, 1985; Selman, 1980).

This represents a major conceptual advance over the previous two age periods during which young children deny that they can have emotions of opposing valences. Our own developmental findings (see Harter & Buddin, 1987) reveal that at this age, the simultaneous experience of positive and negative emotions can initially only be brought to bear on different targets. As one child subject observed, “I was sitting in school feeling worried about all of the responsibilities of a new pet, but I was happy that I got straight As on my report card.” In Fischerian (1980) terms, the child at this level demonstrates a “shift of focus,” directing the positive feeling to a positive target or event and then shifting to the experience of a negative feeling that is attached to a negative event. In middle childhood, the concept that the very same target can simultaneously provoke both a positive and a negative emotion is not yet cognitively accessible. However, by late childhood, positive and negative emotions can be brought to bear

on one target given the emergence of representational systems that better allow the child to integrate emotion concepts that were previously differentiated. Sample responses from our empirical documentation of this progression (Harter & Buddin, 1987) were as follows: “I was happy that I got a present but mad that it wasn’t what I wanted; If a stranger offered you some candy, you would be eager for the candy but worried about whether it was okay.” Elsewhere, we have extended the topic of emotional representations to developmental changes in the understanding of self-affects such as pride and shame. The reader is referred to Harter (1999).

### *Social Processes*

A more balanced view of self in which positive as well as negative attributes of the self are acknowledged is also fostered by new social comparison skills. As our prototypical subject reports, “I’m feeling pretty dumb in math and science, especially when I see how well the other kids are doing.” A number of studies conducted in the 1970s and early 1980s presented evidence revealing that it is not until middle childhood that the child can apply comparative assessments with peers in the service of self-evaluation. From a cognitive-developmental perspective, the ability to use social comparison information toward the goal of self-evaluation requires that the child have the ability, which is not sufficiently developed at younger ages, to relate one concept to another simultaneously. In addition to the contribution of advances in cognitive development (see also Moretti & Higgins, 1990), age stratification in school stimulates greater attention to individual differences between age-mates (Higgins & Bargh, 1987; Mack, 1983). More recent findings reveal that the primary motive for children in this age period to utilize social comparison is for personal competence assessment.

The ability to utilize social comparison information for the purpose of self-evaluation is founded on cognitive-developmental advances or the ability to simultaneously compare representations of self and others. However, it is also supported by the socializing environment. For example, evidence reveals that as children move up the academic ladder, teachers make increasing use of social comparison information (Eccles & Midgley, 1989; Eccles, Midgley, & Adler, 1984) and that students are well aware of these educational practices (Harter, 1996). Moreover, parents may contribute to the increasing salience of social comparison, to the extent

that they make comparative assessments of how their child is performing relative to siblings, friends, or classmates.

### ***Normative Liabilities for Self-Development during Middle to Late Childhood***

A cardinal thesis of this chapter is that cognitive advances bring about, paradoxically, normative liabilities for the self-system. The ability to be able to construct a global perception of one's worth as a person represents a major developmental acquisition—a milestone, as it were—in terms of a shift from mere domain-specific self-perceptions to an integrated sense of one's overall self-esteem. However, other cognitive-developmental acquisitions can serve to lower the valence of this global perception of self, leading to lowered self-esteem. Findings clearly reveal (see Harter, 1999) that beginning in middle childhood self-perceptions become more negative, normatively, compared to the very positive self-perceptions of the majority of young children. The emergence of three cognitive skills is noteworthy in this regard: (1) the ability to use social comparison for the purpose of self-evaluation, (2) the ability to differentiate real from ideal self-perceptions, and (3) increases in social perspective-taking skills.

The ability to employ social comparison for the purpose of self-evaluation (see Maccoby, 1980; Moretti & Higgins, 1990; Ruble & Frey, 1991) leads many, with the exception of the most competent or adequate in any given domain, to fall short in their self-evaluations. If a child therefore judges him- or herself deficient, compared to others, in domains that are deemed important to the self and others, global self-esteem will be eroded. Thus, the very ability and penchant, supported by the culture (e.g., family, peers, schools, and the media) to compare oneself with others makes one vulnerable in valued domains (e.g., appearance, popularity, scholastic competence, athletic performance, and behavioral conduct).

A second newfound cognitive ability to emerge in middle to late childhood involves the capacity to make the distinction between one's real and one's ideal self. From a Jamesian perspective, this skill involves the ability to distinguish between one's actual competencies or adequacies and those to which they aspire and deem important. The cognitive realization that one is not meeting one's expectations (an ability that young children do not possess) will necessarily lower one's overall level of self-esteem, as James's formulation accurately predicts.

Moreover, findings (see Glick & Zigler, 1985; Leahy & Shirk, 1985; Oosterwegel & Oppenheimer, 1993) reveal that the real-ideal discrepancy tends to increase with development. Two causes of such an increase can be identified. First, as noted earlier, social comparison processes lead older children to lower the valence of their self-perceptions, viewing themselves less positively. Second, given increasing perspective-taking skills, children are becoming increasingly cognizant of the standards and ideals that socializing agents hold for their behavior. Moreover, parents, teachers, and peers may normatively raise the bar in terms of their expectations, leading to higher self-ideals.

Increased perspective-taking skills can also *directly* impact self-perceptions, leading them to be more realistic. Protected by limitations in the ability to divine what others truly think of the self, younger children can maintain very positive self-perceptions. The developing ability to more accurately assess the opinions that others hold about one's characteristics, coupled with increasing concern about the importance of the views of others toward the self, normatively leads many older children to realistically lower their self-evaluations.

We can ask whether the processes that lead to more realistic self-evaluations represent liabilities. Many have argued (see review in Harter, 1999) that realistic self-evaluations are more adaptive beginning in middle to late childhood, unlike in early childhood where an overestimation on one's capacities may have a positive motivational function. Yet, in middle to late childhood, despite some potential blows to the ego, the child must seek to realistically readjust his or her self-perceptions and pursue more adaptive paths of development that are consistent with his or her actual attributes.

### ***Individual Differences: Adaptive and Maladaptive Outcomes in Middle to Late Childhood***

Several formulations, supported by empirical evidence, speak to the emergence of individual differences in self-representations and associated self-evaluations. From a Jamesian perspective, those who are genetically blessed with talents and/or who are praised for competence in domains deemed important to success will fare the best in terms of positive self-evaluations.

Moreover, child-rearing practices continue to be critical during middle to late childhood. Parental or caregiver approval is particularly critical in the child's domain-specific sense of competence and adequacy as well as global self-worth. Coopersmith (1967), in his

seminal efforts to unravel the causes of high and low self-esteem in children, described how the socialization practices of parents impact children's self-esteem. Parents of children with high self-esteem were more likely to (a) be accepting, affectionate, and involved in their child's activities; (b) enforce rules consistently and encourage children to uphold high standards of behavior; (c) prefer noncoercive disciplinary practices, discussing the reasons why the child's behavior was inappropriate; and (d) be democratic in considering the child's opinion around certain family decisions.

More recent evidence also reveals that parental support, particularly in the form of approval and acceptance, is associated with high self-esteem and the sense that one is lovable (see review by Feiring and Taska, 1996). Other studies have built on Baumrind's (1989) typology of parenting styles, linking them to child and adolescent self-evaluations. For example, Lamborn, Mounts, Steinberg, and Dornbusch (1991) reported that those with more authoritative or democratic parents reported significantly higher self-evaluations in the domains of social and academic competence than did those with authoritarian or neglectful parenting.

These findings are consistent with the theorizing of Cooley (1902) and attachment theorists (Bretherton, 1991; Bretherton & Munholland, 1999; Sroufe, 1990; Thompson, Chapter 2, this *Handbook*, this volume). Benevolent socializing agents who readily provide nurturance, approval sensitivity, emotional availability, and support for mastery attempts will produce children who mirror and eventually internalize this support in the form of positive self-evaluations. However, in their search for their image in the social mirror, other children may well gaze through a glass darkly. Caregivers lacking in responsiveness, nurturance, encourage, and approval, as well as socializing agents who are rejecting, punitive, or neglectful, will both cause their children to develop tarnished images of self, feeling unlovable, incompetent, and generally unworthy.

Thus, there is considerable evidence that support from parents as significant others in the child's life will have a powerful influence on self-evaluations (be they domain-specific or global in nature) or overall self-esteem (see Harter, 1999). Our own research documents the fact that parental or caregiver support is a major predictor of global self-worth throughout the childhood years. However, as the child moves up the developmental ladder, other sources of support emerge, where peer support becomes increasingly important. Thus, one can ask

the question "Mirror, mirror on the wall, whose opinion is the most critical of all?" At this particular developmental level, we have documented in numerous studies that of four sources of support: (1) parent, (2) teacher, (3) classmate, and (4) close friend. Parental and classmate support correlate most highly with global self-esteem. Why is close friend support not more predictive? We have argued (Harter, 1999) that, by definition, close friend support must be high. Furthermore, when one examines the various *functions* of support from different significant others, support from close friends typically manifests itself in the form of empathy, caring, and sensitivity to emotions and solutions to personal problems. Classmate support, in contrast, is more consistent with Mead's (1934) model of the "generalized other," more seemingly objective feedback about one's competencies, adequacy, and worth as a person.

As we see in the next sections on adolescence, recent work has begun to address the complexity of the *balance* of support from different significant others. Claims of the past (e.g., Rosenberg, 1979) and the present (J. Harris, 1998) suggest that the impact of parent support declines as a child moves from late childhood to early adolescence when the peer influence becomes paramount. However, current research, including our own (Harter, 1999), demonstrates that nothing is further from the truth.

To return to the theme of the importance of parental child rearing, and more pathological implications in the extreme, children subjected to severe and chronic abuse continue to create images of the self that are despicable, given the difficulty overcoming post-traumatic stress disorder (PTSD), including the psychological pain and symptoms that endure in the form of flashbacks and dissociative symptoms (Briere, 1992; Fischer & Ayoub, 1994; Herman, 1992; McCann & Pearlman, 1992; Terr, 1990; van der Kolk, 1987; Westen, 1993; Wolfe, 1989). More than constructing negative self-perceptions, they view the self as fundamentally flawed. Often excessively high and unrealistic parental standards that are unattainable contribute to these negative views of the self. Thus, the Me-self, both at the level of domain-specific self-perceptions and one's sense of global self-esteem, may be irrevocably damaged.

Finally, to return to the interaction of socializing practices and movement to new stages of cognitive development, such movement can be fostered by socializing agents, or alternatively, can be delayed if such environmental support is not forthcoming. One can

imagine scenarios in which there would be little environmental support for the integration of positive and negative attributes or positive and negative emotions. For example, in child-rearing situations where children are chronically and severely abused, family members typically reinforce negative evaluations of the child that are then incorporated into the self-portrait (Briere, 1992; Fischer & Ayoub, 1994; Harter, 1999; Herman, 1992; Terr, 1990; Westen, 1993). As a result, there may be little scaffolding for the kind of self-structure that would allow the child to develop and integrate both positive and negative self-evaluations. Moreover, negative self-evaluations that become automatized (Siegler, 1991) will be even more resistant to change.

Thus, to the extent that there is little or no support for the normative integration of positive and negative attributes, children will not advance cognitively. If the majority of feedback from socializing agents is negative, children in this age range (8 to 12) may remain at the previous level of all-or-none thinking, viewing their behavior as overwhelmingly negative. In addition, at a more affective level, there is a considerable body of research (see review in Harter, 1999) reveals that there is a very robust relationship between negative self-perceptions, including low self-esteem, and depression. Depressive symptoms include lack of energy, profound sadness in the form of depressed affect, and hopelessness. Depression, in turn, is highly predictive of suicidal ideation and suicidal behavior. Thus, caregiving practices resulting in very negative perceptions of the self put children at risk for serious forms of depressive pathology.

In addition to the incorporation of the opinions of significant others, children come to internalize the standards and values of the larger society. Perceptions of one's physical attractiveness, in relation to the importance that is attached to meeting cultural standards of appearance, contribute heavily to one's overall sense of worth as a person (see Harter, 1993, 1999). Those few who feel they have attained the requisite physical attributes will experience relatively high levels of self-esteem. Conversely, those who feel that they fall short of the punishing standards of appearance that represent the cultural ideal will suffer from low self-esteem and depression. Moreover, a related liability can be observed in the eating-disordered behavior of females, in particular, many of whom display symptoms (e.g., associated with anorexia) that are life threatening (Harter, 1999). Our own recent findings (Kiang & Harter, 2004) provide

support for a model in which endorsement of the societal standards of appearance leads to low self-esteem that predicts both depression and eating-disordered behavior. Finally, genetic factors leading to physical characteristics that do not meet cultural standards of attractiveness can also contribute to this pattern that may be particularly resistant to change.

### **Developmental Differences in Self-Representations during Adolescence**

The period of adolescence represents a dramatic developmental transition, given pubertal and related physical changes, cognitive-developmental advances, and changing social expectations. With regard to cognitive-developmental acquisitions, adolescents develop the ability to think abstractly (Case, 1985; Fischer, 1980; Flavell, 1985; Harter, 1999; Higgins, 1991). From a Piagetian (1960) perspective, the capacity to form abstractions emerges with the stage of formal operations in early adolescence. These newfound acquisitions, according to Piaget, should equip the adolescent with the hypothetico-deductive skills to create a formal theory. This observation is critical to the topic of self-development, given the claims of many (e.g., Epstein, 1973, 1981, 1991; Greenwald, 1980; Kelly, 1955; Markus, 1980; Sarbin, 1962) that the self is a personal epistemology, a cognitive construction, or a theory that should possess the characteristics of any formal theory. Therefore, a self-theory should meet those criteria by which any good theory is evaluated. Such criteria include the degree to which it is parsimonious, empirically valid, internally consistent, coherently organized, testable, and useful. From a Piagetian perspective, entry into the period of formal operations should make the construction of such a theory possible—be it a theory about elements in the world or a theory about the self.

However, as becomes apparent, the self-representations during early and middle adolescence fall far short of these criteria. The self-structure of these periods is not coherently organized, nor are the postulates of the self-portrait internally consistent. Moreover, many self-attributes fail to be subjected to tests of empirical validity; as a result, they can be extremely unrealistic. Nor are self-representations particularly parsimonious. Thus, the Piagetian framework fails to provide an adequate explanation for the dramatic developmental changes in the self-structure that can be

observed across the substages of adolescence. Rather, as in our analysis of how self-representations change during childhood, a neo-Piagetian approach is needed to understand how changes in cognitive-developmental I-self processes result in very different Me-self organizational and content at each three age levels: early adolescence, middle adolescence, and late adolescence. As in our examination of self-development during childhood, for each age level we first provide a cameo self-description. What follows is (a) an analysis of the normative-developmental changes in self-representations and self-evaluations, (b) the exploration of the normative liabilities of each age period, and (c) the discussion of the implications for adaptive and maladaptive self-development at each period of adolescence.

### **Early Adolescence: Verbal Cameo of Normative Self-Representations and Self-Evaluations**

I'm an extrovert with my friends: I'm talkative, pretty rowdy, and funny. I'm fairly good-looking if I do say so. All in all, around people I know pretty well I'm awesome, at least I think my friends think I am. I'm usually cheerful when I'm with my friends, happy and excited to be doing things with them. I like myself a lot when I'm around my friends. With my parents, I'm more likely to be depressed. I feel sad as well as mad and also hopeless about ever pleasing them. They think I spend too much time at the mall with my friends, and that I don't do enough to help out at home. They tell me I'm lazy and not very responsible, and it's hard not to believe them. I get real sarcastic when they get on my case. The fact of the matter is that what they think about is still really important. So when they are on my case, it makes me dislike myself as a person. At school, I'm pretty intelligent. I know that because I'm smart when it comes to how I do in classes, I'm curious about learning new things, and I'm also creative when it comes to solving problems. My teacher says so. I get better grades than most, but I don't brag about it because that's not cool. I can be a real introvert around people I don't know well. I'm shy, uncomfortable, and nervous. Sometimes I'm simply stupid, I mean I act really dumb and say things that are just plain stupid. I worry a lot about what others my age who are not my closest friends must think of me, probably that I'm a total dork. I just hate myself when that happens, because what *they* think is really important. (adapted from Harter, 1999)

With regard to the content of the self-portraits of young adolescents, interpersonal attributes, and social skills that influence interactions with others or one's so-

cial appeal are typically quite salient, as findings by Damon and Hart (1988) indicate. Thus, our prototypical young adolescent admits to being talkative, rowdy, funny, good-looking, and downright awesome, characteristics that may enhance acceptance by peers. In addition to social attributes, self-representations also focus on competencies such as one's scholastic abilities (e.g., "I'm intelligent") and affects (e.g., "I'm cheerful" and "I'm depressed").

From a developmental perspective, there is considerable evidence that the self becomes increasingly differentiated (see Harter, 1998, 1999). During adolescence, there is a proliferation of selves that vary as a function of social context. These include self with father, mother, close friends, romantic partners, peers, as well as the self in the role of student, on the job, and as an athlete (Gecas, 1972; N. Griffin, Chassin, & Young, 1981; Hart, 1988; Harter, Bresnick, Bouche, & Whitesell, 1997; Harter & Monsour, 1992; Smollar & Youniss, 1985). For example, as the cameo reveals, the adolescent may be cheerful and rowdy with friends, depressed and sarcastic with parents, intelligent, curious, and creative as a student, and shy and uncomfortable around people whom he or she does not know. A critical developmental task, therefore, is the construction of multiple selves that will undoubtedly vary across different roles and relationships, as James (1892) observed over 100 years ago.

In keeping with a major theme of this chapter, both cognitive and social processes contribute to this proliferation of selves. Cognitive-developmental advances, described earlier, promote greater differentiation (see Fischer, 1980; Fischer & Canfield, 1986; Harter, 1990b; Harter & Monsour, 1992; Keating, 1990). Moreover, these advances conspire with socialization pressures to develop different selves in different relational contexts (see Erikson, 1968; Grotevant & Cooper, 1986; Hill & Holmbeck, 1986; Rosenberg, 1986). For example, bids for autonomy from parents make it important to define oneself differently with peers in contrast to parents (see also Steinberg & Silverberg, 1986; White, Speisman, & Costos, 1983). Rosenberg points to another component of the differentiation process in observing that as one moves through adolescence, one is more likely to be treated differently by those in different relational contexts. In studies from our own laboratory (see Harter & Monsour, 1992; Harter et al., 1997), we have found that the percentage of overlap in self-attributes generated for different social contexts ranges from 25% to 30%

among seventh and eighth graders and decreases during adolescence, to a low of approximately 10% among older teenagers.

Many (although not all) of the self-descriptions to emerge in early adolescence represent abstractions about the self, based on the newfound cognitive ability to integrate trait labels into higher-order self-concepts (see Case, 1985; Fischer, 1980; Flavell, 1985; Harter, 1983; Higgins, 1991). For example, as the prototypical cameo reveals, one can construct an abstraction of the self as "intelligent" by combining such traits as smart, curious, and creative. Alternatively, one may create an abstraction that the self is an "airhead" given situations where one feels dumb and "just plain stupid." Similarly, an adolescent could construct abstractions that he or she is an "extrovert" (integrating the traits of rowdy, talkative, and funny) and that he or she is also an "introvert" in certain situations (when one is shy, uncomfortable, and nervous). With regard to emotion concepts, one can be depressed in some contexts (combining sad, mad, and hopeless) as well as cheerful in others (combining happy and excited). Thus, abstractions represent more cognitively complex concepts about the self in which various trait labels can now be appropriately integrated into even higher-order generalizations.

Although the ability to construct such abstractions reflects a cognitive advance, these representations are highly compartmentalized; that is, they are quite distinct from one another (Case, 1985; Fischer, 1980; Higgins, 1991). For Fischer, these "single abstractions" are overdifferentiated, and therefore the young adolescent can only think about each of them as isolated self-attributes. According to Fischer, structures that were observed in childhood reappear at the abstract level. Thus, just as single representations were compartmentalized during early childhood, Fischer argues that when the adolescent first moves to the level of abstract thought, he or she lacks the ability to integrate the many single abstractions that are constructed to define the self in different relational contexts. As a result, adolescents will engage in all-or-none thinking at an abstract level. For Fischer, movement to a qualitatively new level of thought brings with it lack of "cognitive control," and, as a result, adolescents at the level of single abstractions can only think about isolated self-attributes. Thus, contrary to earlier models of mind (Piaget, 1960), in which formal operations usher in newfound cognitive-developmental abilities that should allow one to create an integrated theory of self, fragmentation of

self-representations during early adolescence is more the rule than the exception (Fischer & Ayoub, 1994; Harter & Monsour, 1992).

Another manifestation of the compartmentalization of these abstract attributes can be observed in the tendency for the young adolescent to be unconcerned about the fact that across different roles, certain postulates appear inconsistent, as the prototypical self-description implies (in contrast, at middle adolescence, there is considerable concern). However, during early adolescence, the inability to integrate seemingly contradictory characteristics of the self (e.g., intelligent versus airhead, extrovert versus introvert, or depressed versus cheerful) has the psychological advantage of sparing the adolescent conflict over opposing attributes in his or her self-theory (Harter & Monsour, 1992). Moreover, as Higgins observes, the increased differentiation functions as a cognitive buffer, reducing the possibility that negative attributes in one sphere may spread or generalize to other spheres (see also Linville, 1987; Simmons & Blyth, 1987). Thus, although the construction of multiple selves sets the stage for attributes to be contradictory, most young adolescents do not identify potential contradictions or experience conflict, given the compartmentalized structure of their abstract self-representations.

Evidence comes from our own research (see Harter et al., 1997; Harter & Monsour, 1992), in which we asked adolescents at three developmental levels, early adolescence (seventh grade), middle adolescence (ninth grade), and late adolescence (11th grade) to generate self-attributes across several roles and then indicate whether any of these attributes represented opposites (e.g., cheerful versus depressed, rowdy versus calm, studious versus lazy, at ease versus self-conscious). After identifying any such opposites, they were asked whether any such pairs caused them conflict—were they perceived as clashing in their personality? Across studies, the specific roles have varied. They have included self with a group of friends, with a close friend, with parents (mother versus father), in romantic relationships, in the classroom, and on the job. Across a number of converging indices (e.g., number of opposites, number of conflicts, or percentage of opposites in conflict) the findings revealed that attributes identified as contradictory and experienced as conflicting were infrequent among young adolescents.

An examination of the protocols of young adolescents reveals that there are potential opposites that go undetected. Examples not identified as opposites by young

adolescents (but that appeared contradictory to our research team) included being talkative as well as shy in romantic relationships, being uptight with family but carefree with friends, being caring and insensitive with friends, being a good student and a troublemaker in school, being self-conscious in romantic relationships but easygoing with friends, as well as being lazy as a student but hardworking on the job. These observations bolster the interpretation (from Fischer's theory) that young adolescents do not yet have the cognitive ability to simultaneously compare these attributes to one another, and therefore they tend not to detect, or be concerned about, self-representations that are potential opposites. As one young adolescent put it, when confronted with the fact that he had indicated that he was both caring and rude, "Well, you are caring with your friends and rude to people who don't treat you nicely. There's no problem. I guess I just think about one thing about myself at a time and don't think about the other until the next day." When another young adolescent was asked why opposite attributes did not bother her, she succinctly exclaimed, "That's a stupid question. I don't fight with myself!" As becomes apparent, this pattern changes dramatically during middle adolescence.

The differentiation of role-related selves, beginning in early adolescence, can also be observed in the tendency to report differing levels of self-esteem across relational contexts. In the prototypical description, the young adolescent reports that with friends, "I like myself a lot"; however, with parents, I "dislike myself as a person." Around "people I don't know well, I just hate myself." Although the concept of self-esteem has, until now, been reserved for perceptions of global self-esteem, we have introduced the construct of relational self-esteem (Harter, Waters, & Whitesell, 1998).

Beginning in the middle school years, adolescents discriminate their level of perceived self-esteem (i.e., how much they like themselves as a person, across relational contexts). We have examined these perceptions across a number of such contexts including self-worth with parents, with teachers, with male classmates, and with female classmates. Factor-analyses reveal clear factor patterns with high loadings on the designated factors (i.e., each relational context) with negligible cross-loadings. We have also examined the discrepancy between individuals' highest and lowest relational self-esteem scores. Although a minority of adolescents (approximately one-fourth) were found to report little variation in self-esteem across contexts, the vast major-

ity (the remaining three-fourths) report that their self-esteem did vary significantly as a function of the relational context. In the extreme, one female participant reported the lowest possible self-esteem score with parents and the highest possible self-esteem score with female classmates.

In addition to documenting such variability, our goal has been to identify potential causes of these individual differences. In addressing one determinant, we adopted Cooley's (1902) looking glass self-perspective, in which the opinions of significant others are incorporated into one's sense of personal worth. Building on our previous empirical efforts (see Harter, 1990b), we hypothesized that context-specific support, in the form of validation for whom one is as a person, should be highly related to self-esteem in the corresponding context. The findings corroborated the more specific prediction that support in a given relationship was more highly associated with relational self-esteem in that relationship, compared to self-esteem in the other three contexts. Thus, the pattern of results suggests a refinement of the looking glass self-formulation, in that validation from particular significant others will have its strongest impact on how one evaluates one's sense of worth in the context of those particular others.

These findings highlight the fact that with the proliferation of multiple selves across roles, adolescents become very sensitive to the potentially different opinions and standards of the significant others in each context. As the cameo description reveals, the adolescent reports high self-esteem around friends who think he or she is "awesome," lower self-esteem around parents who think he or she is "lazy" and "irresponsible," and the lowest level of self-esteem around strangers who probably think "I'm a total dork." As Rosenberg (1986) observes, adolescents demonstrate a heightened concern with the reflected appraisals of others. He notes that other people's differing views of the self (e.g., the respect of the peer group in contrast to the critical stance of parents) will inevitably lead to variability in the self-concept across contexts.

In addition to their sensitivity to feedback from others, young adolescents continue to make use of social comparison information. However, with increasing age, children shift from more conspicuous to more subtle forms of social comparison as they become more aware of the negative social consequences of overt comparisons; for example, they may be accused of boasting about their superior performance (Pomerantz, Ruble,

Frey, & Greulich, 1995). As the prototypical young adolescent describes in the cameo, “I get better grades than most, but I don’t brag about it because that’s not cool.”

### *Normative Liabilities for Self-Development during Early Adolescence*

As with the entry into any new developmental level, there are liabilities associated with these emerging self-processes. For example, although abstractions are developmentally advanced cognitive structures, they are removed from concrete, observable behaviors and therefore more susceptible to distortion. The adolescent’s self-concept, therefore, becomes more difficult to verify and is often less realistic. As Rosenberg (1986) observes, when the self comes to be viewed as a collection of abstractions, uncertainties are introduced because there are “few objective and unambiguous facts about one’s sensitivity, creativity, morality, dependability, and so on” (p. 129). Moreover, the necessary skills to apply hypothetico-deductive thinking to the postulates of one’s self-system are not yet in place. Although the young adolescent may have multiple hypotheses about the self, he or she does not yet possess the ability to correctly deduce which are true, leading to distortions in self-perceptions.

The all-or-none thinking of this period, in the form of overgeneralizations that the young adolescent cannot cognitively control (Fischer, 1980), also contributes to unrealistic self-representations, in that at one point in time one may feel totally intelligent or awesome, whereas at another point in time one may feel like a dork. Thus, the adolescent sense of self will vacillate, given the inability to cognitively control one’s self-representations.

In describing this “barometric self” during adolescence, Rosenberg (1986) points to a different set of more social causes. He cites considerable literature revealing that adolescents experience an increased concern with what their peers think of them, findings that are relevant to Cooley’s looking glass self model. This heavy dependence on the perceptions of other’s opinions tends to set the stage for volatility in one’s assessment of the self. However, there is inevitable ambiguity about others’ attitudes toward the self because one can never have direct access to the mind of another. Thus, attributions about others’ thought processes may change from one time period to another. The second reason for fluctuating self-evaluations inheres in the fact that different significant others have different opinions of the

self, depending on the situation or moment in time. Third, adolescents’ concern with what others think of them leads to efforts at impression management, provoking variations in the self across relational contexts. Finally, at times, adolescents are treated as more adultlike (e.g., on a job) whereas at other times, they are treated as more childlike (e.g., with parents at home). Thus, the self fluctuates in tandem.

Our own findings on the emergence of how self-esteem varies as a function of one’s relationships (what we have termed *relational self-esteem*) is consistent with Rosenberg’s analysis (Harter, 1999). The young adolescent is not yet troubled by what could be viewed as inconsistent self-representations because he or she cannot simultaneously evaluate them as contradictory. However, there are liabilities associated with this inability. The compartmentalization of abstractions about the self precludes the construction of an integrated portrait of self. The fact that different significant others may hold differing opinions about the self makes it difficult to develop the sense that the self is coherent. With movement into middle adolescence, abstract self-descriptors become far less isolated or compartmentalized. However, the emerging structures that follow bring with them new liabilities.

Finally, there are domain-specific normative liabilities that are associated with educational transitions. Young adolescents all shift from an elementary school to either a middle school or junior high school that typically draws on several elementary feeder schools. Thus, they must now move into a group of peers, many of whom they have previously not known (typically two-thirds to three-fourths of the peer group will be new). Given the young adolescent’s heightened concern with how others view the self, an important source of global self-esteem, there may be understandable shifts in global self-esteem, if individuals perceive that their social acceptance is higher or lower than when they were in elementary school.

Eccles and Midgley (1989) have also pointed to different emphases in the educational system during the transition to middle school or elementary school that have implications for perceptions of a child’s scholastic competence. They note that there is considerably more emphasis on social comparison (e.g., public posting of grades, ability grouping, or teachers, in their feedback to classes, verbally acknowledging the personal results of competitive activities). These educational practices

represent a mismatch given the adolescent's needs. At a time when young adolescents are painfully self-conscious, the school system heightens the salience of social comparison in conjunction with publicizing each student's performance. In addition to the greater emphasis on social comparison, the standards for performance shift from *effort* to *ability*, according to Eccles and colleagues. They note that in elementary school, there is more emphasis on effort: "Try harder and you can do better." In middle and junior high schools, however, poorer performance is attributed to lack of scholastic ability, leading the young adolescent to feel that he or she does not have the aptitude to succeed or that he or she lacks intelligence. For those not performing well, these practices can lead to declines in self-perceptions of academic ability, shifts that will be exacerbated in contexts of high public feedback and greater social comparison.

***Individual Differences: Adaptive and Maladaptive Outcomes during Early Adolescence***

The frameworks of James (1892) and Cooley (1902), in conjunction with attachment theory, provide perspectives on the tremendous individual differences that one can observe in self-evaluations beginning in adolescence. From a Jamesian perspective, the congruence or discrepancy between one's perceptions of competence in age-appropriate domains and the *importance of success* attached to each domain have been demonstrated to be a major determinant of one's global self-esteem or self-worth (1990). Thus, those who are able to positively evaluate their successes in domains deemed important to the self will report high self-esteem. A parallel process is the ability to tout the importance of those domains in which one is succeeding. Conversely, those reporting failures in domains of importance will report low self-esteem. Such individuals appear unable to discount the importance of domains in which they are not successful.

Not all researchers in the field endorse the notion that the importance attached to success adds to the prediction of global self-esteem, notably Marsh and his colleagues (Hattie & Marsh, 1996; Marsh, 1993). They base their claims on findings indicating that merely correlating perceived competence or adequacy scores with global self-esteem (ignoring importance) yields values that are comparable to those based on procedures in which perceived importance is also taken into account.

We do not question these statistical findings; they are consistent with our own. We do question the conclusions and suggest that the comparison of these correlations is not the appropriate test (see Harter, 1999).

Why might merely correlating domain-specific competence or adequacy scores with global self-esteem or self-worth result in values comparable to those based on correlating these domain-specific values with global self-worth for just those individuals rating given domains as important? The answer lies in the fact that the vast majority of older children and adolescents (approximately 80%, on average) rate these domains as important, and thus the two correlations will be based on virtually the same set of participants. This is not surprising because as Marsh, himself, acknowledges, those of us that have developed domain-specific measures of self-concept have purposely included those domains important to individuals at various developmental levels.

It is our contention that the more statistically parsimonious empirical models espoused by Marsh and his colleagues in which importance ratings are ignored may obscure the actual psychological processes through which individuals formulate an overall sense of their worth as a person. We would claim, beginning in adolescence, that processes including the ability to think about, to reflect on one's self and the causes of one's overall feelings of self-worth, are not necessarily parsimonious. Considerable literature (see reviews in Harter, 1990a, 1999) reveals the heightened introspectiveness and self-consciousness that emerges in adolescence. Thus, if we truly want to understand the processes underlying adolescents' construction of evaluative judgments about the self (rather than merely predict a value statistically) our own findings indicate that one must take into account the *importance* attached to those self-concept domains that may be relevant to the formulation of an overall view of self.

Elsewhere (Harter, 1999) we have reported on four different empirical approaches that demonstrate the importance of ratings. Additional recent work by MacDonald, Saltzman, and Leary (2003) has demonstrated, with college students, that perceived importance, particularly as it might affect others' judgments of self, directly impacted global self-esteem. In addition, for those interested in clinical or educational interventions, we have also suggested how interventions will be quite different if one takes an approach that only focuses on perceptions of domain-specific competence or adequacy

versus an approach in which one also takes into account perceptions of the importance of success in corresponding domains (Harter, 1999).

Cooley's (1902) looking glass formulation and attachment theorists' explorations into working models of the self (see Bretherton & Munholland, 1999), bolster the social framework for viewing individual differences in self-worth, particularly as young adolescents are becoming more cognizant of their own thinking about themselves. However, "more cognizant," as our earlier developmental analysis reveals, does not necessarily translate into more "realistic." The more abstract self-evaluations are further removed from behavioral reality (see Harter, 1999). In early to middle adolescence, teenagers do not have the ability to engage in hypothetico-deductive thinking to arrive at realistic conclusions about the self. It is for this reason that recent findings (reviewed in Harter, 1999) and more classic reviews (see Shrauger & Schoeneman, 1979) have concluded that *self-perceptions* of approval from significant others will be a better predictor of constructs such as self-esteem than actual measures of support from significant others.

In the previous section on late childhood, the issue was raised as to whose opinion—parents or peers—is most critical to the continuing development of a child's overall sense of self-worth or self-esteem. For many years, textbook renditions of the impact of parents and peers have made the assumption that the influence of parents wanes as a child enters adolescence (see Berndt & Burgoyne, 1996; Harter, 1999). A resurgence of a focus on the impact of peers can also be seen in the work of J. Harris (1998) who makes strong arguments for why parents, with the exception of their genetic contribution, matter little in the psychological development of their children. In contrast, attachment theorists (see Bretherton & Munholland, 1999) continue to assert, as did Bowlby, that the initial attachment with the mother, in particular, is critical to developing a positive working model of self and other that will impact future relationships with peers.

An increasingly sophisticated body of research addresses the more interesting and complex question of the *balance* between parental and peer support because it impacts self-evaluations. Using more advanced statistical techniques, including cluster-analyses and longitudinal predictive designs, recent studies have demonstrated that young adolescents who are able to sustain positive parental support and garner positive

peer approval report more positive self-evaluations (Dubois, Reach, Tevendale, & Valentine, 2001; Roberts, Seidman, & Pederson, 2000).

Therefore, beginning in early adolescence, there is a heightened concern with how others view the self, a normative process that has implications for the salience of those determinants of self-esteem that have been articulated in Cooley's (1902) looking glass self-formulation. If significant others provide support for whom the young adolescent is as a person, for those attributes that the young adolescent feels truly define the self, he or she will experience the self as authentic. However, the construction of a self that is too highly dependent on the internalization of the opinions of others can, under some circumstances, lead to the creation of a false self that does not mirror his or her authentic experience. In our own research (Harter, 1999), we have found that it is not until early adolescence that the concept of acting as a false self becomes very salient in the consciousness of young teenagers. The detection of hypocrisy, not only in others but also in the self, emerges as a critical filter in evaluating others as well as the self.

Our own findings (Harter, Marold, Whitesell, & Cobbs, 1996) reveal that unhealthy levels of false-self behavior are particularly likely to emerge if caregivers make their approval contingent on the young adolescent living up to unrealistic standards of behavior, based on unattainable standards dictated by parents. We have labeled this phenomenon "conditional support" although from interviews we have learned that this is a misnomer in that adolescents do not perceive parental responses, in the face of such demands, as "supportive." Rather, conditionality reflects the psychological hoops through which young adolescents must jump to please the parents, given the parental agenda. Those adolescents who experience such a conditional atmosphere are forced to adopt a socially implanted self: They must learn to suppress what they feel are true self-attributes, in an attempt to garner the needed approval from parental caretakers. Here, the terminology purposely switches from *caregiver* to *caretaker* in a metaphorical effort to convey the fact that such socialization practices "take away" from the care of whom one is as a person, one's true self. Our findings indicate that those experiencing high levels of conditionality from parents will express hopelessness about their ability to please the parents that then translates in high levels of false-self behavior in an attempt to garner some level of needed parental support. Of

particular relevance is that high levels of false-self behavior are directly related to low levels of self-esteem. As our model has revealed (Harter, 1999), low levels of self-esteem are highly correlated with self-reported depressive symptomatology that can, for some adolescents, lead to suicidal thoughts and actions.

Chronic and severe abuse continues to put an adolescent at even more extreme risk for suppressing his or her true self and displaying various forms of inauthentic or false-self behavior. Such a process has its origins in childhood, given the very forms of parenting that constitute psychological abuse. As described earlier, parenting practices that represent lack of attunement to the child's needs, empathic failure, lack of validation, threats of harm, coercion, and enforced compliance all cause the true self to go underground (Bleiberg, 1984; Stern, 1985; Winnicott, 1958, 1965) and lead to what Sullivan (1953) labeled as "not me" experiences.

Our model of the determinants, correlates, and consequences of self-esteem (see Harter, 1999) becomes increasingly relevant at early adolescence and beyond where there is strong empirical support across numerous studies (see review in Harter, 1999). Findings reveal that lack of both parental and peer support can lead to pathological levels of low self-worth, depressed affect, and hopelessness, which may provoke suicidal ideation if not suicidal behaviors.

Our findings (see Harter, 1999) document that while peer support increases in its predictability of global self-esteem between late childhood and early adolescence, the impact of parental support does *not* decline. Previous textbook portrayals of adolescence imply that parental influences decline as a child moves into adolescence. However, nothing is further from the truth when we examine the impact of parental support, including conditionality, on self-processes including false-self behavior, global self-esteem, and the related correlates of depressed affect, hopelessness, and suicidal ideation.

However, the peer culture does come to loom large in adolescence. Peer support and approval, or its absence, is a powerful predictor of what we have labeled the depression /adjustment composite that includes self-esteem or self-worth, affect/mood (along a continuum of depressed to cheerful), and hope (hopeless to hopeful) that has empirically been demonstrated to predict suicidal thinking. Lack of peer approval appears to be more directly linked to perceived inadequacies in the domains of physical appearance, likability by peers, and athletic competence.

**Peer Rejection, Humiliation, and Implications for the High Profile School Shootings.** More recently, we have become focused on the role of peer *rejection*, not merely the lack of peer approval. Our initial interest in this construct came from an analysis of the emerging profiles of the, now, eleven high-profile cases in which White, middle-class older children and adolescents, from small cities or suburbs, have gone on shooting sprees killing peers, and in a few cases, school officials who were random targets rather than specifically identified individuals. What became evident, in the analysis of media reports, is that all of these male youth killers had a history of peer rejection and *humiliation*. As a psychologist who for many years has contributed to (and kept up with) the literature on emotional development in children and adolescents, it was astounding to learn that we have no literature on humiliation. There is ample literature on shame, guilt, embarrassment, but virtually nothing about humiliation. Yet, we can all appreciate the fact (be it from our own experience or the experience of our children) that humiliation is a daily event in schools for many children. For the school shooters, extreme feelings of chronic humiliation by peers, due to excessive teasing, taunting, and physical insults, eventually led them to psychologically "snap," leading to random deaths and in the case of the Columbine teens to suicide.

An examination of the media accounts of the school shooters made it obvious that many of the determinants in our model could be found in the lives of these adolescents (see Harter, Low, & Whitesell, 2003). As a result, we examined a revised model in which we added angry aggression as well as violent ideation. We examined this model in a normative sample of middle school students. Through path-analytic techniques, we demonstrated that the data fit the model exceedingly well: The antecedents in the model, domain-specific perceived inadequacies predicted lack of approval from peers and parents alike. These determinants, in turn, predicted low self-esteem, depressed affect, angry affect, and hopelessness, all of which predicted *both* suicidal ideation and violent ideation. Consistent with the clinical literature on the comorbidity of internalizing and externalizing symptoms, we found a correlation of  $r = .55$  between suicidal and violent ideation toward others. Thus, the determinants in our model, if negative, put adolescents at pathological risk for endangering their own and others' lives.

We have also pursued the emotion of humiliation and its role in contributing to violent ideation. In this Harter,

Low, & Whitesell study (2003), we wrote vignettes that simulated some of the types of humiliating events that were experienced by the school shooters. We then asked middle school students what other emotions they might experience (e.g., anger or depression) and what behaviors they might exhibit, along a continuum from doing nothing to acting violently toward the perpetrators or toward anyone (given the randomness of the actual school shooting events). While the majority of students reported that they would be humiliated (given that the vignettes were designed to be humiliating) we identified a group of violent ideators (in the minority) and a group who did not report that they would think about violent revenge. We then sought to determine what distinguished the two groups, finding that those entertaining violent thoughts expressed higher levels of anger and depression. In addition, the violent ideators reported higher levels of negative determinants in the model, such as more peer rejection, less parental support, lower self-concept scores (e.g., appearance or peer likability), lower self-worth, and greater hopelessness. Thus, certain factors in histories of violent ideators propel them to thoughts of seriously harming others and themselves, which are pathological outcomes that may require clinical interventions given that they may be putting themselves and others at serious risk.

In a subsequent study, we sought to more specifically investigate what were some of the factors that lead humiliation to result in violent ideation as well as suicidal ideation, given the paucity of work on the emotion of humiliation. Our findings have documented that teasing and taunting and bullying, particularly in the presence of an *audience who mocks the victim*, lead to humiliation. Humiliation, in turn, serves to provoke prototypical reactions, including revenge, wanting to hide, or attempts to minimize the humiliation (Harter, Kiang, Whitesell, & Anderson, 2003). We are pursuing this prototypical approach to humiliation currently.

**Is There a Dark Side to High Self-Esteem?** Our own modeling efforts demonstrate that it is *low* self-esteem that is consistently related to suicidal and violent thinking. These findings are consistent with the broader literature (see Harter, 1999) revealing that high self-esteem is a psychological commodity associated with positive adjustment and mental-health outcomes. Low self-esteem, in contrast, has been viewed as a liability and has been associated with poor adjustment in the literature (e.g., depression, anxiety, conduct problems, or teen pregnancy). However, there is current con-

troversy over whether they may also be a dark side to high self-esteem.

So what is the controversy? One vocal group of theorists (Baumeister, Smart, & Boden, 1996) has argued that there is a subset of individuals with high but fragile self-esteem who are often aggressive in response to perceived ego threats. Baumeister and colleagues contend that individuals who report high self-esteem in combination with high narcissism, low empathy, and sensitivity to rejection will, in the face of threats to the ego, exhibit violent tendencies.

We (Harter & McCarley, 2004) believe that Baumeister's composite of predictors has some merit, with the exception of the role of self-esteem. Specifically, we predicted that high narcissism, low empathy, sensitivity to rejection coupled with *low* self-esteem (not high self-esteem) would lead young adolescents, in the face of threats to the ego, to violent ideation. To assess violent ideation, participants read humiliating scenarios that represented threats to the ego and were then asked to rate how they would typically respond in such a situation, ranging from doing nothing to seriously harming the perpetrator. Self-esteem was measured by our Global Self-Worth Scale (Harter, 1985). Narcissism, empathy, and sensitivity to rejection were assessed by adaptations of previously developed measures, all of which were found to be reliable (alphas ranging from .76 to .87). Regression analyses demonstrated that high narcissism and low empathy significantly predicted violent ideation. However, in contrast to Baumeister's claims, higher self-esteem was associated with lower levels of violent ideation. Further, when self-reported conduct (positive to negative) and the frequency of experiencing humiliating events were included in the model, they both explained a substantial proportion of the variance in violent ideation.

In addition to regression analyses, identification of two extreme groups, those high and low on violent ideation differed significantly with violent ideators reporting higher narcissism, lower empathy, and greater sensitivity to rejection, as Baumeister would predict, but *lower* self-esteem that is not consistent with his formulation. In a subsequent study, we added fluctuating self-esteem, conduct, and the frequency of humiliating, rejection events (Harter & McCarley, 2004). These increased the predictability of violence ideation, both in regression analyses and in comparisons of violent and nonviolent ideators. Violent ideators reported fluctuating self-esteem, greater conduct problems and a greater frequency of having established humiliating events that

were ego threatening. Thus, our understanding of thoughts qualifies and broadens the precursors. Not only is self-esteem not predictive of violence but self-esteem and narcissism are uncorrelated ( $r = -.01$ ), indicating that these are different constructs both conceptually, as scales define the two constructs, and empirically. Narcissism entails a sense of entitlement, of superiority, of exhibitionism, whereas high self-esteem is defined as liking and respecting who one is as a person. There is a need to distinguish between these two concepts, conceptually, methodologically, and empirically.

Finally, in this study, we uncovered an interesting finding that is cause for concern. In the high profile cases of the school shooters, the vast majority had not been in any major trouble with the law and had *not* come to the attention of teachers or school personnel as potential troublemakers. Teachers, school officials, and students were astounded that these boys committed such violent acts. Debriefing efforts of the surviving students and families at Columbine, conducted by University of Denver clinicians and some in private practice, revealed that students and their families were realistically fearful that they would not be able to detect who, in the future, might commit such acts because there were few warning signs that they were capable of such behavior. These concerns are real, given findings from Harter and McCarley (2004). In this study, we asked teachers to rate student conduct (e.g., getting in trouble or potential for violent thinking) and among the subgroup of violent ideators who had rated their own conduct as quite negative, teachers incorrectly rated one-third of the group, giving them very positive scores on conduct. This is concerning the difficulty in assessing certain students at risk. Although such violent ideators may not be at risk for violent *action* (given the low percentage of such acts in most schools), violent ideation represents a different kind of pathological risk factor to the extent that it interferes with attention and concentration of scholastic endeavors, with socially appropriate behaviors that would promote positive peer interactions, and so on. The very presence of this subgroup of violent ideators suggests that they represent a type of student with different intrapsychic dynamics compared to those students with histories of conduct problems, delinquency, and acting out patterns, all of whom readily come to the attention of teachers, school officials, and peers. Those not showing these patterns are of concern in terms of their identification. One of our goals is to devise a short-form of our instruments that will allow schools to identify those who may have escaped the attention of school personnel

but are nevertheless at pathological risk. Many of these processes begin in early adolescence (and even late childhood) but continue into middle and later adolescence, as the range of ages of the actual school shooters reveals, continuing the presence of risk factors.

**Pathological Eating-Disordered Behavior.** Our model identifies one self-concept domain that robustly affects global self-esteem across ages and cultures, namely, perceived physical appearance or attractiveness. In reviewing the inextricable link between perceived appearance and self-esteem, between the outer self and the inner self (see Harter, 1999), it became very apparent that this link is profoundly impacted by cultural standards of appearance for each gender. That cultures tout physical attractiveness as the measure of one's worth as a person has been amply demonstrated in contemporary society, as well as historically (Hatfield & Sprecher, 1986). The empirical findings (reviewed in Harter, 1999) indicate that Pearson correlations range from the .40s to the .80s. Moreover, investigators have revealed that these relationships are not merely statistical but are very much embedded in the consciousness of individuals who are aware of this link. In our own work (Kiang & Harter, 2004), we have found strong support for a model in which awareness of current cultural values (e.g., being attractive will lead to higher self-esteem, meeting standards of appearance will make people more popular, and people who are overweight are discriminated against) are highly endorsed. However, there is enough variability in these scores to relate such awareness to perceptions of one's own appearance, which, in turn, predict level of self-esteem and eating-disordered perceptions and behaviors. Specifically, those endorsing these cultural values or links reported more negative views of their appearance, lower self-esteem, more psychological correlates of eating disorders and more eating-disordered behaviors.

This particular study was conducted with college students. However, the seeds of such a model are sown in early adolescence (if not earlier) as teenagers of both genders are well aware of the prevailing norms for desirable appearance. For adult females in the 2000s, one must be tall, very thin, weigh very little (around 110 to 115), have ample breasts, and a pretty face and hair, all of which is an unattainable combination for more than 90% of the female population. Recent statistics (Kilbourne, 1994) indicated that the average American woman is 5'4" and weighs 140. Standards have been exceedingly punishing for females for decades. What is

new in the past 2 decades is the fact that the bar has been raised for males in our society. No longer is sex appeal to be judged by status, wealth, position, and power but by physical standards of attractiveness as well. Muscular build, abs, biceps, physique, hair (on head as well as face) have all come to define the new ideals for men (see Harter, 1999).

These standards are not lost on our young adolescents. Children succumb to the same discouragement about not being able to emulate the models, singers, and movie stars in the limelight. The importance of meeting these standards becomes particularly salient during early adolescence as teenagers face inevitable pubertal changes that signal their impending adulthood. Thus, they look to the adult standards as the physical markers for what defines attractiveness, appeal, social acceptability, all of which determine one's self-esteem.

The genetic throw of the dice lead some young adolescent males and females to fare better than others in the appearance wars. For example, early maturing girls are at a distinct disadvantage given the current emphasis on thinness and height because on average they are heavier and shorter, compared to later maturing girls who tend to be thinner and taller. The pattern is just the opposite for adolescent males in that earlier maturing teens tend to be taller and more muscular, which gives them a physical edge. Thus, beginning in early adolescent, evaluations of one's appearance take on critical implications for one's global self-esteem. Those not meeting the gold standards are at serious risk for pathological forms of depression and possibly suicide, as well as eating disorders that can be life threatening. Although this preoccupation initially becomes salient in early adolescent, it continues throughout the life span.

### **Middle Adolescence: Verbal Cameo of Normative Self-Representations and Self-Evaluations**

What am I like as a person? You're probably not going to understand. I'm complicated! With my really close friends, I am very tolerant. I mean, I'm understanding and caring. With a group of friends, I'm rowdier. I'm also usually friendly and cheerful but I can get pretty obnoxious and intolerant if I don't like how they're acting. I'd like to be friendly and tolerant all of the time, that's the kind of person I want to be, and I'm disappointed in myself when I'm not. At school, I'm serious, even studious every now and then, but on the other hand, I'm a goof-off too, because if you're too studious, you won't be popular. So I go

back and forth, which means I don't do all that well in terms of my grades. But that causes problems at home, where I'm pretty anxious when I'm around my parents. They expect me to get all As, and get pretty annoyed with me when report cards come out. I care what they think about me, and so then I get down on myself, but it's not fair! I mean I worry about how I probably should get better grades, but I'd be mortified in the eyes of my friends if I did too well. So, I'm usually pretty stressed-out at home, and can even get very sarcastic, especially when my parents get on my case. But I really don't understand how I can switch so fast from being cheerful with my friends, then coming home and feeling anxious, and then getting frustrated and sarcastic with my parents. Which one is the real me? I have the same question when I'm around boys. Sometimes, I feel phony. Say I think some guy might be interested in asking me out. I try to act different, like Britney Spears, I'll be a real extrovert, fun-loving and even flirtatious, and think I am really good-looking. It's important to be good-looking like the models and movie stars. That's what makes you popular. I know in my heart of hearts that I can never look like her, so why do I even try. It makes me hate myself and feel depressed. Plus, when I try to look and act like her, then everybody, I mean *everybody* else is looking at me like they think I am totally weird! They don't act like they think I'm attractive so I end up thinking I look terrible. I just hate myself when that happens! Because it gets worse! Then I get self-conscious and embarrassed and become radically introverted, and I don't know who I really am! Am I just acting like an extrovert, am I just trying to impress them, when really I'm an introvert! But I don't really care what they think, anyway. I mean I don't want to care, that is. I just want to know what my close friends think. I can be my true self with my close friends. I can't be my real self with my parents. They don't understand me. What do they know about what it's like to be a teenager? They treat me like I'm still a kid. At least at school, people treat you more like you're an adult. That gets confusing, though. I mean, which am I? When you're 15, are you still a kid or an adult? I have a part-time job and the people there treat me like an adult. I want them to approve of me, so I'm very responsible at work, which makes me feel good about myself there. But then I go out with my friends and I get pretty crazy and irresponsible. So, which am I, responsible or irresponsible? How can the same person be both? If my parents knew how immature I act sometimes, they would ground me forever, particularly my father. I'm real distant with him. I'm pretty close to my mother though. But it's hard being distant with one parent and close to the other, especially if we are all together, like talking at dinner. Even though I am close to my mother, I'm still pretty secretive about some things, particularly the things about

myself that confuse me. So I think a lot about who is the real me, and sometimes I try to figure it out when I write in my diary, but I can't resolve it. There are days when I wish I could just become immune to myself! (adapted from Harter, 1999)

Self-descriptions are likely to increase in length during this period, as adolescents become increasingly introspective and morbidly preoccupied with what others think of them (Broughton, 1978; Elkind, 1967; Erikson, 1959, 1968; Harter, 1990a; Lapsley & Rice, 1988; Rosenberg, 1979). The unreflective self-acceptance of earlier periods of development vanishes, and, as Rosenberg observes, what were formerly unquestioned self-truths now become problematic self-hypotheses. The tortuous search for the self involves a concern with what or who am I (Broughton, 1978), a task made more difficult given the multiple Me's that crowd the self-landscape. There is typically a further proliferation of selves as adolescents come to make finer differentiations; in the cameo, the adolescent describes a self with really close friends (e.g., tolerant) versus with a group of friends (e.g., intolerant) and a self with mother (e.g., close) versus father (e.g., distant). The acquisition of new roles, for example, self at a job, may also require the construction of new context-specific attributes (e.g., responsible).

Moreover, additional cognitive I-self processes emerge that give the self-portrait a very new look (Case, 1985; Fischer, 1980). Whereas, in the previous stage, single abstractions were isolated from one another, during middle adolescence one acquires the ability to make comparisons between single abstractions, namely, between attributes in the same role-related self or across role-related selves. Fischer labels these new structures "abstract mappings," in that the adolescent can now "map" constructs about the self onto one another or directly compare them. Therefore, mappings force the individual to compare and contrast different attributes. It should be noted that abstract mappings have features in common with the "representational" mappings of childhood, in that the cognitive links that are initially forged often take the form of opposites. During adolescence, these opposites can take the form of seemingly contradictory abstractions about the self (e.g., tolerant versus intolerant, extrovert versus introvert, responsible versus irresponsible, and good-looking versus unattractive as in the cameo).

However, the abstract mapping structure has limitations as a means of relating two concepts to one another in that the individual cannot yet truly integrate such

self-representations in a manner that would resolve apparent contradictions. Therefore, at the level of abstract mappings, the awareness of these opposites causes considerable intrapsychic conflict, confusion, and distress (Fischer et al., 1984; Harter & Monsour, 1992; Higgins, 1991), given the inability to coordinate these seemingly contradictory self-attributes. For example, our prototypical adolescent agonizes over whether she is an extrovert or an introvert ("Am I just acting like an extrovert, am I just trying to impress them, when really I'm an introvert?" "So which am I, responsible or irresponsible? How can the same person be both?"). Such cognitive-developmental limitations contribute to the emergence of what James (1892) identified as the "conflict of the different Me's."

In addition to such confusion, these seeming contradictions lead to very unstable self-representations that are also cause for concern (e.g., "I don't really understand how I can switch so fast from being cheerful with my friends, then coming home and feeling anxious, and then getting frustrated and sarcastic with my parents. Which one is the real me?"). The creation of multiple selves, coupled with the emerging ability to detect potential contradictions between self-attributes displayed in different roles, naturally ushers in concern over which attributes define the true self. However, from a normative perspective, the adolescent at this level is not equipped with the cognitive skills to fully solve the dilemma (e.g., "So I think a lot about who is the real me, and sometimes try to figure it out when I write in my diary, but I can't resolve it").

As introduced in the previous section on early adolescence, our own research has been directed toward an examination of the extent to which adolescents at three developmental levels identify opposing self-attributes and report that they are experienced as conflictual (Harter & Monsour, 1992; Harter et al., 1997). We have determined, across several studies, that young adolescents infrequently detect opposites in their self-portrait. However, it was predicted, according to the analysis presented earlier, that there would be a dramatic rise in the detection of opposing self-attributes and an acknowledgment that such apparent contradictions lead to conflict in the self-system at mid-adolescence. Our most recent procedure for examining these issues is described in Harter (1999), as are the findings.

Across three different studies (see Harter et al., 1997), we have found that the number of opposing self-attribute pairs, as well as the number of opposites in

conflict, increases between early and middle adolescence. This pattern of findings supports the hypothesis that the abstract mapping structures that emerge in middle adolescence allow one to detect, but not to meaningfully integrate, these apparent contradictions. Thus, they lead to the phenomenological experience of intrapsychic conflict. We have asked teenagers to verbally elaborate on the opposites and conflicts that they reported on our task. As one 14-year-old put it, "I really think I am a happy person and I want to be that way with everyone, not just my friends; but I get depressed with my family, and it really bugs me because that's not what I want to be like." Another 15-year-old, in describing a conflict between self-attributes in the realm of romantic relationships, exclaimed, "I hate the fact that I get so nervous! I wish I wasn't so inhibited. The real me is talkative. I just want to be natural, but I can't." Another 15-year-old girl explained, "I really think of myself as friendly and open to people, but the way the other girls act, they force me to become an introvert, even though I know I'm not." In exasperation, one ninth-grader observed of the self-portrait she had constructed, "It's not right, it should all fit together into one piece!" These comments suggest that at this age level, there is a need for coherence; there is a desire to bring self-attributes into harmony with one another, yet in mid-adolescence, the cognitive abilities to create such a self-portrait are not yet in place.

For across-role opposites, at every age level, females detect more contradictory attributes than do males. These findings replicate two other studies in which similar gender differences were obtained (see Harter et al., 1997). Moreover, in one study in which we asked subjects to indicate how upset they were over conflicting attributes, the pattern revealed that females become more upset over conflicting attributes across early, middle, and late adolescence, whereas males become less upset. Elsewhere, we have offered a general interpretation of this pattern, drawing on those frameworks that emphasize the greater importance of relationships for females than males (Chodorow, 1989; Eichenbaum & Orbach, 1983; Gilligan, 1982; Jordan, 1991; J. Miller, 1986; Rubin, 1985). These theorists posit that the socialization of girls involves far more embeddedness in the family and more concern with connectedness to others. Boys, in contrast, forge a path of independence and autonomy in which the logic of moral and social decisions takes precedence over affective responses to significant others.

In extrapolating from these observations, we have suggested that in an effort to maintain the multiple relationships that girls are developing during adolescence, and to create harmony among these necessarily differentiated roles, opposing attributes in the self become particularly salient as well as problematic. Boys, in contrast, can move more readily among their different roles and multiple selves to the extent that such roles are logically viewed as more independent of one another. However, these general observations require further refinement, including an empirical examination of precisely which facets of the relational worlds of adolescent females and males are specifically relevant to gender differences in opposing attributes displayed across different contexts.

Closer examination of the gender effects reveals that it is a subset of female adolescents who report more opposites and greater conflict compared to males. We have determined that adolescent females who endorse a feminine gender orientation (eschewing masculine traits) may be particularly vulnerable to the experience of opposing attributes and associated conflict. Feminine adolescent females, compared to females who endorse an androgynous orientation, report more conflict, particularly in roles that involve teachers, classmates, and male friends (in contrast to roles involving parents and female friends). Several hypotheses would be worth pursuing in this regard. Is it that feminine girls report more contradictions in those public contexts where they feel they may be acting inappropriately by violating feminine stereotypes of behavior? Given that femininity as assessed by sex-role inventories is largely defined by caring, sensitivity, and attentiveness to the needs and feelings of others, might female adolescents who adopt this orientation be more preoccupied with relationships, making opposing attributes and accompanying conflict more salient? Moreover, might it be more important for feminine girls to be consistent across relationships, a stance that may be difficult to sustain, to the extent that significant others in different roles are encouraging or reinforcing different characteristics? These are all new directions in which attention to gender issues should proceed.

The challenges posed by the need to create different selves are also exacerbated for ethnic minority youth in this country who must bridge "multiple worlds," as Cooper and her colleagues point out (Cooper, Jackson, Azmitia, Lopez, & Dunbar, 1995). Minority youth must move between multiple contexts, some of which may be

with members of their own ethnic group, including family and friends, and some of which may be populated by the majority culture, including teachers, classmates, and other peers who may not share the values of their family of origin. Rather than assume that all ethnic minority youth will react similarly to the need to cope with such multiple worlds, these investigators highlighted several different patterns of adjustment. Some youth are able to move facily across the borders of their multiple worlds, in large part, because the values of the family, teachers, and peers are relatively similar. Others, for whom there is less congruence in values across contexts, adopt a bicultural stance, adapting to the world of family and to that of the larger community. Others find the transition across these psychological borders more difficult, and some find it totally unmanageable. Particularly interesting is the role that certain parents play in helping adolescents navigate these transitions, leading to more successful adaptations for some than others.

As observed earlier, adolescents during this period become extremely preoccupied with the opinions and expectations of significant others in different roles. As our prototypical respondent indicates, "I care what my parents think about me"; "I want to know what my close friends think"; "I don't care what (everybody else) thinks. I mean I don't want to care, that is"; "I want them (adults at work) to approve of me." Adolescents gaze intently into the social mirror for information about what standards and attributes to internalize. However, as the number of roles proliferates, leading to messages from different significant others that are potentially contradictory, adolescents may become confused or distressed about just which characteristics to adopt. We see this in the cameo self-description with regard to scholastic performance, in that the adolescent feels she "should get better grades" to please her parents but confesses that "I'd be mortified in the eyes of my friends if I did too well." As Higgins (1991) observes, in their attempt to incorporate the standards and opinions of others, adolescents at this level develop conflicting "self-guides" across different relational contexts as they attempt to meet the incompatible expectations of parents and peers. He reports evidence indicating that such discrepancies have been found to produce confusion, uncertainty, and indecision with regard to self-evaluation and self-regulation, which is consistent with our own findings. Moreover, as Rosenberg (1986) notes, the serious efforts at perspective taking that emerge at this

stage make one aware that no human being can have direct access to another's mind, leading to inevitable ambiguity about others' attitudes toward the self, producing yet another source of doubt and confusion.

The potential for displaying differing levels of self-esteem across relational contexts is also exacerbated during this period, to the extent that the significant others are providing different levels of validation for whom one is as a person (see also Rosenberg, 1986). For example, the cameo self-description reveals that the adolescent gets down on herself for not getting the grades her parents expect. She hates herself when she feels peers think she is weird, but she feels good about herself on the job, where supervisors give her more positive feedback. Our own evidence has revealed that not only does self-esteem become differentiated by context beginning in early adolescence but also further differentiated in middle to late adolescence. For example, individuals come to develop different levels of self-esteem with their mothers and their fathers (Harter, 1999); levels that are directly related to their perceptions of approval from each parent.

#### *Normative Liabilities during Middle Adolescence*

Mid-adolescence brings a preoccupation with what significant others think of the self, a task that is made more challenging given the proliferation of roles that demand the creation of multiple selves. The addition of new role-related selves can be observed in the fact that adolescents make finer discriminations (e.g., self with a close friend versus self with a group of friends, and self with mother versus self with father). Moreover, there is relatively little overlap in the personal attributes that define the self in each role. The proliferation of multiple selves ushers in the potential for such attributes to be viewed as contradictory. Moreover, the emergence of new cognitive processes, such as abstract mappings, forces the adolescent to compare and contrast different attributes, exacerbating the likelihood that contradictions will be detected. Mappings, in the form of the identification of opposites, are problematic in that the individual cannot yet truly integrate such self-representations in a manner that would resolve the contradictions. Thus, the adolescent is likely to experience conflict, confusion, and distress. Opposites and associated conflict are particularly likely to occur for attributes in different roles rather than in the same role. Females are particularly likely to display these negative outcomes. Opposing self-attributes also lead to unstable self-representations, in

addition to concern over which characteristics represent one's true self.

With regard to the impact of the socializing environment, adolescents gaze intently into the social mirror for information about what standards and attributes to internalize. However, contradictory messages from different significant others can lead to confusion about just what characteristics to adopt. Differential support, in the form of approval or validation, will also lead to differing levels of self-worth across relational contexts. The contradictory feedback that adolescents may receive from different sources will, therefore, lead to volatility in self-esteem across interpersonal contexts.

Contradictory standards and feedback can also contribute to a lowering of global self-esteem between early and middle adolescence (see findings reviewed by Harter, 1990a, 1990b), to the extent that one cannot meet the expectations of everyone in each relational context. To the extent that the adolescent does not meet the standards of others, he or she is likely to experience less approval, which will lead to lower global self-esteem. Moreover, the abstract mapping structure, coupled with the penchant for introspection, may also contribute to lowered self-esteem in that it facilitates the comparison of one's ideal and real self-concepts. Such a focus can lead to a heightened awareness of the discrepancy between how one perceives the self to be in reality (e.g., "I can get pretty obnoxious and intolerant") and how one would ideally like to be (e.g., "I'd like to be friendly and tolerant all of the time. That's the kind of person I want to be, and I'm disappointed in myself when I'm not"). The realm of physical appearance is particularly critical. Thus, this adolescent wants to look like Britney Spears, knows she doesn't, and this sets up another painful discrepancy between how she would ideally like to look and how she does. In reality, she does not value her appearance, falling far short of the cultural standards for beauty.

Cognitive-developmental advances during mid-adolescence also represent limitations that can lead to distortions in the interpretation of the opinions of significant others. As observed earlier, with the advent of any new cognitive capacities comes difficulty in controlling and applying them effectively. For example, teenagers have difficulty differentiating their own mental preoccupations from what others are thinking, leading to a form of adolescent egocentrism that Elkind (1967) has labeled the "imaginary audience." Adolescents falsely assume that others are as preoccupied with their behavior and appearance as they themselves are.

As our prototypical respondent exclaims, "Everybody, I mean everybody else is looking at me like they think I am totally weird!" With regard to lack of cognitive control, this phenomenon represents overgeneralization (or failure to differentiate) in that adolescents project their own concerns onto others.

Interestingly, the inability to control and to effectively apply new cognitive structures can result not only in a lack of differentiation between self and other, as in the imaginary audience phenomenon, but also in excessive or unrealistic differentiation. The latter penchant can be observed in another form of egocentrism that Elkind (1967) identified as the "personal fable." In creating narratives that come to define the self, the adolescent asserts that his or her thoughts and feelings are uniquely experienced. No one else can possibly understand or experience the ecstasy of his or her rapture or the intensity of his or her despair. Adults, particularly parents, are likely to be singled out in this regard. As the prototypical adolescent exclaims, "My parents don't understand me. What do they know about what it's like to be a teenager?" Her initial comment to the interviewer when asked to describe what she was like ("You're probably not going to understand") also reflects this type of overdifferentiation between self and other.

The liabilities of this period, therefore, are legion with regard to potential conflict and confusion over contradictory attributes and messages, concern over which characteristics define the true self, distortions in the perception of self versus others, and a preoccupation with discrepancies between the real and ideal self-concepts, all of which can lead to lowered self-worth. Some of these processes would appear to be problematic for particular subgroups of adolescents, for example, females who adopt a feminine gender orientation or ethnic minority youth who are challenged by the need to create selves that bridge "multiple worlds," with one's family, ethnic peers and in the mainstream majority culture.

An appreciation for the ramifications of these normative processes is critical in interpreting the unpredictable behaviors, shifting self-evaluations, and mood swings that are observed in many adolescents during this age period. Such displays are less likely to be viewed as intentional or pathological, and more likely to meet with empathy and understanding to the extent that normative cognitive-development changes can be invoked as in part responsible. For many parents, as well as other adults working closely with teenagers, these seemingly inexplicable reactions often lead to perplexity, exasperation, and anger, provoking power struggles

and altercations that strain the adolescent-adult relationship. The realization that this is a normative part of development that should not persist forever may provide temporary comfort to adults who feel beleaguered and ineffectual in dealing with adolescents of this age. Indeed, it gives a more charitable rendering to this period of development.

### ***Individual Differences: Adaptive and Maladaptive Outcomes in Middle Adolescence***

With regard to the focus on meeting cultural standards appearance, females are much more likely to suffer from processes that move into the realm of pathology, including depression and eventual eating disorders. From the perspective of our own model of the causes and correlates of self esteem, an intense preoccupation with attempts to meeting the impossible standards of beauty, coupled with very negative perceptions of one's body image, can lead to extremely low self-esteem, depression, and in the extreme, eating-disordered behaviors. We have documented the links between the high importance attached to physical appearance and negative perceptions of one's body image, leading to extremely negative reports of self-esteem and depression among those in mid-adolescence. In the subsequent section on later adolescence and emerging adulthood, we provide further documentation about how these processes can lead to pathological eating-disordered behaviors.

However, numerous findings (reviewed Harter, 1999; see also Nolen-Hoeksema & Girgus, 1994) reveal that dramatic gender differences in depression emerge in middle adolescence. The discrepancy between impossible ideals for appearance and one's perception of one's own body image contributes to very low self-esteem for some, particularly those who are overweight, which leads to profound depression that can require clinical intervention.

While the potential for such internalizing symptoms looms large for girls during middle adolescence, the potential for the escalation of violence and males, as in the case of the high profile cases of school shootings by White, middle-class adolescents is apparent. Intense rejection by peers, at a time when self-consciousness and the need for approval are so salient, sets the stage for violent ideation that can turn to action. The fragile and vacillating self-structures of this particular period can, in the face of humiliation, lead to lack of control, both over cognitions about the self (Harter, 1999) and behaviors that these cognitions may drive. Given the lack of cognitive control (Fischer, 1980), the adolescent during

this period may act more impulsively on his thoughts. Recent work on the adolescent brain supports the view that the frontal cortex is not yet completely developed, leading to gaps in executive functions that could serve to curb such impulsive, violent intentions and behaviors.

While the fragmented self is a normative liability of this period of middle adolescence, interactions with a history of severe and chronic physical and sexual abuse may lead to pathological outcomes that can continue as PTSD symptoms even though the abuse occurred in early childhood. The effects of abuse on the self-system are legion (see review in Harter, 1999). From a developmental perspective, a history of abuse can lead to dissociative symptoms that serve to further fragment the fragile multiple selves in the process of psychological construction (see also Putnam, 1993; Westen, 1993) at a time when adolescents have normative challenges to integrating their various selves. As a result, there is no core self at the helm, there is little communication between multiple selves that become "alters," comprising the ability to develop an integrated self. As a result, there is the risk for dissociative identity disorders that represent severe pathological conditions that may require years of treatment.

### **Late Adolescence: Verbal Cameo of Normative Self-Representations and Self-Evaluations**

I'm a pretty conscientious person, particularly when it comes to things like doing my homework. It's important to me because I plan to go to college next year. Eventually I want to go to law school, so developing good study habits and getting top grades are both essential. (My parents don't want me to become a lawyer; they'd rather I go into teaching, but law is what I want to pursue.) Every now and then I get a little lackadaisical and don't complete an assignment as thoroughly or thoughtfully as I could, particularly if our high school has a big football or basketball game that I want to go to with my friends. But that's normal, I mean, you can't just be a total "grind." You'd be pretty boring if you were. You have to be flexible. I've also become more religious as I have gotten older, not that I am a saint or anything. Religion gives me a sense of purpose, in the larger scheme of things, and it provides me with personal guidelines for the kind of adult I'd like to be. For example, I'd like to be an ethical person who treats other people fairly. That's the kind of lawyer I'd like to be, too. I don't always live up to that standard; that is, sometimes I do something that doesn't feel that ethical. When that happens, I get a little depressed because I don't like myself as a person. But I tell myself that it's natural to make mistakes, so I don't really

question the fact that deep down inside, the real me is a moral person. Basically, I like who I am, so I don't stay depressed for long. Usually, I am pretty upbeat and optimistic. I guess you could say that I'm a moody person. I'm not as popular as a lot of other kids. You have to look a certain way, have the right body image, wear the right clothes, to be accepted. At our school, it's the jocks who are looked up to. I've never been very athletic, but you can't be good at everything, let's face it. Being athletic isn't that high on my own list of what is important, even though it is for a lot of kids in our school. I try to think that, anyway. But I don't really care what they think anymore, at least I try to convince myself that I don't. I try to believe that what I think is what counts. After all, I have to live with myself as a person and to respect that person, which I do now, more than a few years ago. I'm pretty much being the kind of person I want to be. I'm doing well at things that are important to me like getting good grades. That's what is probably most important to me right now. Having a lot of friends isn't that important to me. I wouldn't say I was unpopular, though. While I am basically an introvert, especially on a date when I get pretty self-conscious, in the right social situation, like watching a ball game with my friends, I can be pretty extroverted. You have to be adaptive around other people. It would be weird to be the same kind of person on a date and with my friends at a football game! For example, when our team has a winning season and goes to the playoffs, everyone in the whole school is proud; what the team does reflects on all of us. On a date, the feelings are much more intimate, just between you and the other person. As much as I enjoy my high school friends and activities, I'm looking forward to leaving home and going to college, where I can be more independent, although I'm a little ambivalent. I love my parents, and really want to stay connected to them, plus, what they think about me is still important to how I feel about myself as a person. So leaving home will be bittersweet. But sometimes it's hard to be mature around them, particularly around my mom. I feel a lot more grown-up around my dad; he treats me more like an adult. I like that part of me because it feels more like my true self. My mom wants me to grow up, but another part of her wants me to remain "her little baby." I'll probably always be somewhat dependent on my parents. How can you escape it? But I'm also looking forward to being on my own. (adapted from Harter, 1999)

With regard to the content of the self-representations that emerge in late adolescence and early adulthood, typically, many of the attributes reflect personal beliefs, values, and moral standards that have become internalized, or alternatively, constructed from their own experiences (see findings by Damon & Hart, 1988). These characteristics are exemplified in the prototypical cameo, in that

the adolescent expresses the personal desire to go to college, which requires good grades and discipline in the form of study habits. Although classmates tout athletics as the route to popularity, there is less concern at this age with what others think ("I used to care but now what I think is important"). In addition, there is a more realistic focus on one's future selves (e.g., not only becoming a lawyer, but also an ethical lawyer, as a personal goal). Noteworthy in this narrative is the absence of an explicit reference to the potential origins of these goals; for example, parental encouragement or expectations that one pursue such a career. Moreover, this adolescent's career choice does not conform to the parents' occupational goals for their child.

The failure to acknowledge the socialization influences that might have led to these choices does not necessarily indicate that significant others, such as peers and parents, had no impact. Findings (see Steinberg, 1990) reveal that the attitudes of adolescents and their parents are quite congruent when it comes to occupational, political, and religious decisions or convictions. That the impact of significant others is not acknowledged suggests that older adolescents and young adults have come to "own" various values as personal choices, rather than attribute them to the sources from which they may have been derived (Damon & Hart, 1988). In Higgins' (1991) terminology, older adolescents have gone through a process in which they have actively selected among alternative "self-guides" and are no longer merely buffeted about by the expectations of significant others; that is, self-guides become increasingly internalized and less tied to their social origins. Moreover, there is a greater sense of direction as the older adolescent comes to envisage future or "possible" selves (Markus & Nurius, 1986) that function as ideals toward which one aspires.

Another feature of the self-portrait of the older adolescent can be contrasted with the period before, in that many potentially contradictory attributes are no longer described as characteristics in opposition to one another. Thus, being conscientious as a student does not appear to conflict with one's lackadaisical attitude toward schoolwork: "That's normal, I mean, you can't just be a total 'grind.' You'd be pretty boring if you were. You have to be flexible." Similarly, one's perception of the self as ethical does not conflict with the acknowledgment that one also has engaged in some unethical behaviors ("It's natural to make mistakes"). Nor does introversion conflict with extroverted behaviors. "You have to be adaptive around other people. It would be

weird to be the same kind of person on a date and with my friends at a football game!”

There are cognitive acquisitions that allow the older adolescent to overcome some of the liabilities of the previous period, where potentially opposing attributes were viewed as contradictory and as a cause of internal conflict. The general cognitive advances during this period involve the construction of higher-order abstractions that involve the meaningful intercoordination of single abstractions (see Case, 1985; Fischer, 1980; Fischer & Canfield, 1986). For example, the fact that one is both introverted and extroverted can be integrated through the construction of a higher-order abstraction that defines the self as “adaptive.” The observation that one is both depressed and cheerful or optimistic can be integrated under the personal rubric of “moody.” Similarly, “flexible” can allow one to coordinate conscientiousness with the tendency to be lackadaisical. The higher-order concept of “ambivalence” integrates the desire to be independent yet still remain connected to parents. Moreover, “bittersweet” reflects a higher-order abstraction combining excitement over going to college with sadness over leaving one’s parents. Such higher-order abstractions provide self-labels that bring meaning and therefore legitimacy to what formerly appeared to be troublesome contradictions in the self.

Neo-Piagetians, such as Case (1985), Fischer (1980), and colleagues, observe that developmental acquisitions at these higher levels typically require greater scaffolding by the social environment in the form of support, experiences, instruction, and so on for individuals to function at their optimal level. If these new skills are fostered, they will help the adolescent to integrate opposing attributes in a manner that does not produce conflict or distress. Thus, efforts to assist the adolescent in realizing that it is normal to display seemingly contradictory traits, and perhaps quite appropriate, may alleviate perceptions of conflict. Moreover, helping teenagers to provide higher-order labels that integrate opposing attributes (e.g., flexible, adaptive, moody, and inconsistent) may avert some of the distress that was salient during middle adolescence. These suggestions derive from the observations of Fischer, Case, and others to the effect that these cognitive solutions will not necessarily emerge automatically with development. Nor will the potential benefits derived from movement to late adolescence and early adulthood necessarily accrue; that is, the levels described in this chapter represent a normative sequence of development. However, the age levels are somewhat arbitrary in that certain in-

dividuals may not attain a given level at the designated age period. Development may be delayed or even arrested if there is not sufficient support for the transition to a new level of conceptualization, particularly for the higher stages.

### *The Role of the Socializing Environment*

More recent evidence (see Harter et al., 1997) indicates that the ability to resolve potentially contradictory attributes may be more difficult for some role-pair combinations than for others, particularly for females. For example, when all role pairs are combined, there is no decline in the number of opposing attributes identified across roles. For older adolescent females, there is actually a further increase. The fact that six roles were included in the study generating the new data (compared to only four in the original Harter and Monsour study) may have been partly responsible, because the inclusion of additional roles increased the probability that opposing attributes might be detected; there were 15 possible role pairs that might contain contradictions compared to only six role pairs in the original study. In increasing the number of roles, we also separated the reports of self-attributes with mother and with father (whereas in the earlier study, we merely inquired about self with parents).

The separation of self-attributes with each parent potentially enhances the likelihood that characteristics with each may contradict attributes in roles with peers. Examples generated by adolescent respondents in middle to late adolescence included being short-tempered with mother versus a good listener in romantic relationships; respectful with father versus assertive with friends; distant from father but attentive with a romantic interest. Adolescent bids for autonomy from parents (Cooper, Grotevant, & Condon, 1983; Hill & Holmbeck, 1986; Steinberg, 1990), coupled with the increasing importance of the peer group (Brown, 1990; Savin-Williams & Berndt, 1990), would lead to the expectation that attributes expressed with mother and father might well differ from those displayed with peers (i.e., friends and romantic partners), leading to a greater potential for contradictions.

However, the separation of self with mother and self with father also creates the potential for attributes with mother to be in opposition to attributes with father. The potential for attributes with each parent to appear contradictory can be observed in the cameo, where the prototypical older adolescent feels much more mature with father than with mother. Moreover, such conflicts begin

to be observed in mid-adolescence, where the prototypical teenager indicated that she was “close” with her mother but “distant” with her father, a difference that became problematic if they were all together such as talking at dinner.

When the findings are broken down by relationship pairs, opposing attributes and associated conflict were most frequent for the combination of self with mother versus self with father, beginning in mid-adolescence, and increasing in late adolescence, a pattern that we have since replicated in a subsequent study. Examples have included being close with mother versus distant with father; stubborn with mother versus respectful with father; open with mother but not with father; at ease with mother but defensive with father; and hostile with mother but cheerful with father. Moreover, such opposites between self with mother versus self with father, as well as associated conflict, increased dramatically for the older girls in particular.

The fact that older female adolescents reported increasing contradiction, whereas male adolescents did not, suggests that cognitive-developmental explanations are incomplete. The separation of attributes with mother and with father, in particular, would appear to make it more difficult for certain adolescents to cognitively resolve or normalize the contradictions (produced by the opposing attributes with mother versus father) that are provoked by these roles, as well as those attributes with each parent that contradict the characteristics that one displays with peers. Contradictions between self with parents and self with peers are more understandable, given developmental bids for autonomy. However, why should adolescents (particularly females) report increasingly different characteristics with mother and father?

Here, we can only speculate. Family therapists observe that children and adolescents typically develop different relationships with each parent, which may cause the salient attributes in each relationship to vary considerably. Contributing to these dynamics is the fact that each parent may have a different set of expectations about those characteristics that he or she values and therefore attempts to foster. First, the adolescent may become caught in a struggle between two parents who are encouraging and reinforcing different facets of his or her personality, provoking opposing attributes and resulting conflict. Second, both of these roles, self with mother and self with father, occur in the same general context (i.e., the family), whereas other multiple roles

are not as likely to be called on simultaneously. These particular conditions may exacerbate the contradictions and conflicts that adolescents experience in their respective roles with mother versus father. These family dynamics appear to be relevant to the increase in across-role opposing attributes for female adolescents in particular, who may be more likely to be sensitive to the fact that they are behaving differently with mother versus father. As observed in the previous section on the period of mid-adolescence, females display more concern over relationship issues, which may make opposing attributes more salient. Adolescent females may also feel that, to remain connected to both mother and father, it is important to be consistent across these relationships—a task that can be problematic for the reasons cited earlier.

Although the gender literature suggests that connectedness is more critical to females than to males (Chodorow, 1989; Eichenbaum & Orbach, 1983; Gilligan, 1982; Gilligan, Lyons, & Hanmer, 1989; Jordan, 1991; J. Miller, 1986; Rubin, 1985), the adolescent literature reveals that it is important for teenagers of both genders to remain connected to parents in the process of individuation and the establishment of autonomy (Cooper et al., 1983; Hill & Holmbeck, 1986; Steinberg, 1990). As our prototypical subject reveals, while it is important to go to college where he or she can be more independent, it is also important to stay connected to parents.

Contextual factors, such as the family, therefore will conspire with cognitive development to impact the extent to which opposites and conflicts are experienced. In another example, the role of context can be observed in cross-cultural research by Kennedy (1994). Kennedy has adapted our procedure in comparing the self-understanding of American and Korean youth. He finds that there are different age-related peaks in conflict among adolescents in the two cultures. Korean youth report increased conflict between opposing attributes in 10th and 12th grades, findings that he interprets as the demands of the school context at those particular grade levels. In Korea, 10th grade is the 1st year of high school, and the new students are required to be deferential to the juniors and seniors, a relationship that many 10th graders find oppressive. Kennedy argues that these demands exert a strain on the self-system and destabilize students' sense of self as they struggle to find a niche in the peer hierarchy of high school. During 12th grade, there are different demands, for example, intense preparation for the college entrance exams. This pres-

sure leads to challenges in balancing the demands of academics, peer relationships, and family commitments, resulting in greater conflict.

Future research should attend to such contextual factors and attempt to assess the underlying processes more directly. To return to our own findings in this regard, it would be of interest to determine whether the conflict between self-attributes with mother versus father is more intense if the adolescent is living in a two-parent family where both mother and father are in the same household, or if the parents are divorced and living apart. One hypothesis is that living under the same roof with both parents makes it difficult to avoid conflict if different attributes in each relationship are demanded simultaneously. Alternatively, conflict may be exacerbated in the situation of divorce to the extent that in an acrimonious separation, each parent intensifies his or her differential expectations for the attributes they want the adolescent to display as part of a power struggle in which the adolescent becomes a pawn. Such processes would be intriguing to investigate.

Finally, with regard to developmental changes in the self, evidence from longitudinal studies documents that self-esteem or global self-worth improves in later adolescence (see Engel, 1959; O'Malley & Bachman, 1983; Rosenberg, 1986; Simmons, Rosenberg, & Rosenberg, 1973). Several interpretations of these gains have been suggested (see Harter, 1990b; McCarthy & Hoge, 1982). Reductions in the discrepancy between one's ideal self and one's real self, between one's aspirations and one's successes, according to James's (1892) formulation, may be in part responsible. As the prototypical adolescent indicates, he or she has more self-respect now, compared to a few years ago and observes that "I'm pretty much being the kind of person I want to be. I'm doing well at things that are important to me like getting good grades and being ethical." Gains in personal autonomy and freedom of choice may also play a role, in that the older adolescent may have more opportunity to select performance domains in which he or she is successful. Such freedom may also provide one with more opportunity to select those support groups that will provide the positive regard necessary to promote or enhance self-esteem, consistent with the looking glass self-formulation. Increased role-taking ability may also lead older teenagers to behave in more socially acceptable ways that enhance the evaluation of the self by others, such that the favorable attitudes of others toward the self are internalized as positive self-worth.

These others include parents. Although it has been common in treatments of adolescent development to suggest that the influence of peers increases, whereas the impact of parental opinion declines, findings do not support the latter contention. As our cameo subject indicates, "What my parents think about me is still important to how I feel about myself as a person." Our own findings reveal that the correlation between classmate approval and global self-esteem does increase during childhood and adolescence; however, the correlation between parental approval and global self-esteem, which is high in childhood, does not decline during adolescence (Harter, 1990b). The latter correlation does decline, however, during the college years among students who are away from home.

More specific evaluations of self-esteem continue to vary by relationship context (Harter, Waters, & Whitesell, 1998), throughout the high school years, as adolescents make finer distinctions (e.g., between their self-esteem with mother and with father). However, we did not anticipate the fact that for the vast majority of individuals, self-esteem in one particular relational domain is much more highly related to global self-esteem than is relational self-esteem in all other contexts. The specific domain occupying this position varies from adolescent to adolescent. For example, with our prototypical adolescent, self as student in the academic domain is most important ("Getting good grades is what is most important to me now") and his or her self-esteem in that particular context is higher than in other domains. Thus, focusing on that particular context would appear to be very adaptive in that it should promote more positive feelings of global self-esteem.

### *Normative Liabilities during Late Adolescence*

Many of the limitations of the preceding period of mid-adolescence would appear to be overcome as a result of changes during late adolescence. Attributes reflecting personal beliefs, values, and standards become more internalized, and the older adolescent would appear to have more opportunity to meet these standards, thereby leading to enhanced self-esteem. The focus on future selves also gives the older adolescent a sense of direction. A critical cognitive advance can be observed in the ability to construct higher-order abstractions that involve the meaningful integration of single abstractions that represent potential contradictions in the self-portrait (e.g., depressed and cheerful do not conflict because they are both part of being moody). The older

adolescent can also resolve potentially contradictory attributes by asserting that he or she is flexible or adaptive, thereby subsuming apparent inconsistencies under more generalized abstractions about the self. Moreover, older adolescents are more likely to normalize potential contradictions, asserting that it is desirable to be different across relational contexts and that it would be weird or strange to be the same with different people.

Nevertheless, conflict between role-related attributes does not totally abate in later adolescence. Conflict will be more likely to occur if the new skills that allow for an integration of seeming contradictions are not fostered by the socializing environment. Furthermore, opposing attributes across particular role combinations, notably self with mother versus self with father, continue to be problematic in late adolescence, especially for girls. To the extent that one's mother and father elicit or reinforce opposing attributes, cognitive solutions for integrating seeming contradictions would appear to be more difficult to invoke.

Last, although the internalization of standards and opinions that the adolescent comes to own as personal choices and attitudes toward the self represents a developmental advance, there are liabilities as well associated with this process. As Rosenberg (1986) observes, the shift in the locus of self-knowledge from an external to internal source can introduce uncertainty. As long as major truths about the self derive from omniscient and omnipotent adults, then there is little doubt about their veracity. However, when the locus of self-knowledge shifts inward and adolescents must rely on their own autonomous judgment and insight to reach conclusions about the self, the sense of certainty can be compromised.

***Individual Differences: Adaptive and Maladaptive Self-Processes and Outcomes in Late Adolescence/Early Adulthood***

Many of the pathological processes that have been described in the earlier periods of adolescence can be observed, even if in a somewhat different form, due to developmental advances. Preoccupation with impossible cultural standards of attractiveness looms even larger as the older adolescent anticipates emerging adulthood, making it even more critical to attain these standards to be socially acceptable and successful in the new adult world order (Harter, in press). For females, failure to meet these standards can lead to more pathological processes that may include eating disorders.

For example, in one of our studies conducted by Danis (see Harter, 1999), two eating-disordered groups among women college students were identified, those with symptoms of anorexia and those with symptoms of bulimia. These two groups were compared to a control sample, college women who did not display such symptoms. Both the anorexic and bulimic group reported significantly higher scores on the importance of appearance, toward the very top of the four-point scale, compared to the normative sample. They each reported extremely low scores with regard to their evaluation of their physical appearance, creating a large discrepancy: importance scores vastly higher than perceived appearance scores. This discrepancy, clearly predicted very low self-esteem scores for the two eating-disordered groups compared to the normal sample. These low self-esteem scores, in turn, were highly predictive of extremely high levels of self-reported depression. Of particular interest were the findings that although both eating-disordered groups reported this negative constellation of symptoms, those in the bulimic group were most at risk given the lowest ratings of perceived physical appearance, self-esteem, and depression. Danis interpreted this difference between the two eating-disordered groups in terms of perceptions of control. She argued that those with symptoms of anorexia were objectively thinner, leading them to possibly feel more successful in terms of their weight control. The bulimics, who by definition binge and purge, were interpreted to be less in control; moreover, on average, this group was heavier. That said, those with anorexia are more at risk for malnourishment that can affect bone development, brain development, body development in general, and, in the extreme, they are at risk for death. Those with bulimic symptoms are also at risk for a variety of physical symptoms, including damage to the mouth and esophagus as well as other compromising physical growth symptoms. There are also numerous psychological symptoms including disruptions in the family, compromised academic achievement, and impaired social functioning.

Male adolescents are at continued risk for violence, particularly the type of violence that emanates from peer rejection and humiliation. Chronic rejection and humiliation are likely culprits for violent ideation (Harter, 2004) and for violent action, as in the case of the school shooters. Unlike the impulsive acts of the school shooters in middle adolescents, the acts of those (e.g., Eric Harris and Dylan Kleibold from Columbine)

who were older teens were far more *playful*. For over a year, they had developed their strategies, some of which were revealed in Harris's written manifesto. While this is speculative, at this point, in examining the media accounts of the 11 high-profile school shooting cases, it would appear that the dynamics may be different from what we normally consider to be delinquent, conduct-disordered behavior that had come to the attention of teachers, school officials, school psychologists, peers, and parents. In most of these cases, there had been few warning signs with regard to the male shooters having been in trouble with the law, having been identified as troublemakers in the school, having clinical diagnoses, or being placed in special classes for student with a penchant for acting out. As noted earlier (Harter & McCarley, 2004), we found that 33% of those in a normative sample reporting to us that they had serious thoughts of harming others who humiliated them went undetected by their classroom teachers who were given parallel rating forms. Thus, there is a need to discriminate the form of violence that has recently emerged from previous acts that have been committed by known delinquents and conduct-disordered youth who have come to the attention of school and mental health professional, and who commit different types of crimes; for example, drive-by shootings to target one individual versus the random shooting of as many classmates as possible. The dynamics may be different at different developmental stages (e.g., more playful among older adolescents).

The construction of multiple selves, while a normative process, can also have pathological implications. It was pointed out in the section on middle adolescence that the effects of abuse can lead to dissociative symptoms that prevent one's multiple selves from being integrated. In the severest cases, this can lead to dissociative identity disorder (what used to be termed multiple personality disorder). Abuse has also been found to impact the valence (positive or negative) of those attributes judged to be one's core self (versus more peripheral attributes). Normatively, we have found that when asked to rate the attributes across multiple relational context with regard to whether they are central core characteristics or more peripheral, less important attributes that define the self, normative samples of older attributes will define their most important attributes as *positive* and assign their more negative characteristics (less important attributes) to the periphery of the self (Harter & Monsour, 1992). This self-protective strategy has been

defined, normatively, as "benefectance" by Greenwald (1980); namely, seeing one's positive attributes as central to the self and one's negative attributes as more peripheral.

Our colleagues Fischer and Ayoub (1994) employed our multiple selves procedure with an inpatient sample of seriously abused older adolescent girls, finding just the opposite pattern. Compared to a normative sample, the abused patients identified *negative* attributes as their core self, relegating what few positive characteristics they could identify as peripheral. Herein, we can detect another deleterious effect of abuse on self-processes leading to potential pathological outcomes that require clinical intervention that can hopefully restore a more positive balance of self-perceptions.

## STABILITY VERSUS CHANGE IN SELF-REPRESENTATIONS

Initially, it is important to address the question of whether concepts of self, either at a domain-specific or more global level, are immutable or subject to change. If self-representations are relatively stable, then practitioners should be less sanguine about the possibility of promoting positive self-evaluations in individuals with negative self-images. Alternatively, if self-representations are potentially malleable, practitioners can be more optimistic, particularly if there is a cogent analysis of the particular causes of a given individual's negative self-evaluations.

The initial focus in this section is on literature relevant to the actual stability and/or change in the valence of self-representations—how favorably the self is evaluated. A central theme in the literature has been do self-evaluations, notably self-esteem and domain specific self-concepts, change normatively with development? Equally of interest is whether there are individual differences in the extent to which self-evaluations change. Herein is the big debate. Is self-esteem more traitlike or statelike? We return to this controversy after reviewing the normative patterns of self-esteem development (a description of a third issue, do self-evaluations change as function of the situation or short-term intervals, can be found in Harter, 1999).

### Normative-Developmental Change

With regard to normative-developmental change, the evidence reveals that self-evaluative judgments become less positive as children move into middle childhood

(Frey & Ruble, 1985, 1990; Harter, 1982; Harter & Pike, 1984; Stipek, 1981). Investigators attribute such a decline to the greater reliance on social comparison information and external feedback, leading to more realistic judgments about one's capabilities (see also Crain, 1996; Marsh, 1989). A growing number of studies suggest that there is another decline at early adolescence (ages 11 to 13), after which global evaluations of worth and domain-specific self-evaluations gradually become more positive over the course of adolescence (Dusek & Flaherty, 1981; Marsh, Parker, & Barnes, 1985; Marsh, Smith, Marsh, & Owens, 1988; O'Malley & Bachman, 1983; Piers & Harris, 1964; Rosenberg, 1986; Savin-Williams & Demo, 1993; Simmons, Rosenberg, & Rosenberg, 1973).

Many of the changes reported coincide with the educational transition to junior high school. Eccles and colleagues (Eccles & Midgley, 1989; Eccles et al., 1984; Wigfield, Eccles, Mac Iver, Reuman, & Midgley, 1991), and Simmons and colleagues (Blyth, Simmons, & Carlton-Ford, 1983; Simmons & Blyth, 1987; Simmons, Blyth, Van Cleave, & Bush, 1979; Simmons & Rosenberg, 1975) have postulated that differences in the school environments of elementary and junior high schools are in part responsible. Junior high school brings more emphasis on social comparison and competition, stricter grading standards, more teacher control, less personal attention from teachers, and disruptions in social networks, all of which lead to a mismatch between the structure of the school environment and the needs of young adolescents. The numerous physical, cognitive, social, and emotional changes further jeopardize the adolescent's sense of continuity, which may, in turn, threaten self-esteem (Leahy & Shirk, 1985). A number of these studies (e.g., Blyth et al., 1983; Nottelmann, 1987; Simmons & Blyth, 1987; Simmons et al., 1979; Wigfield et al., 1991) also report lower self-esteem for girls than for boys (see also Block & Robins, 1993, who find that the gender gap widens from ages 14 to 23).

The magnitude of the decline in perceptions of overall worth is also related to the timing of school shifts and to pubertal change (Brooks-Gunn, 1988; Brooks-Gunn & Peterson, 1983; Simmons & Blyth, 1987). Those making the shift from sixth to seventh grade show greater losses of self-esteem than those who make the school transition a year later, from seventh to eighth grade. Moreover, students making the earlier change, particularly girls, do not recover these losses during the high school years. Early-maturing girls fare the worst.

They are the most dissatisfied with their bodies, in part, because they tend to be somewhat heavier and do not fit the cultural stereotype of female attractiveness emphasizing thinness, as is discussed further in the section on the link between self-esteem and perceived appearance. This, in turn, has a negative effect on their self-worth. Furthermore, according to the developmental readiness hypothesis (Simmons & Blyth, 1987), early maturing girls are not yet emotionally prepared to deal with the social expectations that surround dating or with the greater independence that early maturity often demands (see Lipka, Hurford, & Litten, 1992, for a general discussion of the effects of being "off-time" in one's level of maturational development).

Several interpretations have been offered for the gradual gains in self-esteem that follow from eighth grade through high school (McCarthy & Hoge, 1982). Gains in personal autonomy may provide more opportunity to select performance domains in which one is competent, is consistent with a Jamesian analysis. Increasing freedom may allow more opportunities to select support groups that will provide esteem-enhancing approval, is consistent with the looking glass self-formulation. Increased role-taking ability may also lead teenagers to behave in more socially acceptable ways that garner the acceptance of others. A study by Hart, Fegley, and Brengelman (1993) provides some confirming evidence. In describing their past and present selves, adolescents asserted that with time, they have become more capable, mature, personable, and attractive, describing how they shed undesirable cognitive, emotional, and personality characteristics.

An analysis of changes in mean level of self-worth, however, may mask individual differences in response to educational transitions (see also Block & Robins, 1993). Findings from our own laboratory (see Harter, 1999) on both the transition to junior high school and to college have identified three groups—those whose self-worth increases, decreases, or remains the same. In our own framework, we contend that self-worth leading to an examination of instability or stability as a function of those determinants identified by James (competence in domains of importance) and Cooley (approval from significant others). Results indicate that those whose self-worth increased across educational transitions displayed greater competence in domains of importance and reported more social approval in the new school environment. Students whose self-worth decreased reported both a decline in competence for valued domains and re-

ported less social support after the transition. Students showing no changes in self-worth reported negligible changes in both competence and social support. Demo & Savin-Williams (1992) have also adopted a more idiographic approach, demonstrating that while nearly half of their sample demonstrated stability in their perceptions of overall worth, the remaining subjects manifested varying degrees of instability.

In this literature, there remains controversy, however, among those who claim that self-representations are relatively enduring and those who contend that self-representations are more malleable. One camp of investigators reports evidence that the self-concepts of adults are relatively stable. For example, Swann (1996) provides evidence demonstrating individuals' elaborate and ingenious strategies for self-verification; people go to great lengths to seek information that confirms their self-concept and are highly resistant to information that threatens their view of self (see also Baumeister, 1993; Epstein, 1991; Greenwald, 1980; Rosenberg, 1979). According to Swann, people do not want feedback that may contradict their existing identities. Because such identities provide a psychological blueprint for action, they are the guideposts for how we are to behave. Epstein similarly observes that "people have a vested interest in maintaining the stability of their personal theories of reality, for they are the only systems they have for making sense of their world and guiding their behavior" (p. 97). In Swann's (1996) most recent treatment of this topic, he observes that those with negative self-evaluations are actually ambivalent, in that praise puts them in conflict. Although favorable evaluations would be welcome, they also require unfavorable evaluative feedback, to the extent that such individuals desire verification. He notes that such people are "caught in a crossfire in which the warmth produced by favorable evaluations is chilled by incredulity" (p. 14).

Precisely how this relates to children and adolescents has yet to be determined, given our developmental analysis of normative fluctuations in self-esteem. Just how the adult literature relates to phenomena among younger individuals remains an intriguing issue, all the more so as the field integrates genetic and brain developmental factors. There is a growing consensus that, as James originally suggested, individuals possess both a baseline self-concept and a barometric self-concept (see reviews by Demo & Savin-Williams, 1992; Rosenberg, 1986). Thus, people have a core sense of self that is rel-

atively consistent over time; however, there are also situational variations around this core self-portrait. Others have come to a similar conclusion, postulating that individuals display both trait and state self-esteem (Heatherton & Polivy, 1991; Leary & Downs, 1995). According to some, an individual's baseline sense of self is difficult to alter. Theorists have argued, in the context of hierarchical models of the self, that higher-order schemas, such as global self-worth or esteem, are far more resistant to modification than lower-order, situation-specific constructs (Epstein, 1991; Hattie, 1992). Epstein notes that such higher-order schemas have typically been acquired early in development and are often derived from emotionally significant experiences to which the individual may have little conscious access, making the beliefs difficult to alter.

With regard to the barometric self, adolescence is a time when fluctuations appear to be the more flagrant (Blos, 1962; Demo & Savin-Williams, 1992; Harter, 1990a; Leahy & Shirk, 1985; Rosenberg, 1986). Those of a cognitive-developmental persuasion (e.g., Fischer, 1980; Harter, 1990a; Harter & Monsour, 1992; Higgins, 1991) have attributed these fluctuations to limitation in the ability cognitively to control seemingly contradictory self-attributes (shy versus outgoing), particularly during middle adolescence. Psychoanalytic thinkers (e.g., Blos, 1962; Kohut, 1977) attribute fluctuations to the intense heightened narcissism and self-preoccupation of adolescents whose self-esteem swings from grandiosity to battered self-devaluation. Rosenberg (1986) focuses more on how socialization factors influence the volatility of the self during adolescence. Thus, he observes that the adolescent is preoccupied with what others think of the self but has difficulty divining others' impressions, leading to ambiguity about the self. Moreover, different significant others may have different impressions of the self, creating contradictory feedback. We have recently taken a different perspective, demonstrating that for some adolescents self-esteem remains quite constant across time and context, whereas for others there is considerable variation. We have attempted to investigate the causes, as is discussed in the next section (see also, Harter, 2004).

### Individual Differences

Considerable attention has been given to the issue of whether self-esteem is best viewed as a state or trait (see Trzesniewski, Donnellan, & Robins, 2003, for a

recent review of this issue). A focus on individual differences in the extent to which self-evaluations are stable or malleable is the primary context in which issues of stability and change in self-evaluations have been examined. Studying adult participants, Kernis and colleagues have examined this issue in its complexity (Greenier, Kernis, & Waschull, 1995; Kernis, 1993; Kernis, Cornell, Sun, Berry, & Harlow, 1993). According to these investigators, there are those whose self-evaluations are more stable and there are those prone to short-term fluctuations in self-esteem. The latter group demonstrate enhanced sensitivity to evaluative events, ego involvement (versus task involvement), preoccupation with self-evaluation, and over reliance on social sources of self-esteem (see also Deci & Ryan, 1987; Rosenberg, 1986). Our own findings indicating greater fluctuations in self-worth for those who consciously endorse a looking glass self-orientation (approval determines self-worth) are consistent with this individual-difference approach (Harter, Stocker, & Robinson, 1996). Moreover, we speculated that the developmental precursors may have involved parenting characterized by inconsistent and/or conditional approval. Greenier et al. (1995) also conjecture that inconsistent as well as controlling feedback will undermine the development of a stable sense of worth (see also Deci & Ryan, 1987, 1995).

Our own position (see Harter, 2004), more consistent with Kernis's, asks whether self-esteem is stable over time for individuals (is it a trait?) or is it subject to fluctuations (more statelike) and therefore the question is false and misguided. We have taken the stance (based on several strands of research) that the construct of self-esteem (or self-worth), in and of itself, is neither a trait nor a state per se (see also DuBois et al., 2002). Rather for *some* individuals self-esteem is stable, whereas for others self-esteem is subject to change. Among adolescents, we have found evidence for this position with regard to self-esteem during the transition to junior high school. As mentioned earlier, some students enhance their self-esteem, others decline in self-esteem, and for a third group self-esteem remains stable. We linked changes versus stability to change or stability in the competence/importance relationship (from James) and to stability or change in social support (from Cooley). Others (see Fenzel, 2002) have related change versus stability in self-worth across transitions to the ability to negotiate the challenges of middle school.

In a second study (Harter, Stocker, & Robinson, 1996) we found that certain adolescents reported virtually no short-term fluctuations in their self-esteem over a period of months, whereas others reported great instability, patterns that could be accounted for by their orientation to the approval of others. In a third study (Harter, Waters, & Whitesell, 1998), we found that self-worth varied across relational context (a concept we have labeled "relational self-worth"), with the majority of adolescents reporting different levels of self-worth or esteem depending on whom they were with—father, mother, female peers, or male peers. To summarize, we found that over a relatively long period of time (in the first study) and over short periods of time (in the second study) and across relationship contexts some individuals behaved in a traitlike fashion, whereas others behaved in a statelike fashion. Thus, trait and state attributions lie in individuals, not in the constructs themselves.

Does the conceptualization of self-esteem as neither a trait nor a state cast doubt on the field of personality, which depends on the identification of relatively stable traits? Not necessarily. Many thoughtful investigators are asking just such questions. In a recent study by Hair and Graziano (2003), these investigators examined the stability of self-esteem and the Big Five Personality attributes in a longitudinal study of those moving from middle school to high school. Findings revealed much greater stability over the transition for the personality attributes (Extraversion, Agreeableness, Conscientiousness, Emotional Stability, and Openness to Experience) than for self-esteem, suggesting that the Big Five, as conceptualized, are much more traitlike in nature than is self-esteem, which is amenable to change if its documented causes change, *or* stability if the causes do not change.

## GENDER DIFFERENCES IN GLOBAL AND DOMAIN-SPECIFIC SELF-EVALUATIONS

There is now an emerging body of literature that has examined gender differences in subscale scores among older children, adolescents, and college students. For the most part, the findings are quite consistent with regard to a number of gender differences as well as similarities. A major and consistent finding is that females, at every age beginning in middle to late childhood report lower global self-worth than do males. We find this across the life span; however, differences are greatest in middle to

late adolescence. An impressive meta-analysis on gender differences in self-esteem by Kling, Hyde, Showers, and Buswell (1999) confirms this finding in that the largest mean effect size favoring boys in the 15- to 18-year-old group. In their meta-analysis these differences are significant, but small and robust across many samples. Interestingly, these differences have not changed in the period between the 1970s and the 1990s despite seeming societal gains for females.

Kling et al. (1999) speculate on several reasons for these gender differences. One potential cause involves the gender role stereotypes that are reinforced in the school setting. Boys are socialized to use dominance, whereas girls are oriented toward shared social activities (see Maccoby, 1990). Girls' influence attempts are more likely to take the form of a polite suggestion, whereas boys are more likely to try to influence others by direct demands (Leaper, 1991). These differing strategies designed to the other present imbalances in mixed-gender interactions in which boys come to ignore the girls' attempt to interact with or influence boys (Maccoby, 1990). Kling et al. conclude that girls' general ability to influence and to gain valuable resources, particularly in unsupervised mixed-gender groups, may make them feel less important and less powerful than boys, which could adversely impact their self-esteem. Maccoby reports that these differences can be observed as early as the preschool years.

Kling et al. (1999) also suggest that different opportunities for athletic participation could also contribute to gender differences in self-esteem. Although Title IX certainly opened more doors for female children and adolescents to participate in sports, more emphasis and status has been given to male athletes and male sports programs. Furthermore, despite greater opportunities for girls, many do not take advantage of the options, fearing it will undermine their femininity. However, studies do show that among males and females who do participate in sports, self-esteem is higher than for those who do not engage in athletics. Our own research still reveals a significant mean difference in perceived athletic ability, favoring males.

J. Crocker and Major's (1989) theoretical model regarding social stigma and self-esteem provides another explanation for the modest gender differences in self-esteem. Stigmatized grounds, in this case females, protect their self-concept by (a) attributing negative feedback they receive to prejudice against members of their group, (b) comparing their own out-

comes with members of their own disadvantaged group rather than the advantaged group, and (c) devaluing those domains in which their group does not do well, and, in contrast, valuing those domains in which their group does do well.

Kling et al. (1999) put forth a powerful explanation for gender differences in self-esteem, consistent with our own interpretation on the inextricable link between perceived physical appearance and global self-worth, where correlations range from .66 to .82 across numerous studies. We have argued elsewhere that (Harter, 1999), consistent with Kling's observations, combination of the importance of appearance for females combined with the punishing standards of appearance for females profoundly contributes to their devaluation of their looks. Movies, magazines, and TV all tout the importance of good looks that are impossible to achieve, in part, because many of these looks are due to air-brushing, computer simulation, and the combining of different (the best) body parts from models or movie stars to "achieve the look." Very few ads tout the importance of a physically *fit* female as desirable but rather showcase thinness combined with height and large breasts as the glamour, the ideal of the decade.

Elsewhere, we have depicted gender data across 13 of our own samples from the domains of older children and adolescence where differences are quite marked with girls scoring only at the midpoint of the scale and with boys reporting much higher on both appearance and athletics (Harter, 1999).

Moreover, this pattern has been found to be highly robust across different countries where gender differences for physical appearance and athletic competence are similar in magnitude and highly significant. Thus, in addition to other findings in the United States (see also Hagborg, 1994), the more favorable perceptions of physical appearance and athletic competence by male children and adolescents has been found in other English-speaking countries such as England (Fox, Page, Armstrong, & Kirby, 1994), Australia (Trent, Russell, & Cooney, 1994), and Ireland (Grandlese & Joseph, 1993). The very same pattern has been documented across a range of non-English-speaking countries, including the French-speaking areas of Switzerland (Bolognini, Plancheral, Bettschart, & Halfon, 1996; Pierrehumbert, Plancheral, & Jankech-Caretta, 1987), Italy (Pedrabissi, Santinello, & Scarpazza, 1988), Holland (van Dongen-Melman, Koot, & Verhulst, 1993), China (Meredith, Abbott, & Zheng, 1991; Stigler,

Smith, & Mao, 1985), Japan (Maeda, 1997), and Korea (Rhee, 1993).

The very same gender pattern favoring males on both perceived athletic ability and attractiveness persists at the college level, and the two domains would appear to interact. Our own data reveal that female students feel significantly worse about their appearance ( $M = 2.57$ ) and their athletic competence ( $M = 2.67$ ) than do males ( $M$ s of 2.88 and 3.00, respectively). These same gender differences have been reported in other college samples as well (P. Crocker & Ellsworth, 1990; Klein, O'Bryant, & Hopkins, 1996; McGregor, Mayleben, Buzzanga, Davis, & Becker, 1992).

Interpretations of the gender differences in perceived athletic competence have focused on the fact that, historically, sports have been largely a male domain, with far more opportunities for athletic competition that would allow boys to develop their physical skills. Moreover, male sports figures represent powerful role models that male children and adolescents are eager to emulate. Despite the gains that some females have achieved in entering the world of sports, women athletes have not, for the most part, been viewed as role models for those girls and female adolescents in the mainstream culture.

In the United States, the current female role models are glamorous women who are extremely thin, an image that is not consistent with the muscular, mesomorphic body types of most female athletes. Moreover, images of female attractiveness are very punishing in that they are unattainable by the vast majority of girls and women in the culture. As a result, most females fall far short of these ideals, resulting in the pattern of findings obtained for perceived physical appearance—that females feel particularly inadequate.

The role of adherence to cultural standards of appearance, in consort with pubertal development for adolescent girls extends previous findings (see reviews by Graber, Peterson, & Brooks-Gunn, 1996; Simmons & Blyth, 1987). Early maturing girls, in particular, report lower self-esteem than do those whose pubertal timing is more normative (see Lamb, Jackson, Cassidy, Priest, 1993; William and Currie, 2000). Given the current ideal of thinness for females, early maturing girls must contend with the fact that they are heavier, with larger breasts and wider hips. Because they do not fit the physical mold that the culture dictates, their self-esteem is compromised and they thus acknowledge that they are simply too fat. Their early maturation status also introduces social problems in that they are not psychologi-

cally prepared for the sexual advances or taunts that they may received. As Williams and Currie (2000) document, two predictors of self-esteem combine during this period to predict self-esteem: (1) body size ("I'm too fat," whereas many late maturers feel they are too thin) and (2) the perception of how good-looking they are overall.

Moreover, when both genders are considered, evidence indicates that girls and boys experience pubertal changes differently (Graber, Peterson, & Brooks-Gunn, 1996). Boys express greater satisfaction with the changes (e.g., becoming taller, more muscular, and lower voice) changes that signal masculinity (Nolen-Hoeksema & Girus, 1994). In contrast, girls lose their prepubertal body (an image currently valued in our society with regard to thinness) and can be distressed by their new sexual status (Usmiani & Daniluk, 1997; see also Furnham, Badmin, & Sneade, 2002, for links between body dissatisfaction, low self-esteem, and eating-disordered behavior).

Body dissatisfaction becomes critical to the extent that it leads to other mental health concerns such as eating-disordered behavior. There is overwhelming evidence that it is also associated with depression (see reviews by Allgood-Merton, Lewinsohn, & Hops, 1990; Harter, 1999; Marcotte, Fortin, Potvin, & Papillon, 2002; Nolen-Hoeksema & Girgus, 1994; Rosenberg, Schoenback, Schooler, & Rosenberg, 1995; Tobin-Richard, Boxer, Kavrell, & Peterson, 1984). Pollack also reports a strong relationship between body dissatisfaction and depression such that those who perceived themselves to be of normal weight were less depressed than those who thought were overweight or underweight. In a related study, Furnham and Calnan (1998) presented findings revealing that over two-thirds of adolescent females were dissatisfied with their weight. All females wanted to weigh less. However, males were divided between those (38%) who wanted to gain weight and those (31%) wanted to lose weight. The wish to gain weight was associated with the desire to become more muscular and achieve the masculine ideal of the V-shaped figure.

The playing field has shifted for men in recent years. In former years, males could be judged attractive not only on the basis of their physical features, where they was much more latitude than for females, but by virtue of the fact that they have money, status, or power. (A magazine poll of women just after the Gulf War ended revealed that General Norman Schwarzkopf was judged

to be the sexiest man in America.) This observation was made 15 years ago. It is my conjecture, as I look around my world and steep myself in gender literature on appearance and contemporary magazine articles and advertisements that trends are changing rapidly and the bar has been raised for men. Standards of appearance for men have become more important, more salient in our culture as well as more difficult to obtain. Muscles, abs, calves, the V-body shape, and hair (both facial hair and head hair or its absence) all must conform to new and punishing expectations for males, beginning in childhood. Workout centers and plastic surgeons are repeating big benefits but is our culture, when the focus has become so much more on the outer, physical self than on the inner, psychological self?

Returning to the overall pattern of gender differences obtained for both athletic competence and physical appearance, the pattern favoring males is qualified by an examination of particular subgroups of females. For example, in the study of college students by P. Crocker and Ellsworth (1990), the investigators separately examined a subgroup of physical education majors. They found that the females in this group reported significantly higher perceptions of their athletic ability than did the normative sample as a whole. Moreover, among physical education majors, the female students did not differ from the male students. The advantage conferred by the physical education program did not, however, transfer to the domain of physical appearance, where females continued to feel significantly worse about their looks than did males. Marsh and Jackson (1986) report a similar pattern in that female athletes, beginning at the high school level, reported higher physical ability than did nonathletes, although the groups did not differ significantly in their perceptions of their physical appearance.

We have also found across several adolescent samples that gender orientation impacts the perceptions of females in particular. Those females endorsing a feminine orientation (where they identify with feminine sex-role stereotypes but reject masculine attributes) report more negative perceptions of their athletic ability ( $M = 2.41$ ) and their physical appearance ( $M = 2.43$ ) than do androgynous females who endorse both feminine and masculine items ( $M_s = 2.92$  and  $2.87$ , respectively). The scores of these androgynous females do not differ significantly from those of either masculine or androgynous males, for whom scores range from 2.92 to 3.18 across the two subscales. Thus, feminine girls are at particular risk for unfavorable evaluations of their physical selves.

To the extent that they view athletics as a male domain, they are likely to avoid sports activities that would allow them to develop physical skills. However, their primarily feminine orientation would appear to lead them to emphasize the importance of physical attractiveness. Attentiveness to this domain may well serve to highlight the difficulty of attaining the impossible standards of beauty that are touted by the culture. As a result, they judge their appearance quite unfavorably relative to the judgments of androgynous females and to both androgynous and masculine males.

Femininity, therefore, will represent a liability in each of these physical domains to the extent that it is not combined with masculine attributes. It should be noted that the feminine girls also reported significantly more negative perceptions of their scholastic competence ( $M = 2.80$ ) compared to their androgynous female peers ( $M = 3.14$ ). Eschewing such masculine attributes as assertiveness and competitiveness, while identifying primarily with such interpersonal attributes as connectedness and concern for others, may divert their attention from academic pursuits. However, such a feminine orientation leads to perceptions of social acceptance and behavioral conduct that are comparable to those of androgynous females, as might be expected given its interpersonal focus.

With regard to gender differences in other domains, at the college level, significant gender differences favoring males have also been found for perceived creativity (Klein et al., 1996; McGregor et al., 1992). In our own data, the gender difference in creativity approaches significance. Thus, while females do not differ from males in their perceptions of either general intellectual ability or scholastic performance, they do judge their creativity to be inferior relative to the ratings of male college students. The gender socialization literature (see Basow, 1992; Beale, 1994; Eagly, Beall, & Sternberg, 2004; Eisenberg, Martin, & Fabes, 1996; Ruble & Martin, 1998) emphasizes that boys receive more encouragement and opportunities for exploration and inventiveness that may, in turn, lead to males' enhanced perceptions of creativity at the college level. (Because the domain of creativity has not been included on the instruments for older children and adolescents, researchers have not yet determined whether there are gender differences at younger ages.)

Across some samples in this country and abroad, gender differences in perceived behavioral conduct favor girls. Two studies at the college level report that

females score higher on the morality subscale. However, other studies find no gender differences in conduct or morality. Moreover, when differences are obtained, as in our own samples, they are much smaller in magnitude than the highly consistent gender differences found for athletic competence and physical appearance, favoring males. With regard to global self-worth, studies in this country as well as abroad reveal either no gender differences, or a small but nonsignificant difference, favoring males. Thus, males and females evaluate themselves similarly with regard to their perceptions of overall worth as a person, where scores typically remain around 3.0. In summary, the pattern reveals markedly more favorable self-evaluations for males with regard to perceptions of both athletic prowess and physical attractiveness. At the college level, males also report greater creativity than do females. These differences have been documented across numerous samples and are exacerbated when comparisons are made between feminine girls and males of either androgynous or masculine orientations.

## CROSS-CULTURAL COMPARISONS

It has become increasingly common for investigators in other countries to administer self-concept scales, such as our own, to children and adolescents in their own culture. As noted earlier, the finding that males feel better about their athletic competence and physical appearance than do females has been exceedingly consistent across countries. However, there are potential pitfalls in administering measures developed for a given culture to those from other countries. At a minimum, any meaningful interpretation requires that these instruments show comparable psychometric properties. However, attention must also be directed to culturally relevant content, because domains and/or items in a given subscale may need to be tailored to each culture.

Across the studies in non-American countries, the factor pattern itself has been shown to be quite robust. It has been replicated in other English speaking countries, such as Canada (P. Crocker & Ellsworth, 1990) and Australia (Trent, Russell, & Cooney, 1994). It has also been replicated in non-English-speaking samples from Quebec (Boivin, Vitaro, & Gagnon, 1992; Gavin & Herry, 1996), Switzerland (Pierrehumbert et al., 1987), Germany (Asendorpf & van Aken, 1993), Italy (Pedrabissi,

Santinello, & Scarpazza, 1988), Greece (Makris-Botsaris & Robinson, 1991), Japan (Maeda, 1997; Sakurai, 1983), Korea (Rhee, 1993), and China (Stigler et al., 1985). For the most part, the reliabilities have been good to adequate. In certain countries, particular items have attenuated the reliability for a given subscale and have not loaded on their designated factor (although the overall subscale structure has been demonstrated). Some of these item difficulties may reflect translation issues. However, the existence of such items should serve as a red flag that a given instrument may require revisions at the item level to be culturally sensitive to potential differences in how the domains are best defined in a given country.

There are further cautions about the use of our instruments in countries such as China and Japan. For example, Meredith et al. (1991) have reported that only 20 of the 36 items on the Self-Perception Profile for Children factored appropriately. Moreover, in both this Chinese sample as well as the sample studied by Stigler et al. (1985), reliabilities were far from acceptable. The Global Self-Worth subscale was particularly problematic in both studies (alphas of .57 and .54). Lee (C. Lee, personal communication, April 5, 1987) found similar problems with a Chinese American sample and thoughtfully concluded that the concept of global self-worth as defined in the American mainstream culture may not be an appropriate construct to include on an instrument examining meaningful self-perceptions among the Chinese. The Meredith et al. (1991) study reported relatively low reliabilities across all subscales (ranging from .44 to .61) suggesting that there exist items that are inappropriate for each of the domains.

Meredith, Wang, and Zheng (1993) have also argued that there are additional domains of relevance to Chinese children that are not included on our American instruments. As a first step, they added several other possible dimensions and asked Chinese children to rate their importance. Among these additions were items tapping group orientation (e.g., willingness to help others), social conduct (e.g., respect for parental and teacher authority), and social acceptance (e.g., engaging in behaviors such as getting good grades that would meet with peer and adult approval). Such an approach is commendable in that it addresses culturally sensitive issues involving the inclusion of domains that are most relevant for a given culture.

Of further concern is that in Chinese (Stigler et al., 1985), Japanese (Maeda, 1997; Sakurai, 1983), and Korean (Rhee, 1993) samples, the means are considerably lower than are scores in U.S., Canadian, Australian, and European samples. (The domain of social acceptance is perhaps the only exception.) Stigler et al. (1985) offer two possible interpretations for the low scores of his Chinese sample. The first is that the Chinese appear to display a self-effacing style that leads them to be more modest in their report of personal qualities. The second is that our structured alternative format, in which we contrast statements about "Some kids" versus "Other kids," implicitly demands a form of social comparison with others. Stigler and colleagues observe that such social comparison is frowned on in China, where individual differences in competence are downplayed. Thus, Chinese children's unwillingness to report that they may be superior to others leads to a pattern of low scores that may not truly reveal their private perceptions of personal adequacy. These same interpretations may well apply to other Asian countries such as Japan and Korea.

In summary, the use of our instruments would appear to be particularly problematic in Asian cultures where (a) the content of certain items may not be relevant or meaningful, (b) other culturally sensitive content is needed, and (c) response tendencies (e.g., a self-effacing style coupled with an avoidance of social comparison) may require different item content, a different response format, and an instructional set to maximize the report of a true evaluation of one's perceived competencies.

It should be noted that we have never recommended the use of our instruments in other countries, particularly in cultures in which the self may be construed differently, or in which perceptions of self may not be that central to individuals' functioning. Rather, we urge that investigators adopt a more culture-specific perspective, focusing on the very meaning of self-constructs and their potential correlates for a given culture. An emphasis on correlates and consequences of self-perceptions is particularly essential because it is important to address the issue of whether self-judgments do have any predictable impact on other systems (e.g., behavioral or emotional) of interest: Investigators in any country, our own included, need to be clear about the purpose of examining self-perceptions and should attend to their functional role.

The need for such an approach in China is particularly pressing. The intellectual vacuum created by the

Cultural Revolution extended to psychology where, for 2 to 3 decades, progress and productivity was effectively halted. This vacuum has exacerbated the current search for methods, measures, and paradigms from Western countries that may be applicable. As I observed at a recent conference in Beijing, many Western psychologists are eager to share their theoretical and methodological wares with their Chinese colleagues. However, in our zeal to be benevolent (or in our less than benevolent quest for fame), we need to guard against imposing frameworks and related instruments that may be inappropriate for a given culture either because they do not adequately tap the construct in question or because the construct may not be that critical to the functioning of individuals in that culture, or both.

## ETHNIC DIFFERENCES IN OUR OWN CULTURE

Most of the work on ethnic differences has been comparisons between the self-esteem of African Americans and Europeans in this country. For many years it was merely assumed that Blacks, as they were called at the time, would have lower self-esteem due to their initial status as slaves, their treatment by White society, their status as second-class citizens, and therefore their cultural marginalization. However, with the advent of attention to the Black community by psychologists, using appropriate methodologies, these myths and assumptions were challenged. Two recent, excellent meta-analyses (Gray-Little & Hafdahl, 2000; Twenge & Crocker, 2000) have clearly documented that African Americans in our culture have higher self-esteem than European-Americans, and these and other investigators have developed trenchant analyses of why this might be the case.

The majority of the studies they have reviewed focus on subject populations ranging from late childhood to early adulthood. These analyses indicate few gender differences. However, the studies do suggest an increase in self-esteem as African Americans go through the stages of childhood, adolescence, and young adulthood. The question becomes what are the reasons for what has seemed to be, for some, counterintuitive findings?

Gray-Little and Hafdahl (2000) form two related questions that capture the reader's attention. First, why do Blacks *not* have lower self-esteem? Second, why do

they have higher self-esteem compared to Whites? From a Cooley, symbolic-interactionist perspective, which the authors embrace as a social framework on reflected self-appraisals, one needs to ask to whom do Blacks turn as the significant others for feedback about the self? They suggest that Blacks do *not* turn to the larger White society as their reference groups but rather turn to the Black community as their source of support and acceptance; these are the people whose opinions are most important to them. Adhering to these values, accepting them, makes them less vulnerable to their marginalization by the White culture, and allows them to develop a sense of meeting the expectations of their ethnic in-group, thereby experiencing high self-esteem (as the Jamesian hypothesis would predict).

It is not that the findings indicate that Black self-esteem is equal to that of Whites. Rather, meta-analyses confirm that it is actually higher. Several processes emerge as explanations. For example, social comparison looms large as a factor in impacting an individual's self-esteem. To the extent that Blacks are comparing themselves to other Blacks, rather than White norms for success, this potentially enhances their self-esteem.

A related mechanism suggested by Gray-Little and Hafdahl (2000) is that Blacks engage in a quest for a positive social identity that emphasizes their desirable distinctiveness. To do this means to adopt a Black racial identity, to view your racial heritage as positive, articulated, and meaningful, and that identity is therefore incorporated into your sense of worth as a person.

According to Twenge and Crocker (2002), stigmatization, previously thought to be a potential source of negative self-esteem, has been cast in a new light in these reviews. Developing a positive racial identity may enable racial minorities to attribute negative outcomes to prejudice, to make in-group comparisons, or to use other self-protective mechanisms that membership in a stigmatized group affords. Thus, one devalues the stigmatizing of the majority culture. These authors also point to interesting cohort effects in that the civil rights movement has had an effect. They are quick to point out that there is a time lag in the effects of such movements, approximately 20 years, and they liken this to gains for women given the women's movement. Thus, self-esteem effects in favor of Blacks have increased more recently.

It should be noted that the basic processes underlying self-esteem formation among African Americans appears to be similar to that of White adolescents (see review in Harter, 1990b). Given the notion that an

individual incorporates the attitudes of significant others toward the self, the context for self-esteem development in African Americans involves the African American family, peers, and community. Thus, African American children and adolescents internalize the opinions of parents and siblings, as well as African American friends, teachers, and coaches, who serve as their primary social reference groups. Interestingly, the relationship between the attitudes of significant others toward the self and self-esteem has been found to be somewhat stronger among African Americans than among European-Americans (Rosenberg & Simmons, 1972). It has been suggested that the African American community is a source of positive self-concept in African American children and that, under certain conditions, the African American family can filter out destructive racist messages from the White community, supplanting such messages with more positive feedback that will enhance self-esteem (Barnes, 1980).

In keeping with one theme of this chapter, the predictiveness of James's formulation, more recent work (Gray-Little & Hafdahl, 2000) applies such an analysis to the level of self-esteem in African American youth (see also Harter, 1990a). To the extent that African American values differ from those of Whites, different domains will be judged important. For example, there is a stronger correlation between school grades and self-esteem among European Americans than among African Americans, suggesting that the two racial groups may well base their self-esteem on different attributes (Epps, 1975). If we assume that people value those things at which they do well, and try to do well in those domains that they value, we see that African American adolescents may come to value those nonacademic arenas in which they feel they excel and over which they have some control and devalue their negative academic experiences (see Hare, 1985). It has also been suggested (Hunt & Hunt, 1977) that African American male youth, in particular, substitute compensatory values in areas where they can perform more successfully. For example, athletic prowess, musical talent, acting ability, sexuality, and certain antisocial behaviors may become more highly valued than academic performance.

While these theories can be applied to ethnic groups as a whole, it is critical to appreciate the fact that while average levels of self-esteem are somewhat higher among African Americans compared to European Americans there is still tremendous overlap in the distributions, and considerably variability in each group

that can also be explained by the theories advanced. We now need to focus on understanding how these processes affect the lives of individual youth, with an eye toward prevention and intervention. Twenge and Crocker (2002) also suggest that we now need to move away from questions about which broad racial groups have higher or lower self-esteem on average and that we need to focus more on questions about individual differences in each culture, including their causes.

More recently, toward this goal, a recent study (Bean, Bush, McKenny, & Wilson, 2003) examined the support offered to African American high school students for academic achievement and global self-esteem. Findings indicated that maternal support and acceptance was significantly related to academic achievement and to adolescent self-esteem (whereas father support was unrelated). They observed that mothers occupy a central role in many African American families including more responsibility for child rearing (see also Collins, 1993). They point out that the mother's role can be seen as especially pivotal because they often take on the instrumental responsibilities and expressive and emotional functions in the family due to the difficulties that African American males have historically encountered in carrying out provider roles (Fine & Schwebel, 1988).

Rowley, Sellers, Chavous, and Smith (1998) provide perhaps a summary statement that can account for many of the more recent findings. They focus on the relationship between *private* racial regard and *personal* self-esteem. Attitudes regarding African Americans were significantly related to the self-esteem of those individuals for whom race plays an important role in defining themselves. Such attitudes were unrelated to self-esteem for those whose race is less central to their definition of self. Thus, African Americans' attitudes about their race are only important to their self-esteem if race is a personally affirmed identity.

## CONCLUSIONS

The study of self-development continues to thrive as new theoretical, methodological, and empirical perspectives emerge. There continues to be an interesting marriage between historical formulations about the self, stemming from James (1890), Cooley (1902), Baldwin (1897), and Mead (1934), and more recently Bowlby (1979) and Ainsworth (1979) and many contemporary perspectives that are represented in this chapter. Histor-

ical perspectives have concentrated more heavily on the social construction of the self. More recent treatments have respected this historical perspective, expanding it into how social influences vary depending on the developmental level of the child and the individual differences in the role of caregivers.

Cognitive-developmental differences, at the impetus of neo-Piagetians, have heightened our appreciation for how more subtle and discrete changes in cognitive advances and limitations influence self-development. The I-self has been transmitted into those changing cognitive processes that determine how the Me-self (one's verbalizable sense of self) will necessarily change with age. The field has far more appreciation for how broad stages, previously conceived as childhood and adolescence, must be broken down into the mini-substages in each broad categories of development. With regard to changes in self-development, we have identified three substages in childhood and three substages in adolescence, where self-development makes major leaps in content and organization. Normative cognitive advances and limitations clearly define the self. The contributions of child-rearing practices also make major contributions in terms of the positivity or the negativity of self-evaluations. Genetic advances have also led to speculations about the self.

Two themes have been emphasized: (1) the role of cognitive-development and (2) the role of socializing influences on the self. These clearly lead to normative-developmental trends in self-development. Equally important is how such influences lead to individual differences, particularly in self-evaluations. Thus, major attention has been devoted to theory and empirical findings on such individual differences.

Our explorations need to extend beyond individual differences, to include gender and ethnic differences in our own cultural and cross-cultural considerations. Sensitivity to gender and cultural differences are critical in understanding how the self is constructed. These are the future directions that the study of self-development must take.

### DISTAL PREDICTORS OF CHILDREN'S SOCIAL SKILLS AND PEER RELATIONSHIPS 617

Temperament, Social Behaviors, and Peer Relationships 617  
Parent-Child Attachment Relationships, Social Behaviors, and Peer Relationships 619  
Parenting and Children's Social Behaviors and Peer Relationships 621

### CHILDHOOD PEER EXPERIENCES AND LATER ADJUSTMENT 625

Academic Adjustment 625  
Psychological Adjustment 627

### CONCLUSIONS 629

Three Critical Challenges 630  
Three Questions in Search of Answers 631

### REFERENCES 631

Experiences with peers constitute an important developmental context for children. In these contexts, children acquire a wide range of behaviors, skills, attitudes, and experiences that influence their adaptation during the life span. Experiences with peers affect social, emotional, and cognitive functioning beyond the influences

of family, school, and neighborhood. In this chapter, we present the current research related to these claims. We begin by commenting briefly on developments in the study of children's peers since the publication of the last *Handbook of Child Psychology* in 1998. Our previous chapter distinguished between processes and effects

---

The writing of this manuscript was supported, in part, by a grant from the National Institute of Mental Health (# MH58116) to Kenneth H. Rubin and by grants from the

---

Social Sciences and Humanities Research Council of Canada and the *Fonds Québécois de la recherche sur la société et la culture* to William M. Bukowski.

at the levels of the interactions, relationships, and groups. Our goal is to provide an updated examination of current theory and research on peer relationships and development.

The task of reviewing the literature on peer interactions, relationships, and groups becomes more challenging as the literature becomes more extensive and diverse. The number of relevant papers published in the past 8 years is substantially larger than the number published in any previous 8-year period. Since the publication of our 1998 chapter, several major books have appeared, including:

*Children's Peer Relations* (Slee & Rigby, 1998)

*Sociometry Then and Now: Building on 6 Decades of Measuring Experiences with the Peer Group* (Bukowski & Cillessen, 1996)

*Family and Peers: Linking Two Social Worlds* (Kerns, Contreras, & Neal-Barnett, 2000)

*The Role of Friendship in Psychological Adjustment* (Nangle & Erdley, 2001)

*Peer Harassment in School: The Plight of the Vulnerable and Victimized* (Juvonen & Graham, 2001)

*How Children and Adolescents Evaluate Gender and Racial Exclusion* (Killen, Lee-Kim, McGlothlin, & Stangor, 2002)

*Peer Rejection: Developmental Processes and Intervention Strategies* (Bierman, 2003)

*Enemies and the Darker Side of Peer Relations* (Hodges & Card, 2003) *Children's Friendships: The Beginnings of Intimacy* (Dunn, 2004)

*Children's Peer Relations: From Development to Intervention* (Kupersmidt & Dodge, 2004)

Perhaps even more important, a number of trade books on peer relationships are now available for parents and teachers, including:

*Queen Bees and Wannabees: Helping Your Daughter Survive Cliques, Gossip, Boyfriends, and Other Realities of Adolescence* (Wiseman, 2002)

*The Unwritten Rules of Friendship: Simple Strategies to Help Your Child Make Friends* (Elman & Kennedy-Moore, 2003)

*The Friendship Factor* (Rubin, 2003)

Not only have the topics of children's peer interactions, relationships, and groups experienced increased

research and public attention, but the study of the peer system has also become increasingly diverse, more articulated, and more naturalistic. Its diversity is seen not only in the wide range of topics that are studied but also in the participation of children from cultures other than those typically found in Western research. Topics recently introduced to the discipline include the significance of peers and friendships as children mark transitions from one school setting to another; cultural and cross-cultural meanings of acceptable and unacceptable social behaviors and relationships; perceived popularity; jealousy and other emotional processes related to the maintenance and dissolution of peer relationships; the statistical (and conceptual) modeling of growth and change in peer interactions and relationships; peer victimization; mutual antipathies; early romantic relationships; and the relative contribution of peers and friendships to well- and ill-being.

Prior emphases on rejection as necessarily "bad" and friendship as necessarily "good" have been replaced by models that emphasize how sets of variables function together via mediation and moderation to affect outcome. The past decade has seen several changes in peer research, including an increase of interest in victimization, a decrease in interest in *sociometric* rejection, increases in the emphasis on biology and emotion, a concern with the peer *group* per se, and an interest in developing process-oriented explanatory models to account for the factors underlying risk.

In parallel to these changes, research on peer interactions, relationships, and groups has focused on an increasingly articulated set of measures. Although the use of omnibus measures of aggression, withdrawal, sociability, sociometric status, and victimization continues, the use of more specific measures, drawn from more refined thinking about individual characteristics and social interactions, has increased. Now, for example, aggression is measured according to whether it is direct, indirect, relational, physical, reactive, or proactive; withdrawal is measured to the extent that it reflects social reticence, social immaturity, preference for objects rather than people, or social exclusion. Research designs have changed also. The once prevalent preference for one-time-only studies has been coupled with the more frequent use of longitudinal designs that allow an examination of prediction as well as intra-individual change. Thus, the literature on peer interactions, relationships, and groups continues to evolve toward higher levels of complexity and specificity.

In the first section of this chapter, we pay homage to those researchers who established areas of investigation that are still active today. Next, we suggest that the peer system consists of multiple levels of analysis, namely individual characteristics, social interactions, dyadic relationships, and group membership and composition. Our thesis is that interactions, relationships, and groups reflect social participation at different interwoven orders of complexity. Our goal, in introducing these levels of analysis, is to establish a framework for further discussion of the development and significance of children's peer experiences. Moreover, discussion of the interaction, relationships, and group levels of social complexity allows subsequent commentary on conceptual and assessment issues that pertain to individual differences in children's behavioral tendencies and peer relationships. These different levels of analysis receive different amounts of treatment in the theoretical accounts of the significance of peer experiences for normal development. These issues are discussed in the next section where we present theories relevant to the understanding of the peer system.

Next, we describe normative patterns of development from infancy through late childhood and early adolescence. Researchers who study children's peer experiences have long maintained a healthy interest in measurement and measurement issues. In the fifth section, we distinguish between individuals, interactions, relationships, and groups in a discussion of measurement issues. In the final sections, we update the voluminous literature that has emerged concerning the origins and consequences of individual differences in children's experiences with peers. We pay particular attention to the proximal and distal correlates of variables associated with individual differences in popularity and friendship. We consider also the developmental prognosis for children whose peer interaction patterns and relationships are deviant from the norm. The chapter concludes with a discussion of some of the directions that future research might take.

## PEER INTERACTIONS AND RELATIONSHIPS—AN HISTORICAL OVERVIEW

The study of children's peer interactions and relationships has had a long and rich history. Charlotte Buhler (1931), in the first *Handbook* chapter on peer interactions and relationships, cited 253 papers, 156 of which

were published in German. Among these early German studies were developmental examinations of social interaction in infants and toddlers; studies of antisocial "tendencies" in children and adolescents; investigations of the evolution of different leadership roles played by children in their peer groups, and observational studies of the development of friendship networks. Thus, prior to World War II, German laboratories were producing research on topics not unknown to contemporaneous peer relationships researchers. Often, the correlates or concomitants of these relationship variables were examined, such as family constellation, institutionalization, and poverty. We continue to grapple with these topics today.

### Early North American Research

North American research concerning children's peer interactions and relationships began to blossom in the 1920s when the first Child Welfare Research Stations came into existence. These interdisciplinary research centers produced new observational and statistical procedures to examine developmental and individual differences in children's social behaviors, interactions, and peer relationships. Research reports from these centers emphasized the development of social participation (Parten, 1932); assertiveness (Dawe, 1934); sympathetic and altruistic behaviors (L. Murphy, 1937); conflict and aggression (Maudry & Nekula, 1939); leadership, dominance, and ascendant behavior (Hanfmann, 1935); friendship (Challman, 1932); group dynamics (K. Lewin, Lippitt, & White, 1939); and peer group structure and composition (Moreno, 1934).

By the beginning of World War II, the study of children's social behaviors, interactions, and peer relationships began to wane as many persons who did developmental research had joined the war effort. Nevertheless, during this period, increased attention was directed to topics relevant to group processes and democratic values. Interest in these topics had been heightened by the sociopolitical events associated with the war and led to research on the interface between individual characteristics (e.g., leadership), interactions between group members, and group dynamics. For example, one line of research was concerned with factors that might evoke and maintain intra- and intergroup harmony and conflict. It is not a coincidence that one of the conditions of the K. Lewin et al.'s (1939) classic study of the effect of leadership on peer group processes was labeled "democratic," whereas another was labeled "authoritarian."

A second area of research that flourished during this time of concern with group composition and processes was sociometry. Following the work of Moreno (1934), the war period is noted for the further development of sociometric techniques that provided researchers with a means of studying acceptance and rejection (see Bronfenbrenner, 1944). These techniques were immediately used to study a variety of questions concerning the correlates of children's experiences with peers. Publications by Northway (1944) and Bonney (1944) serve as historical exemplars for current researchers interested in the factors related to children's experiences in groups.

### Post-World War II

The arrival of the Cold War fostered limited research concern about children and their extrafamilial social relationships. Instead, attention was directed to children's academic and intellectual prowess. With the launching of the Sputnik satellite by the USSR in 1957, the pressures to train children to become academically oriented and skilled at earlier ages and at faster rates than ever before moved developmental researchers away from the earlier focus on children's social worlds.

In the 1960s, the rediscovery of the Piaget's developmental theory provided an impetus for a structurally oriented research climate that captured the interest of psychologists throughout the Western world. A brief glance at archival child psychology and development journals during the 1960s and 1970s will reveal the domination of the Piagetian *Zeitgeist*, in conjunction with, or in opposition to, the behaviorist *Zeitgeist*. This focus on cognition, coupled with continued interest in achievement motivation and behavior, created an environment that was not particularly attuned to the significance of peer interaction and relationships. Nevertheless, researchers in the 1960s and early 1970s appeared to accept the premise that young children were egocentric and were neither willing, nor able, to understand the thoughts, feelings, and spatial perspectives of their peers. Egocentrism also stood in the way of making mature moral judgments and decisions. Given these assumptions, the mind-set seemed to be that studying children's peer relationships would not be productive, at least until the mid-elementary school ages when concrete operations emerged and when egocentric thought vanished.

The coupling of this research and educational climate with the social policy mandate of the mid-1960s regarding the eradication of poverty, led to the development of

early education programs for which the primary foci were cognitive and language development and the development of an achievement orientation in young children. Accordingly, nursery schools moved away from emphasizing the development of relationships and social skills and instead aimed to prepare "at-risk" children for elementary school. Additionally, the achievement-oriented middle classes of the 1960s and 1970s increasingly favored cognitively oriented preschool programs.

Despite the emphasis on early cognitive and language development, the preschool and day-care movements of the 1960s and 1970s may have been partly responsible for the reemergence of peer relationships research. In particular, the growth of early education and care centers in North America was dictated, not only by the need to prevent educational failure among the socioeconomically impoverished, but also by the need for out-of-home care for dual income middle-class households. Given that North American children were entering organized peer group settings at earlier ages than ever before and given that children were remaining with peers in age-segregated schools for more years than their cohorts of previous generations, it would have been shortsighted and irresponsible for developmental researchers to ignore the importance of children's peer relationships and social skills.

The current theories about the significance of peer interactions and relationships for normal development are certainly not new. Piaget (1932) himself implicated peer *interaction*, discourse, and negotiation as crucial elements likely to provoke higher levels of operational thinking. Mead (1934) and Sullivan (1953) also wrote persuasively about the importance of friendship and peer *relationships* for adaptive development. Thus, by the end of the 1960s, the time appeared ripe for child developmentalists to be reminded of their early roots. This reminder was issued by Hartup in his 1970 *Manual of Child Psychology* chapter. This chapter, and Hartup's (1983) revision, proved provocative. In 1998, we provided the *Handbook* with an updated look at the literature on peer interactions, relationships, and groups.

The large amount of research attention directed to the study of children's peer interactions, relationships, and groups in the 1980s occurred at the same time that a new approach to understanding the development of psychopathology was proposed. A basic tenet of the approach was that the study of normative development and individual differences and the study of psychopathology were mutually enriching activities (Sroufe & Rutter,

1984). The study of peer interactions and relationships was ideally suited to the field of developmental psychopathology. Researchers recognized that theories, constructs, variables and measures of peer interactions, and relationships were valuable and useful for the study of normal development *and* for the study of maladjustment. The result of this confluence has been that the study of peer interactions, relationships, and groups and the study of the development of psychopathology have become highly complementary activities (e.g., Deater-Deckard, 2001). On the one hand, children's problems with peers, regardless of their source, may contribute to the genesis of behavioral or emotional disorder; on the other hand, children with behavioral and emotional difficulties may be rejected and/or victimized by their peers from the earliest years of life (Hay, Payne, & Chadwick, 2004). A prominent example of the liaison between the study of peers and the study of maladjustment can be seen in current research on bullying and victimization. Following extreme incidents in schools and among youth in groups, investigators became increasingly interested in identifying the complex interactions between individual and group factors that account for the harm that peers can inflict on each other.

In summary, the study of peer interactions, relationships, and groups has a long and rich history. The topics that have attracted the attention of peer researchers have varied in response to intellectual Zeitgeists, advances in theory and research in other domains of developmental psychology, and to social and political events. Currently, peer research balances concerns with the study of individual differences with the study of basic processes. The features of this balance are evident in the sections that follow.

### INTERACTIONS, RELATIONSHIPS, AND GROUPS: ORDERS OF COMPLEXITY IN CHILDREN'S PEER EXPERIENCES

Children's experiences with peers can be best understood by referring to several levels of social complexity—in individuals, in interactions, in relationships, and in groups (Hinde, 1987). Moreover, events and processes at each level are constrained and influenced by events and processes at other levels. *Individuals* bring to social exchanges more or less stable social orientations, temperaments that dispose them to be more or less

aroused physiologically to social stimuli, and a repertoire of social skills for social perception, cognition, and social problem solving. Over the short term, their *interactions* with other children vary in form and function in response to fluctuations in the parameters of the social situation, such as the partner's characteristics, overtures, and responses. Further, most interactions are embedded in longer-term *relationships* and thus are influenced by past and anticipated future interactions. Relationships may take many forms and have properties that are not relevant to interactions. At the same time, the nature of a relationship is defined partly by the characteristics of its members, its constituent interactions, and, over the long term, the kinds of relationships individuals form depend on their history of interactions in earlier relationships. Finally, individual relationships are embedded in *groups* or networks of relationships with more or less clearly defined boundaries (e.g., cliques, teams, or school classes). As the highest level of social complexity, groups are defined by their constituent relationships and, in this sense, by the types and diversity of interactions that are characteristic of the participants in those relationships. But groups are more than mere aggregates of relationships; through emergent properties, such as norms or shared cultural conventions, groups help define the type and range of relationships and interactions that are likely or permissible. Further, groups have properties and processes, such as hierarchical organization and cohesiveness, which are not relevant to description of children's experiences at lower levels of social complexity.

To further complicate matters, at any level of social organization the understanding of participants will necessarily differ from that of outsiders. Humorous anecdotes shared between friends, for example, can strike outsiders as unnecessarily cruel (e.g., gossip). Children with many friends can still feel lonely; and seemingly innocuous acts can have great significance to members of a friendship, who understand them differently than do outsiders. Given that neither insiders nor outsiders can claim any specific hegemony on the truth, researchers must be prepared to cross and re-cross perspectives as the problem dictates.

The complexity of the multiple, interrelated levels of social organization that underpin peer experiences can make the prospect of understanding these experiences and their influence on children seem truly dim. Historically, distinctions between the various levels and perspectives of children's peer experiences often have been

blurred. For example, investigators have confused phenomena from different levels (e.g., failing to distinguish between group acceptance and friendship) or perspectives (e.g., accepting one child's declaration as evidence of friendship without verifying the reciprocity of this sentiment), and have also sometimes been too facile in making inferences about experiences at one level from measurements at another (e.g., assuming that children who are aggressive in interaction cannot be well-liked or those who are socially removed and withdrawn from interaction cannot have friends). Nevertheless, over the past 25 years, recognition and articulation of the multiple levels of analysis and perspectives that comprise the peer system have greatly increased. Especially significant in this regard has been the contribution of Robert Hinde (e.g., 1987, 1995) who has articulated the features and dialectical relations between successive levels of social complexity.

Borrowing heavily from Hinde, in this section we discuss the nature of three successive levels of complexity in children's experiences with peers—*interactions*, *relationships*, and *groups*. Our goal is to set the framework for subsequent discussion of the development and significance of children's peer experiences. The interaction, relationship, and group levels of social complexity are also important to the conceptualization and assessment of individual differences in children's behavioral tendencies because individuals can be compared with respect to their functioning at these levels; therefore, the present section serves as an orienting framework for our later discussion of measurement issues. As we indicated, a hierarchy of social complexity should include processes at work at the *individual* (versus interactional, relationship, or group) level of description. These processes would include children's socioemotional/temperamental dispositions, and social knowledge and skills repertoires. In the literature on children's peer experiences, the individual level has been the focus of much interest. However, rather than introduce this well-developed literature here, we embed its discussion into sections on children's interactions and relationships.

### Interactions

The simplest order of complexity of peer experience involves interactions. *Interaction* refers to the social exchange of some duration between two individuals. Behaviors that simply (and only) complement one another (like riding on either end of a teeter-totter) would

ordinarily not be considered true interaction unless it was amply clear that they were jointly undertaken. Instead, the term *interaction* is reserved for dyadic behavior in which the participants' actions are interdependent such that each actor's behavior is both a response to, and stimulus for, the other participant's behavior. At its core, an interaction comprises "such incidents as Individual A shows behavior X to Individual B, or A shows X to B and B responds with Y" (Hinde, 1979, p. 15). Conversational turn-taking is a quintessential illustration: Thus, Child A requests information from Child B ("What's your name?"), Child B responds ("My name is Lara. What's yours?"), Child A replies ("Camilla."), and so on.

Such a simple exchange as that of Camilla and Lara belies the richness and complexity of the ways that children of most ages communicate with and influence one another. Thus, besides introducing themselves, children in conversation may argue, gossip, comfort, and support one another, self-disclose, and joke, among other things. And, during interaction, children cooperate, compete, fight, withdraw, respond to provocation, and engage in a host of other behaviors that includes everything from ritualized sexual contact to rough-and-tumble (R&T) play to highly structured sociodramatic fantasy. Typically, researchers have been less interested in cataloguing the myriad of interactional experiences than in understanding the origins and consequences of three broad childhood behavioral tendencies: (1) moving toward others, (2) moving against others, and (3) moving away from others. As a consequence, our understanding of children's experiences at the interactional level is disproportionately organized around the constructs of sociability and helpfulness, aggression, and withdrawal. As much of this literature is oriented toward individual differences among children along these dimensions of interaction, we review this research in later sections. Developmental trends in these behaviors are described in the subsequent section.

Although many social exchanges have their own inherent logic (as in the question-answer sequence of Camilla and Lara), it is also the case that the forms and trajectories of episodes of interaction are shaped by the relationships in which they are embedded. For example, friends are more committed to resolving conflict with each other than nonfriends, are more likely than nonfriends to reach equitable resolutions, and continue to interact following a disagreement (Laursen, 1993; Laursen, Finkelstein, & Betts, 2001; Laursen, Hartup, & Koplas, 1996; Laursen & Koplas, 1995; Newcomb &

Bagwell, 1995). Beyond this, children engaged in interaction vary their behavior as a function of their short-term and long-term personal goals, their understanding of their partner's thoughts and feelings in the situation, the depth of their repertoire of alternative responses, and various "ecological" features of the context of the interactions (such as the presence of bystanders), the physical setting, their own and their partner's relative standing in the group, and the operative local customs or "scripts" for responding. It is precisely the demonstration of such range and flexibility in responding to the challenges of interpersonal interaction, *when considered at the individual level of analysis* that many writers think of as social competence (e.g., Bukowski, Rubin, & Parker, 2001; Rose-Krasnor, 1997).

### Relationships

Relationships introduce a second and higher-order level of complexity to children's experiences with peers. *Relationships* refer to the meanings, expectations, and emotions that derive from a succession of interactions between two individuals known to each other. Because the individuals are known to each other, the nature and course of each interaction is influenced by the history of past interactions between the individuals as well as by their expectations for interactions in the future. It has been suggested that the degree of closeness of a relationship is determined by such qualities as the frequency and strength of influence, the diversity of influence across different behaviors, and the length of time the relationship has endured. In a close relationship, influence is frequent, diverse, strong, and enduring. Alternatively, relationships can be defined with reference to the predominant *emotions* that participants typically experience in them (e.g., affection, love, attachment, or enmity). Hinde (1979) further suggests that an essential element of a relationship is *commitment* or the extent to which the partners accept their relationship as "continuing indefinitely or direct their behaviors toward ensuring its continuance or toward optimizing its properties" (p. 29). Finally, it is important to note that, although as social scientists we may speak of abstract categories of relationships (e.g., sibling, best friend, or enemy), children view each instance of these relationships in a particularized way; to children, relationships of even the same general category are not interchangeable.

As a form of social organization, dyadic relationships share features with larger social organizations, such as a

family, a class, or a team. In a particularly insightful analysis, McCall (1988) noted that dyads, like larger organizational structures, undergo role differentiation, specialization, and division of labor: "Members' lines of action differ one from the other yet remain interdependent in certain ways" (p. 473). Moreover, participants in a relationship are aware that their relationship, though it may be very much their own local creation, is supported by an objectified, institutionalized social form: "When persons say they are friends, usually they can point to cultural images, rules of conduct, and customary modes of behavior to confirm their claims" (Suttles, 1970, p. 98). In addition, parties to a relationship have a sense of shared membership and belonging: "A sense of shared fate tends to arise as members discover that the surrounding world treats them not so much as separate individuals but rather as a couple, or unit" (McCall, 1988, p. 471). Finally, the creation of a shared culture is a vital part of dyadic relationships. This shared culture includes normative expectations regarding appropriate activities, patterns of communication and revelation, relations to external persons and organizations, and so on. It also includes private terms, or neologisms, for shared concerns or common activities, and rituals, or "dyadic traditions," arising from the routinization of recurrent dyadic activities (such as meeting at the same place after school, flipping a special coin to resolve a dispute, or engaging in an exclusive "buddy shake" to mark a joint promise or planned behavior).

These are all features that relationships have in common with other, larger social organizations. However, McCall indicates that there are certain attitudinal features of the participants in a dyadic relationship that are distinct to this level of social organization and vital to understanding its functioning and impact on interactions and individuals. For example, unlike most social organizations, dyadic relationships do not vary in membership size. Having only two members, the dyad is peculiarly vulnerable, for the loss of a single member terminates the dyad's existence. Because members appreciate this vulnerability, issues of commitment, attachment, and investment loom larger in dyadic relationships than in other forms of social organization. Indeed, an understanding of the surface behavior of members of relationships can be elusive unless note is taken of the deeper meaning of behavior in relation to the relationship's mortality. This same sense of mortality is likely to contribute to a special sense of uniqueness ("there has never been a friendship quite like ours") and to what

McCall calls a “sense of consecration,” or a feeling that each member must take responsibility for what happens in the relationship.

### Friendship

In the literature on children’s peer experiences, one form of dyadic relationship has received attention above all others—*friendship*. The issue of what constitutes friendship is a venerable philosophical debate beyond the scope of this chapter. However, some points from this debate warrant noting here because of their operational significance.

First, there is widespread agreement that friendship is a *reciprocal* relationship that must be affirmed or recognized by both parties. Reciprocity is the factor that distinguishes friendship from the nonreciprocal attraction of only one partner to another. From an assessment perspective, methods that do not verify that the perception of friendship is shared between partners prove difficult because children are sometimes motivated by self-presentational goals to designate as friends other children who do not view them as friends in return. Thus, in the absence of assessing reciprocity, methods of identifying friends may confuse desired relationships with actual ones.

A second point of consensus is that *reciprocity of affection* represents an essential, though not necessarily exclusive, tie that binds friends together (Hays, 1988). The interdependence of the two partners derives primarily from socioemotional rather than instrumental motives. It is customary for children to seek one another out for instrumental reasons. Similarity of talents or interests may bring together children who might not otherwise interact. For example, work and sports teams, musical groups, and even delinquent gangs include members who are not necessarily friends. Similarities or complementarities of talents and interests may lead to friendship and can help sustain them; however, they do not constitute the basis of the friendship itself. The basis is reciprocal affection.

Third, friendships are voluntary, not obligatory or prescribed. In some cultures and in some circumstances, children may be assigned their “friends,” sometimes even at birth (Krappmann, 1996). Although these relationships may take on some of the features and serve some of the same interpersonal ends as voluntary relationships, most scholars would agree that their involuntary nature argues against confusing them with friendship.

Until recently, the study of children’s dyadic relationships with peers was focused almost exclusively on the study of friendship. Researchers are now turning to the study of mutual antipathies and enmities (e.g., Abecassis, Hartup, Haselager, Scholte, & van Lieshout, 2002; Hodges & Card, 2003). Whereas the topic of disliking is certainly not new (e.g., Hayes, Gershman, & Bolin, 1980), the emphasis of recent research has been on the frequency of mutual antipathies, their correlates, and their developmental significance.

A final point is that relationships must be understood according to their place in the network of other relationships. For example, children’s friendships are influenced by the relationships they have at home with parents and siblings. Children’s conceptualizations and feelings about their primary relationships are internalized and lead to (a) expectations about what relationships outside of the family might and should be like, and (b) particular interpersonal behaviors and interactions with peers that reflect their internalized models of relationships (Belsky & Cassidy, 1995). Whereas parent-child relationships may influence the early development and maintenance of children’s peer relationships, it would make sense to expect that the relations between relationship systems become increasingly reciprocal and mutual with increasing child age: The quality of the child’s peer relationships is likely to influence the quality of the parent-child relationship and perhaps even the relationship between the child’s parents.

### Groups

A *group* is a collection of interacting individuals who have some degree of reciprocal influence over one another. Groups can be formed spontaneously, out of common interests or circumstances, or due to formal external structures (e.g., groups of students organized into classes in school). Hinde (1979) suggests that a *group* is the structure that emerges from the features and patterning of the relationships and interactions present in a population of children. Accordingly, groups possess properties that arise from the manner in which the relationships are patterned but are not present in the individual relationships themselves. Examples of such properties include *cohesiveness*, or the degree of unity and inclusiveness exhibited by the children or manifest by the density of the interpersonal relationships; *hierarchy*, or the extent of intransitivity in the ordering of the individual relationships along interesting dimensions (e.g., If Fred dominates

Brian and Brian dominates Peter, does Fred dominate Peter?); and *homogeneity* or *homophily*, or consistency across members in the ascribed or achieved personal characteristics (e.g., sex, race, age, intelligence, or attitudes toward school). Finally, every group has *norms*, or distinctive patterns of behaviors and attitudes that characterize group members and differentiate them from members of other groups.

Many of our most important means for describing groups speak to these core characteristics or processes. Thus, researchers may address the degree to which the relationships and interactions in a group are segregated along sex or racial lines (e.g., Killen, Crystal, & Watanabe, 2002; Killen, Lee-Kim, McGlothlin, & Strangor, 2002); they may compare the rates of social isolation among groups that differ in composition; or they may investigate the extent to which a group's hierarchies of affiliation, dominance, and influence are linear and interrelated. In addition, group norms can be used as a basis for distinguishing separate "crowds" in the networks of relationships among children in high school (e.g., Brown, 1989). The emergent properties of groups also shape the experiences of individuals in the groups (e.g., Espelage, Holt, & Henkel, 2003). Thus, crowd *labels* constrain, in important ways, adolescents' freedom to explore new identities; *status hierarchies* influence the formation of new friendships; *segregation* influences the diversity of children's experiences with others; and *cohesiveness* influences children's sense of belonging. As such, the group can influence the individual. Indeed, many of the classic developmental studies concerned the peer group per se, including that of K. Lewin et al. (1939) concerning group climate, and Sherif, Harvey, White, Hood, and Sherif's (1961) examination of intragroup loyalty and intergroup conflict. In addition, theorists stressing the importance of children's peer experiences (e.g., Cairns, Xie, & Leung, 1996; Xie, Cairns, & Cairns, 1999, 2001) have generally conceptualized the group as an important developmental context that shapes and supports the behaviors of its constituent members.

In spite of the importance of the group, there has been, until recently, little attention paid to the assessment of group phenomena (see Bukowski & Sippola, 2001). This is surprising because researchers often cite experiences with peers with reference to the "peer group." Cairns et al. (1996) argued that this neglect could be attributed to the complex conceptual and methodological issues related to the study of group

structure and organization. However, recently a number of complex statistical procedures have allowed the study of peer groups and peer group effects on children.

Finally, it is worth noting that the construct that has dominated the peer literature during the past 25 years, namely that of *popularity*, is both an individual- and a group-oriented phenomenon. Measures of popularity refer to the group's view of an individual in relation to the dimensions of liking and disliking (Bukowski & Hoza, 1989; Bukowski, Sippola, Hoza, & Newcomb, 2000; Parker, Saxon, Asher, & Kovacs, 1999). In this regard, popularity is a group construct and the processes of rejection and acceptance are group processes. Yet, despite this reality, most peer researchers treat popularity as characteristic of the individual (Asher, Parker, & Walker, 1996; Newcomb, Bukowski, & Pattee, 1993). This confusion exemplifies the significance of recognizing the inextricable links between different levels of analysis. As Bronfenbrenner (1944) wrote over 50 years ago, the study of the peer system requires the "envisagement of the individual and the group as developing organic units" (p. 75).

## Culture

It is important to recognize that each of the social levels described earlier falls under the all-reaching umbrella of the cultural macrosystem (e.g., Bronfenbrenner & Crouter, 1983). By culture is meant "the set of attitudes, values, beliefs, and behaviors shared by a group of people, communicated from one generation to the next" (Matsumoto, 1997, p. 5). Cultural beliefs and norms help interpret the acceptability of individual characteristics and the types and ranges of interactions and relationships that are likely or permissible.

As it happens, the cultural and cross-cultural study of children's peer interactions, relationships, and groups has a brief history. A central question asked in this body of work is rather intriguing: Do the "meanings" and significance of given social behaviors or social relationships differ from culture to culture, or are there cultural universals in interpreting given social behaviors and relationships? For example, is social competence defined in a similar fashion across cultures? And what about aggression or socially wariness? Are these behaviors similarly defined and interpreted from culture to culture? Are children's friendships conceptualized in similar ways across culture? Are such relationships viewed as similarly significant from culture to culture? These are

but a few questions that are only now being examined by researchers the world over.

Given that the majority of the world's inhabitants do not reside in culturally Westernized countries, the cross-cultural work on peer interactions, relationships, and groups requires careful note: Child development is influenced by many factors. In any culture, children are shaped by the physical and social settings in which they live as well as culturally regulated customs, childrearing practices, and culturally based belief systems (Harkness & Super, 2002). The bottom line is that the psychological "meaning" attributed to any given social behavior is, in large part, a function of the ecological niche in which it is produced. If a given behavior is viewed as acceptable, then parents (and significant others) will attempt to encourage its development; if the behavior is perceived as maladaptive or abnormal, then parents (and significant others) will attempt to discourage its growth and development. And the very means by which people go about encouraging or discouraging the given behavior may be culturally determined and defined. Thus, in some cultures, the response to an aggressive act may be to explain to the child why the behavior is unacceptable; in others, physical discipline may be the accepted norm; in yet others, aggression may be ignored or perhaps even reinforced (for discussions, see Bornstein & Cheah, *in press*; Harkness & Super, 2002). Another issue is the degree to which cultures allow or encourage peer interactions. For example, in kin-based societies, such as Kenya, peer interactions are discouraged because parents fear the potential for competition and conflict (Edwards, 1992). It would appear most sensible for the international community of child development researchers not to generalize to other cultures their own culture-specific theories of normal and abnormal development. In this regard, we describe relevant extant research pertaining to cross-cultural similarities and differences in children's peer interactions and relationships throughout this chapter.

## Summary

To understand children's experiences with peers, researchers have focused on children's interactions with other children and on their involvements in peer relationships and groups. Analyses in each level—interactions, relationships, groups—are scientifically legitimate and raise interesting questions. However, re-

searchers have not always demonstrated a clear understanding of the important ways in which processes at one level are influenced by those at the others. They have sometimes overlooked ways in which conclusions drawn at single levels of analysis can be limited. For example, the observation of two children at play can reveal the rates at which they display different behaviors and the patterning of these behaviors with respect to one another. It can be misleading, however, to attribute these characteristics of interaction solely to individual differences in social competence or temperament; one must also consider relational interdependencies—unique adjustments made by Person A and Person B to one another that define their particular relationship. And events transpiring in a given relationship also reflect realities outside the relationship; for example, tensions produced by individuals' loyalties to other friends in the peer group may affect the quality of social interaction between two specific children.

Until recently, studying individual, dyadic, and group measures was challenging, both conceptually and statistically. Advances in multilevel modeling techniques and in the availability of more-or-less user-friendly software have given researchers the tools to examine the effects of group, dyadic, and individual variables simultaneously. These procedures can be used to assess how the effects of variables describing individual tendencies (e.g., aggressiveness, sociability, or inhibition) on an outcome (e.g., one's subsequent aggressiveness, sociability, or reticence) will vary as a function of dyadic-relationship characteristics (e.g., quality of friendship; quality of the mother-child relationship). In turn, a researcher can assess variations in dyadic effects due to the characteristics of the groups in which they are embedded. The use of these techniques is nearly perfectly suited to some forms of peer relationships research. They have been used with success already (e.g., Kochenderfer-Ladd & Wardrop, 2001).

Yet, despite the remarkable methodological advantages of procedures, such as multilevel modeling, they alone cannot deal with the conceptual ambiguity of many measures currently used in peer research. Specifically, a measure that putatively assesses one level of social analysis may, to some extent, reflect phenomena at another level. For example, having dyadic friendships with aggressive peers, or belonging to an aggressive peer group may reflect individual tendencies such as sociability, risk-taking, and tolerance of aggressiveness

and those who are aggressive. At the same time, friendships with aggressive others also carry meaning at the relationship (dyadic friendship) or group levels. Thus, when researchers are examining the effects of group membership, they must also distinguish between the effects of the group per se and the effects of having dyadic relationships in that group. This problem is especially important when one wishes to distinguish between friendship effects and group effects. To the extent that a child's friendships are likely to be embedded in the child's group, researchers need to carefully account for all of these effects and to distinguish between them. Attempts to distinguish between the effects of friendship and the effects of belonging to a peer group are inadequate, or at least limited, when the effects of only one friend are accounted for. In such an instance, some "group effects" may actually be "friendship effects" or the other way around.

Finally, our emphasis on multiple levels of analysis provides us with a basic conceptual model of social competence. Researchers have often treated measures of peer experiences (e.g., sociometric status) as indices of social competence. Our view is that social competence in the peer system refers to a child's capacity to engage effectively and successfully at each level of analysis and in his or her relevant culture. A competent child will be able to (a) become engaged in a peer group structure and participate in group-oriented activities, (b) become involved in satisfying relationships constructed on balanced and reciprocal interactions, and (c) satisfy individual goals and needs and develop accurate and productive means of understanding experiences with peers on both the group and dyadic levels.

## **THEORIES RELEVANT TO THE STUDY OF CHILDREN'S PEER INTERACTIONS, RELATIONSHIPS, AND GROUPS**

### **Personality Theorists**

#### ***Psychoanalytic Perspectives***

Psychoanalytic or neo-psychoanalytic theorists have rarely ascribed developmental significance to children's peer interactions or relationships. Instead, they regard much of the child's development as resulting from parental behavior and the quality of the parent-child re-

lationship. Perhaps the only psychoanalytically oriented theorist to ascribe developmental significance to children's peer relationships is Peter Blos. For Blos (1967), the major event of adolescence is the process of *individuation* by which adolescents restructure their childhood relationships with their parents and strive to achieve qualitatively different relationships with peers. Individuation involves renegotiating dependency relationships with parents; such renegotiation is precipitated, in part, by adolescent sexual drives. It also involves the introduction of new themes into relationships with peers. Responding to erotic drives, the adolescent turns toward the peer group as a means of finding sexual outlets and venues of emotional closeness; previously, such closeness was available only from parents.

As a function of restructuring their relationships with parents, adolescents come to experience turmoil and anxiety accompanied by feelings of despair, worthlessness, discouragement, and vulnerability. According to Blos, adolescents' capacities to cope with these feelings and experiences rest with their ability to establish qualitatively distinct forms of supportive relationships with peers. In the process of separating from parents and prior to achieving a state of personal autonomy, adolescents turn to peers for "stimulation, belongingness, loyalty, devotion, empathy, and resonance" (Blos, 1967, p. 177).

One potential pitfall of the individuation process for adolescents is that some teenagers become overly dependent on peers, conforming to the norms and standards of the group too readily as part of their search for security outside the family. Blos (1967) argued that, in such cases, dependence on peers is problematic because it precludes the promotion of independence and autonomy. But more generally, it is argued that the peer group is a major determinant of an adolescent's ability to achieve a sense of autonomy and independence from the family.

The effects of the psychoanalytic tradition on peer relationships research can be seen most strongly in two areas of research. The first one takes its inspiration from the argument embedded in *attachment theory* (Bowlby, 1969/1982) that peer relationships are motivated by a human need for relatedness. According to this view, being associated with others increases security because it reduces anxiety and promotes the internalization of positive relational schemas of others. As children develop mechanisms to distinguish between friends and

enemies, they are increasingly able to manage their emotions and behavior. A second idea taken from psychoanalytic theory has appeared more recently. Sandstrom and Cramer (2003) applied the concept of *defense mechanisms* to the understanding of girls' responses to rejection. Their findings indicate that the use of denial and projection following rejection vary as a function of sociometric status with their use highest among rejected and neglected girls. They point to the potential adaptive benefits of this use.

### ***Sullivan's Theory of Personality Development***

In his developmental model of interpersonal relationships, Sullivan characterized children's peer relationships during the early childhood and the early school-age years as organized largely around play and common activities. During the juvenile period (from approximately age 7 to 9 years), children become increasingly concerned about their place in the peer group as a whole and a sense of belonging to the group becomes increasingly important.

As children entered early adolescence, Sullivan proposed that they begin to develop "chumships" or close, intimate mutual relationships with same-sex peers. As a relationship between "co-equals," chumships were distinct from the hierarchical relationships that children experienced with their parents. Accordingly, Sullivan argued that this close relationship was a child's first true interpersonal experience based on reciprocity and exchange between equals and that the *function* of peer relationships was to promote a sense of well-being. He proposed that it was in chumships that children had their first opportunities to experience a sense of self-validation. This validation would emanate, in large part, from their recognition of the positive regard and care that their chums held for them. Sullivan went so far as to argue that the positive experiences of having a "chum" in adolescence would be so powerful as to enable adolescents to overcome trauma that may have resulted from prior family experiences. Conversely, Sullivan believed that the experience of being isolated from the group, during the juvenile period, would lead a child to have concerns about his or her own competencies and his or her acceptability as a desirable peer. Consequently, Sullivan suggested that children who are unable to establish a position in the peer group would develop feelings of inferiority that could contribute to a sense of psychological ill-being. One posited outcome of the lack of supportive chumships was the development of loneliness, or

"the exceedingly unpleasant and driving experience connected with the inadequate discharge of the need for human intimacy" (Sullivan, 1953, p. 290).

### ***Symbolic Interactionism***

Following the lead of William James (1890), who posited that humans have "an innate propensity to get ourselves noticed, and noticed favorably, by our kind" (p. 293), Mead (1934) argued that people defined themselves according to how they believed they were perceived by others. To Mead, for example, the ability to self-reflect, to consider the self in relation to others, and to understand the perspectives of others was largely a function of participation in organized, rule-governed activities with peers. He suggested that exchanges among peers, whether experienced in the arenas of cooperation or competition, conflict or friendly discussion, allowed the child to gain an understanding of the self as both a subject and an object. Understanding that the self could be an object of others' perspectives gradually evolved into the conceptualization of a "generalized other" or an organized and coordinated perspective of the "social" group. In turn, recognition of the "generalized other" led to the emergence of an organized sense of self. Thus, according to symbolic interactionist theory, exchanges between the individual and the peer group are essential to the formation of a "self" concept and a concept of the "other," two constructs thought to be mutually interdependent.

### **Cognitive Developmental Perspectives**

#### ***The Piagetian Perspective***

Piaget (1932) suggested that children's relationships with peers could be distinguished, in both form and function, from their relationships with adults. The latter relationships were construed as being complementary, asymmetrical, and falling along a vertical plane of dominance and power assertion. As such, children's interactions with adults about cognitions, ideas, and beliefs were thought to be marked by more emotional wariness and less openness and spontaneity than their interactions with age-mates. By contrast, peer exchanges allowed children to actively explore their ideas rather than to risk their devaluation and criticism by adult authority figures. It was also proposed that children come to accept adults' notions, thoughts, beliefs, and rules, not necessarily because they understand them, but rather because obedience is viewed as required. Along the

same lines, adults were less likely to follow the dictates of children. Peer relationships, alternatively, were portrayed as being balanced, egalitarian, and as falling along a more-or-less horizontal plane of dominance and power assertion. Thus, it was in the peer context that children could experience opportunities to examine conflicting ideas and explanations, to negotiate and discuss multiple perspectives, to decide to compromise with, or to reject, the notions held by peers. These peer interactive experiences were believed to result in positive and adaptive developmental outcomes for children, such as the ability to understand others' thoughts, emotions, and intentions.

Empirical support for these contentions is drawn from neo-Piagetian research demonstrating that when children work together to solve given problems, they are more likely to advance their knowledge base through discussion than if they work independently and alone. Developmental change occurs because differences of opinion provoke cognitive disequilibria that are sufficiently discomfiting so as to elicit attempts at resolution. Each interactor must construct, or reconstruct, a coordinated perspective of the original set of ideas to re-instate a sense of cognitive equilibrium.

From this perspective, it is *intrapersonal* cognitive conflict that evokes a search for homeostasis and resultant developmental change. This intrapersonal conflict may be instigated by disagreements about ideas, thoughts, beliefs; however, it is unlikely that mean-spirited *interpersonal* conflict and hostility brings with it cognitive advancement. Recent views on the role of conflict center on the notion that disagreements between peers about things personal, interpersonal, and impersonal are best resolved through the cooperative exchange of explanations, questions, and reasoned dialogue (e.g., Laursen et al., 2001; Shulman & Laursen, 2002). If the exchange of conflicting ideas is marked by hostility, dysregulated or disabling emotions are not likely to promote cognitive growth and development.

Contemporary perspectives on the role of peer exchange for developmental growth can be seen in the work of co-constructivist thinkers such as Azmitia (Azmitia, Lippman, & Ittel, 1999; Azmitia & Montgomery, 1993) and Rogoff (1997). These writers introduce the notion that the quality of the relationship between the peers who are interacting with each other may contribute to cognitive and social-cognitive growth and development. For example, *friends* can challenge each other with relative impunity. Given that friends are

more sensitive to each others' needs, and more supportive of each others' thoughts and well-being than nonfriends, it may be that children are more likely to talk openly and challenge each others' thoughts and deeds in the company of friends than nonfriends. If this were the case, one would expect exchanges between friends to be more promoting of cognitive and social-cognitive growth than nonfriend peer exchanges. Data supportive of this view are reviewed in later relevant sections.

### *Vygotsky's Perspective*

According to Vygotsky (1978), cognitive growth and development are a function, in large part, of interpersonal exchange. Vygotsky invoked the principle of the "zone of proximal development" (*ZPD*) to explain the significance of social interaction. The *ZPD* represented the distance between what the child could do independently and what he or she could do with the collaboration or assistance of others. Vygotsky indicated that typically assistance was provided by the child's parents. Researchers such as Tudge (1992; Hogan & Tudge, 1999) and Rogoff (1997) have argued that the child's peers can play the role of co-constructivist. Thus, pairing with a more competent, "expert" peer may assist the child's movement through the *ZPD* (e.g., Duran & Gauvain, 1993).

One difference between the Piagetian and Vygotskian perspectives of the links between peer interaction, peer relationships, and growth and development lies in Piaget's belief that it was peer *conflict* that evoked change, whereas Vygotsky contended that it was *cooperation* and the pooling of ideas that promoted change. Contemporary accounts suggest that conflicting ideas and differences in opinion actually elicit cooperation between partners. If partners are positively disposed to one another, it behooves them to discuss their differences, to negotiate, to compromise—in short, to cooperate and to move forward, not only cognitively, but also emotionally in their relationship. Thus, studies of the role that *conflict* plays in cognitive and social-cognitive growth include, in the phenomenon's definition, components of disagreement as well as explanation, questions, agreements, and compromise. A rapprochement between the Piagetian and Vygotskian positions would suggest that *intrapersonal* cognitive conflict triggers the child's attempts to regain some semblance of cognitive homeostasis. If such intrapersonal cognitive conflict is associated with conflictual, negative-spirited interpersonal exchange, cognitive growth is less likely to result than

anger, fear, or some other disabling emotion. Alternately, if cognitive conflict is associated with “reasoned dialogue” (Damon & Killen, 1982), cooperative co-construction may occur resulting in a new, more cognitively mature perspective.

In summary, research based on the constructivist theories of Piaget and Vygotsky reveals that:

- Children can, and do, make cognitive advances when they *cooperatively* exchange and discuss conflicting perspectives on various issues (MacDonald, Miell, & Morgan, 2000).
- Children working together can solve problems that neither partner is capable of solving alone (Golbeck, 1998).
- Discussing problems with a peer who has superior knowledge is more likely to evoke intrapersonal conflict and cognitive advancement than discussions with a less competent peer (Duran & Gauvain, 1993; Garton, 2001; Tudge, 1992).
- Transactive exchanges during which children openly criticize each others’ ideas and clarify and elaborate their own ideas are more often observed in the company of friends than of nonfriends (e.g., Azmitia & Montgomery, 1993).

### **Learning and Social Learning Theories, Peer Interaction, and Peer Relationships**

Although its influences are less explicit than implied, social learning theory has had a powerful effect on the study of peer interactions, perhaps more so than any other perspective. The traditional learning theory perspective has been that children are behavior control and behavior change agents for each other. Peers punish or ignore nonnormative social behavior and reward or reinforce positively those behaviors considered culturally appropriate and competent. Thus, to the extent that children behave in a socially appropriate manner, they develop positive relationships with their peers; to the extent that children behave in a socially incompetent or nonnormative manner, peer rejection may result.

Perhaps the most relevant and influential social learning was that formulated originally by Bandura and Walters (1963). In their monograph, *Social Learning and Personality Development*, Bandura and Walters noted that children can learn novel social behaviors by observing others. Moreover, children could use observational

information about the consequences of specific social behaviors to guide their own exhibition or inhibition of these behaviors. This modeling perspective provides a powerful argument for how the social behaviors of children are quickly and effectively organized, reorganized, and redirected. Observational learning promotes adaptation to new circumstances and new relationships (Cairns, 1979). As Cairns noted, however, once learned, social behaviors are subject to maintenance and change; thus, it is argued that the demonstration of socially learned behaviors will be maintained or inhibited by its actual or expected consequences. Further, the social contexts in which reinforcement and punishment occur (or are expected to occur) matter. The source of the reinforcement or punishment, how, when, and where the consequences are administered, and whether the child believes that he or she can actually produce the desired behavior all affect the production, reproduction, or inhibition of the given behavior. For example, Bandura (1989) speculated that children set standards of achievement for themselves and that they are likely to self-administer reinforcement when the standards are met and punishment when they are not. Self-reinforcement is applied when children see themselves as having exceeded the norms for their relevant comparison group of peers; self-punishment is consequent to having failed to meet perceived group norms.

Also, children’s beliefs, cognitions, and ideas about the administrators of rewards/punishment can influence the strength of the given behaviors. Is the administrator a competent or incompetent peer, an aggressive or nonaggressive age-mate, or a younger or older child? Moreover, the age of the child who is processing this social information must assuredly be of some significance. To the extent that researchers have generally ignored these issues, social learning theory still has some way to go in advancing an understanding of the establishment, maintenance, and dissolution/inhibition of children’s peer-directed behaviors.

### **Human Ethology**

Ethology is “the subdiscipline of biology concerned with the biological bases of behavior, including its evolution, causation, function, and development” (Cairns, 1979, p. 358). Although there is no particular ethological theory pertaining specifically to the evolutionary significance of peer interaction or peer relationships,

the *methods* and *constructs* used by animal behaviorists have often been adopted by those who study children's social behaviors, peer relationships, and the structural dynamics of the peer group (e.g., Hawley, 2003). To the extent that Bowlby's (1973) ethologically oriented theory of parent-infant attachment relationships has come to influence the study of peer relationships, some consideration of human ethological theory is warranted.

The questions asked by ethologists were outlined by Tinbergen (1951). He suggested that when an organism produces a given behavior, the scientist must ask: (a) Why did the individual demonstrate the particular behavior at the specific time she or he did? (b) How did the individual come to produce such a behavior at such times? and (c) What is the functional significance or survival value of the produced behavior? These questions focus concern on features of motivation, learning and development, and evolutionary adaptation, respectively.

A central tenet of ethological theory is that social behavior, relationships, and organizational structures are limited by biological constraints related to their adaptive, evolutionary function (Hinde & Stevenson-Hinde, 1976). Thus, *aggression*, for example, is viewed as a means by which members of the species survive; protect themselves, their significant others, and their progeny; and ensure reproductive success (Lorenz, 1966). *Altruism* is also seen as a basic facet of human nature, ensuring survival of the species. Likewise, the *attachment relationship* formed during infancy between parent and child not only guarantees the protection of the young from discomfort and threatening predators but also provides the child with an internalized "working model" (Bowlby, 1973) of what human relationships could, should, or might be like. In this latter case, the quality of the primary relationship engenders a set of internalized relationships expectations that affect the initiation and maintenance of extrafamilial (e.g., peer) relationships.

Given the assumption that behavior is best understood when observed in natural settings, ethological theory has influenced contemporary methodologies. Thus, investigators have devoted considerable effort to distinguish *observationally* between different forms and functions of what, on the surface, appear to be the same basic behavioral phenomena. For example, one can distinguish between physical, verbal, and relational aggression (the *forms*) and between hostile and instrumental aggression (the putative *functions*; see Little, Jones, Henrich, & Hawley, 2003). Such distinctions are drawn on the basis

of examining the gestures and facial expressions of the interacting individuals, as well as the ecological (venues) and interpersonal (quality of relationships) contexts in which social interactions occur.

Ethological theory and the questions derived from it evoke analyses of the psychological meanings of different forms of the same behavior (Hawley, 2003). For example, do instrumental and hostile aggressions have different developmental origins and different proximal and distal causes (e.g., Prinstein & Cillessen, 2003)? Similarly, does the frequent expression of behavioral solitude when engaging in constructive activity have different developmental origins and different proximal and distal causes than the frequent expression of behavioral solitude when observing others from afar (Coplan, Rubin, Fox, Calkins, & Stewart, 1994; Henderson, Marshall, Fox, & Rubin, 2004)? Likewise, does a given behavior have the same psychological meaning when produced by a 2-, 4-, and 10-year-old? And finally, does a given behavior have the same psychological meaning when produced by children of the same age, but in different cultures? These are questions pertinent to the study of peer *interaction*. And, given the normalcy/abnormalcy of social behaviors in different contexts and at different ages (Cillessen & Mayeux, 2004), it is also clear how questions derived from ethological theory are relevant to the study of children's peer *relationships*.

### Group Socialization Theory

If there was a publication that brought the study of the peer group to the attention of the general reader during the past 10 years it was Judith Rich Harris's essay on group socialization theory (1995) and the book, *The Nurture Assumption*, based on it (1998). Issued just after the writing of our earlier *Handbook* chapter, Harris's essay and book claimed: (a) The effects of parenting on development were, at best, small; (b) the effects of genes on development were strong; and (c) the effect of peer relationships, and especially the peer group, were strong also. At the risk of oversimplification, Harris's ideas can be summarized as follows: First, she criticized research on parenting as being methodologically and substantively flawed. She objected to the claim that parents influence their children because most studies of parenting failed to produce strong effect sizes and were methodologically flawed due to their use of correlational designs rather than of explicitly experimental

methods. Second, in support of her arguments regarding the influence of genes, she appropriately called on findings that point to genetic effects on various aspects of development. Third, Harris's claims about the effects of the peer system were, in part, predicated on the view that young people are driven by an atavistic desire to be part of a group. According to Harris, an important repercussion of these tribal motivations is that young people, in an effort to be part of a group, will change their behavior in response to group norms and expectations.

Thus, it was proposed that once children find themselves outside the home, they take on the norms prevalent in the groups in which they spend their time . . . and, for the most part, those groups comprise other children. Drawing from social psychological perspectives on the significance of group norms (a motivation to "fit in"), in-group biases and out-group hostilities, and social cognitive views of group processes, it was argued that children's identities develop primarily from their experiences in the peer group. Although Harris's (1998) views that parent-child and other dyadic relationships (including friendships) are relatively unimportant for individual development has drawn many criticisms (e.g., Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000), the elements of her thesis that stressed the significance of peer interactions, relationships, and groups for normal and abnormal development provided some vindication to peer researchers. For decades, these researchers have been challenged by theorists, researchers, and policy-makers who have cited the primacy of parenting and the parent-child relationship. With Harris's counterchallenge, a gauntlet was dropped; researchers were called on to address some central questions about the causal roles that genes, biology, family, and peers play in child and adolescent adjustment and maladjustment.

The claims of this book were presented and debated in the review sections of newspapers and magazines and on many "prime time" television programs. The essay managed to win some public praise, typically from people who do not study peer relationships. For good reason, persons who have been advocates of behavioral genetic explanations of a wide variety of social behaviors and personality characteristics (e.g., Pinker, 2002; Rowe, 1995) were supportive of Harris's (1995, 1998) claims of genetic influence. Scholars who study parenting wrote reasoned critiques of Harris's thesis regarding the relative unimportance of parental

socialization (Collins et al., 2000). Perhaps at the writing of the *next* version of this *Handbook* chapter, reliable evidence pertaining to the power of peer group influence will be presented as supporting the provocative thesis proposed by Harris. In the meantime, contemporary research (described later) on the ways in which the composition of peer networks change as a function of children's individual interests and behavioral characteristics may be taken as some evidence of the transactional push-and-pull between individual inclinations and peer group norms.

## PEER INTERACTIONS, RELATIONSHIPS, AND GROUPS: A DEVELOPMENTAL PERSPECTIVE

Children's peer experiences become increasingly diverse, complex, and integrated with development. In some cases, the impetus for these developments rests in children (i.e., changes in interpersonal understanding or interpersonal concerns), while others derive from situational or contextual phenomena (Bierman, 2003). In the following sections, we review many developmental mileposts in the *interactional* (changes in the frequency or forms of specific behaviors), *relational* (changes in qualities of friendships or patterns of involvement in friendships), and *group* (changes in configurations of and involvement in cliques and crowds) levels of children's involvement with other children.

### Infancy and the Toddler Years

Research on the normative development peer interactions and relationships during infancy and toddlerhood has waned during the past decade. Instead, the focus has appeared to shift from normative development to individual differences to the extent that toddlers initiate social interaction and are capable of regulating social and emotional behavior.

#### *Interaction*

Early researchers of children's peer experiences were impressed by what they regarded as the significant social shortcomings in infants. Buhler (1935), for example, reported that prior to the first 6 months of life, babies were oblivious to each other's presence. And it was argued that throughout much of the 1st year infants were interested in each other as objects but not as

social partners with whom the development of a relationship was possible (e.g., Maudry & Nekula, 1939). Such a view appears less often in contemporary readings, but it has not disappeared completely; for example, it has been noted that the peer interactions of infants are diffuse and fragmented. These interactions are seen as illustrating the inability of babies to comprehend the social and cognitive needs, capacities, or zones of proximal development of their age-mates (Hay, 1985).

Infants do have obvious social limitations. Yet, careful observation of infants reveals remarkable strides taken during the 1st year of life. These include (a) the seemingly intentional direction of smiles, frowns, and gestures to their play partners (Hay, Nash, & Pederson, 1983); (b) the careful observation of peers representing a clear sign of social interest (Eckerman, 1979); and (c) the response, often in kind, to their play partner's behaviors (Mueller & Brenner, 1977). During the 2nd year of life, toddlers demonstrate monumental gains in their social repertoires. With the emergence of locomotion and the ability to use words to communicate, interactive bouts become lengthier (Eckerman & Stein, 1990), and toddler play becomes organized around particular themes or games. According to Ross (1982), the typical toddler "game" involves extended and patterned interchanges characterized by the mutual exchange of gaze, the direction of social actions to one another, the production of appropriate responses to these social actions, and the demonstration of turn-taking behaviors. Often, these toddler games are marked by reciprocal imitative acts. Reciprocity of imitation suggests not only that a given child is socially interested in the playmate to the point at which she or he is willing to copy that playmate's behavior but also that she or he is also aware of the partner's interest in him or her (i.e., an awareness of being imitated). Mutual imitation, which increases rapidly during the 2nd year, appears to lay the basis for later emerging cooperative interchanges involving pretense (Howes, 1992).

In summary, social skills in toddlerhood comprise (a) the ability to coordinate behavior with that of the play partner; (b) imitation of the peer's activity and an awareness of being imitated; (c) turn-taking that involves *observe peer—respond to peer—observe and wait—respond to peer* interchange sequences; (d) the demonstration of helping and sharing behaviors; and (e) the ability to respond appropriately to the peer partner's characteristics.

These developments promote more effective social commerce between toddlers and contribute a generally positive affective quality to their interaction (Hay, Castle, Davies, Demetriou, & Stimson, 1999). However, toddler social interaction is also marked by conflict (e.g., Hay, Castle, & Davies, 2000; Hay & Ross, 1982; Rubin, Hastings, Chen, Stewart, & McNichol, 1998). Rubin et al. (1998) found that over 70% of 25-month-old children participated in a conflict situation at least once in a 50-minute laboratory setting. In a comparable setting, Hay and Ross (1982) observed 87% of 21-month-old toddlers engaged in at least one conflict. As such, it appears that conflict is neither infrequent nor limited to a small percentage of toddlers.

Indeed, it appears as if many of those toddlers who frequently instigate conflicts with peers are the most socially outgoing and initiating (National Institute of Child Health and Human Development Early Child Care Research Network, 2001; Rubin et al., 1998). It is also the case that (a) toddlers who lose conflicts are more likely than the initial victor to initiate the immediately subsequent conflict (Hay & Ross, 1982); and (b) toddlers are highly attentive to, and are more likely to imitate and initiate interactions with, highly sociable age-mates (Howes, 1983, 1988). Taken together, these data suggest that during the 2nd year of life, toddlers do display social skills of modest complexity.

### Relationships

It has been demonstrated that toddlers are more likely to initiate play, direct positive affect to, and engage in complex interactions with familiar than unfamiliar playmates (Howes, 1988, 1996). But can familiarity be equated with the existence of a relationship? According to Ross and Lollis (1989), toddlers do develop positive relationships as they become increasingly familiar with one another. Indeed, these toddler relationships allow the observer to predict the sorts of interchanges that will transpire between dyadic partners (Ross, Conant, Cheyne, & Alevisos, 1992). It is the predictability of the quality of interchange that marks a dyad as constituting a friendship.

Ross and colleagues have carried out an elegant series of studies to demonstrate that toddlers can and do develop relationships and that their relationships can be characterized in several different ways. Ross et al. (1992) begin by noting that a relationship may be inferred when:

Neither the characteristic behavior of Child One, nor the behavior that others typically direct to Child Two, nor the independent, additive influences of both factors taken together are sufficient to predict the behavior of Child One to Child Two. In that sense, relationships cannot be derived from the individual characteristics of the participants; the relationship itself influences the interaction between them. (p. 1)

To this end, Ross and colleagues have demonstrated that toddlers develop *reciprocal* relationships, not only by the mutual exchange of positive overtures, but also by agonistic interactions. Positive interactions are directed specifically to those who have directed positive initiations to the child beforehand; conflict is initiated specifically with those who have initiated conflictual interactions with the child beforehand.

To the extent that reciprocal interchanges of positive overtures may characterize particular dyads, it may be said that toddlers do have friendships. Although the terms of reference vary from those of Ross and colleagues, other researchers have proposed that toddlers have "friends." For example, Howes (1988) defined toddler friendship as encompassing the response to a peer's overture at least *once*, the production of at least *one* complementary or reciprocal dyadic exchange, and the demonstration of positive affect during at least *one* such exchange. Vandell and Mueller (1980) identified toddler friends as those who initiated positive social interaction more often with each other than with other potential partners. During the toddler period, friendships, as defined earlier, do exist; however, it is doubtful that they carry the same strength of psychological meaning as the friendships of older children. Nevertheless, these early relationships may lay the groundwork for the establishment and maintenance of friendships throughout the childhood years.

### Groups

Even young toddlers spend much of their time in small groups such as with day-care mates. But there is not much empirical evidence that this level of social organization is salient to, or influential on, these young children. Nevertheless, some authors (e.g., Legault & Strayer, 1991) have observed dominance hierarchies even in small groups of young toddlers, as well as in subsets of children who invest greater attention and interaction to one another than to outside nonmembers. Interestingly, some members of these groups appear

more central to their functioning than others, perhaps illustrating the earliest examples of individual differences in popularity and influence.

### New Directions

Major advances in the study of infants' and toddlers' peer interactions and relationships have derived primarily from examinations of *individual differences* in factors such as sociability, behavioral inhibition, conflict, and the regulation of emotional and behavioral tendencies. Much of this research meshes with the current Zeitgeist in which the study of developmental psychopathology dominates in many quarters. Thus, researchers have discovered that those toddlers who frequently initiate conflict with age-mates, especially those who are unable to regulate their emotions and behaviors, evidence difficulties of an externalizing nature in subsequent years (Hay et al., 2000; Rubin, Burgess, Dwyer, & Hastings, 2003). And those toddlers who evidence fearfulness and wariness when faced with unfamiliarity in social settings evidence difficulties associated with social reticence, shyness, and anxiety as preschoolers (e.g., Rubin, Burgess, & Hastings, 2002) and elementary school children (Reznick et al., 1986). Because the focus appears to be turning primarily in the direction of the development of psychopathology, it is important to note that researchers are beginning to find that early individual differences in cooperative, sharing and helping behaviors presage consequent positive aspects of peer interaction. Thus, for example, Howes and Phillipsen (1998) have demonstrated that toddlers' competent play with peers predicts socially competent activity at 4 years and less maladaptive interactive activity at 9 years. Whether individual differences in the peer interactional tendencies of infants and toddlers predict subsequent social relationship and/or group phenomena is, as yet, unknown.

Another new direction derives from the cross-cultural observation of toddlers. Researchers have recently found that Asian toddlers are more compliant than their North American counterparts (Chen, Rubin, et al., 2003); and Chinese and Korean toddlers appear to be more socially inhibited than Italian and Australian toddlers (Chen et al., 1998; Rubin et al., in press). Why these early differences in social behavior exist is only now being explored. Researchers interested in children's peer relationships would do well to examine whether such early cultural differences predict vari-

ability in the peer acceptance of children who best “match” their respective cultural norms for compliant and socially outgoing behaviors.

## Early Childhood

### Interaction

From 24 months to 5 years, the frequency of peer interaction increases and becomes more complex. Parten (1932) described six social participation categories that purportedly unfolded as stages as children matured. In order of presumed maturity, these categories included: unoccupied behavior, solitary play, onlooker behavior (the child observes others but does not participate in the activity), parallel play (the child plays beside but not with other children), associative play (the child plays and shares with others), and cooperative play (the child engages others in interaction that is well coordinated and defined by a division of labor). From her data, Parten concluded that between the ages of 2 and 5 years, children engage in increasing frequencies of associative and cooperative play and in decreasing frequencies of idle, solitary, and onlooker behavior.

A more critical reading of Parten’s study and subsequent attempts at replication, however, suggests a more complex set of conclusions (e.g., Rubin, Watson, & Jambor, 1978). To begin with, children at all ages engage in unoccupied, onlooking, solitary, parallel, and group activities. Even at 5 years, children spend *less* of their free play time in classroom settings interacting with others than being alone or near others (Rubin et al., 1978). Indeed, the frequency of “parallel” play appears to remain constant from 3-to-5 years (Rubin et al., 1978). Yet, despite its modest placement in Parten’s hierarchy of social participation, parallel play appears to serve as an important bridge to more truly interactive exchanges. More precise, sequential observations of preschool interaction reveal that parallel play often serves as an entrée into more complex, cooperative activity (Robinson, Anderson, Porter, Hart, & Wouden-Miller, 2003). Put another way, competent entry into ongoing peer activity appears to involve the ability to observe what the play participants are doing (onlooking activity), to approach and play beside potential play partners (parallel play), and, finally, to engage the players in conversation about the ongoing activity. A simple consideration of the frequency of particular forms of social participation

masks the functional significance of the behavior. Watching and playing near, but not with, others are not necessarily immature. Rather, these behaviors may be sequenced in a competent manner to gain entry into an ongoing play activity.

Further attesting to the limits of Parten’s original social participation categories is the fact that the categories of solitary, parallel, and group behavior comprise a variety of play forms that differ in cognitive complexity (see Rubin, Fein, & Vandenberg, 1983, for a review). Thus, whether alone, near, or with others, children may produce simple sensorimotor behaviors (*functional play*, e.g., aimlessly bouncing a ball), construct structures from blocks or draw with crayons (*constructive play*), or engage in some form of pretense (*dramatic play*). These cognitive forms of play, when examined in their social context, reveal interesting developmental trends. For example, solitary-sensorimotor behaviors become increasingly rare over the preschool years, while the relative frequency of solitary-construction or exploration remains the same (Rubin et al., 1978). Furthermore, the only types of social interactive activity to increase over the preschool years are sociodramatic play and games-with-rules (see Goncu, Patt, & Kouba, 2002, for a recent review): Age differences are apparent only for particular forms of social participation. Thus, in contrast to Parten’s characterization, it does not appear to be a simple matter of solitary play disappearing over time and being replaced by social interactive activity. Importantly, it is the *form* that solitary or parallel or social activity takes that is of developmental significance.

Perhaps the most complex form of group interactive activity during the preschool years is *sociodramatic play* (Goncu et al., 2002). The ability to engage easily in this form of social activity represents mastery of one of the essential tasks of early childhood—the will and skill to share and coordinate decontextualized and substitutive activities. Researchers have reported that by the 3rd year of life, children are able to share symbolic meanings through social pretense (e.g., Howes, 1988). This is a remarkable accomplishment, as it involves the capacity to take on complementary roles, none of which matches real-world situations, and to agree on the adoption of these imaginary roles in a rule-governed context.

The ability to share meaning during pretense has been referred to as *intersubjectivity* (Goncu, 1993). Goncu (1993) has reported that quantitative differences are present in the extent to which the social interchanges

of 3- versus 4.5-year-olds comprise indices of shared meaning or intersubjectivity. For example, the social interactions of older preschoolers involve longer sequences or turns. With increasing age, play partners become better able to agree with each other about the roles, rules, and themes of their pretense. They are also better able to maintain their play interactions by adding new dimensions to their expressed ideas. These developments reflect the preschooler's capacity to take the perspective of the play partner and, even more important, reflect the increasing sophistication of preschooler's naive "theory of mind" (Watson, Nixon, Wilson, & Cagape, 1999).

The demonstration of elaborate forms of social pretense during the preschool years is impressive. But is the experience of sociodramatic play developmentally significant? According to Howes (1992), sociodramatic play serves three essential developmental functions. First, it creates a context for mastering the communication of meaning. Second, it provides opportunities for children to learn to control and compromise; these opportunities arise during discussions and negotiations concerning pretend roles and scripts and the rules guiding the pretend episodes (Sawyer, 1997). Third, social pretense allows for a "safe" context in which children can explore and discuss issues of intimacy and trust. Researchers have demonstrated that engaging in sociodramatic play is associated with social perspective-taking skills and the display of skilled interpersonal behavior.

In summary, as pretend play becomes more interactive, it serves increasingly sophisticated psychological functions. At first, social pretense provides opportunities for developing communication skills (Sawyer, 1997). Subsequently, it allows children opportunities to negotiate over roles, rules, and play themes and to practice a variety of roles in particular play scripts (Goncu, 1993). Thus, the addition of understanding pretense and sharing this understanding with others represents a significant milestone in the social lives of young children.

Beyond the developmental differences in how much children interact with one another or engage in cooperative endeavors requiring shared meanings, several other significant advances are made during the preschool period. For one, prosocial caring, sharing, and helping behaviors become more commonplace with increasing age. Researchers have demonstrated that 4-year-olds direct prosocial behavior to their peers more often than 3-year-olds (e.g., Benenson, Markovits, Roy, & Denko, 2003).

And the disposition to behave in a caring, sharing, and helpful manner in early childhood appears rather stable (Eisenberg et al., 1999). Dodge, Coie, & Lynam (Chapter 12, this *Handbook*, this volume) note that aggression increases until age 3 and then declines.

Importantly, the nature of conflict changes from the toddler to the preschool period. During toddlerhood, most conflict appears to center on toys and resources; during the preschool years, conflict becomes increasingly centered on differences of opinion (Chen, Fein, & Tam, 2001; Laursen & Hartup, 1989)—a reflection of the child's growing ability to focus on others' ideas, attitudes, and opinions.

Finally, preschoolers spend a great deal of time simply conversing with their playmates. And their conversations reflect numerous interpersonal goals (e.g., negotiating roles and rules in play; arguing and agreeing; Hay et al., 2004). Older preschool-age children direct more speech to their peers than do their younger counterparts (Levin & Rubin, 1983). And they are more likely to try to make explicit communicative connections with their play partners' ideas (Goncu, 1993; Sawyer, 1997). However, the successful outcome of verbally directed communication is predicted by its technical quality. Preschoolers whose language is comprehensible, who assure that they have obtained listener attention, and who are within arms' length of their social targets are more likely to meet their social goals than those who verbal directives are less skillfully evinced (Mueller, 1972). Relatedly, throughout the preschool years, children demonstrate age-related increases in social-communicative competence. For example, they begin to alter their speech to suit the needs of their listeners (Shatz & Gelman, 1973). Similar adjustments to the characteristics of their social targets have been reported in studies of interpersonal problem solving overtures (Krasnor & Rubin, 1983). These data reflect developmental growth in metacommunicative awareness and "mind-reading" (Dunn, 1999).

Taken together, the data reviewed earlier raise questions concerning Piaget's assumption that the speech of preschoolers is characterized primarily by its socially egocentric quality. Indeed, approximately 60% of preschoolers' utterances are socially directed, comprehensible, and result in appropriate responses (Levin & Rubin, 1983; Mueller, 1972). Furthermore, it has been shown that young children recognize when their verbal repertoires are limited and, in such circumstances, will resort to the use of gestures to communicate meaning

(e.g., Sawyer, 1997). Studies of gestural communication actually shed light on Piaget's original ideas concerning egocentric thought and speech. Piaget recognized the significance of gestural communication and wrote that in the explanations of young children, "gestures play as important a part as words." (Piaget, 1959, p. 77). It may well be that Piaget's "take" on communicative competence has been poorly understood, or at best, misjudged. In Piaget's own research, he indicated that only 35% to 40% of young children's utterances were "egocentric." This leads to the conclusion that in almost 60% of the cases, young children demonstrated communicative competence. If one were to add to *verbal* expression the comprehensible use of gestures, preschoolers would clearly be regarded as communicatively skilled.

### Relationships

During early childhood, children express preferences for some peers over others as playmates. It appears that one important influence on this process is that preschoolers are attracted to peers who are similar to them in some noticeable regard. For example, similarities in age and sex draw young children together. Furthermore, preschoolers appear to be attracted to, and become friends with peers whose behavioral tendencies are similar to their own, a phenomenon known as *behavioral homophily* (e.g., Kandel, 1978; Ryan, 2001).

Once preschoolers form friendships, their behavior with these individuals is distinctive from their behavior with other children who are familiar but not friends. Among the features that mark the friendships of preschool-age children are supportiveness and exclusivity (Sebanc, 2003). Children as young as 3.5 years direct more social overtures, engage in more social interactions, and play in more complex ways with friends than nonfriends (e.g., Dunn & Cutting, 1999; Dunn, Cutting, & Fisher, 2002). As well, preschool-aged friends tend to cooperate and exhibit more positive social behaviors with each other than with nonfriends (e.g., Dunn et al., 2002). Ladd, Kochenderfer, and Coleman (1996) have shown that not all friendships in early childhood are equally stable. Those friendships that involve higher levels of positive friendship qualities (e.g., validation) and lower levels of negative friendship qualities (e.g., low conflict) are most likely to be stable.

Typically, researchers who study friendship rely on children as informants about with whom they are friends. It has been argued that a "true" friendship is

one that relies on friendship nominations from *both* dyadic partners; a unilateral, nonreciprocated friendship has often been taken to mean "wishful thinking" on the part of the single nominator. In keeping with this perspective, Vaughn (2001) recently reported that (a) older preschoolers are more likely to participate in reciprocated friendships than are younger preschoolers; (b) preschoolers who nominate each other as friends interact more frequently with each other than those dyads in which only a unilateral nomination of friendship is evinced.

Importantly, not all young children have a best friend. Approximately 75% of preschoolers have reciprocally nominated best friendships (Dunn, 1993). Friendless preschoolers are less likely than befriended children to initiate and maintain play with peers (e.g., Howes, Matheson, & Wu, 1992). And during this period of early childhood, the ability to make friends, friendship quality, and stability of young children's friendships are associated with, and predicted by, social-cognitive and emotional maturity. For example, the abilities to understand emotional displays and social intent and to perspective-take are associated with friendship formation, maintenance, and friendship quality (Dunn & Cutting, 1999; Dunn et al., 2002; Ladd & Kochenderfer, 1996). Furthermore, the young child's ability to regulate emotions is associated with and predictive of both the number of mutual friends and friendship quality (Walden, Lemerise, & Smith, 1999).

It is not only the positive aspects of behavior that differentiate preschool friendships from nonfriendships—compared to nonfriends, preschool friends also demonstrate more quarreling and more active (assaults and threats) and reactive hostility (refusals and resistance; Dunn & Cutting, 1999; Laursen & Hartup, 1989). Moreover, Hartup and his colleagues (Hartup, Laursen, Stewart, & Eastenson, 1988) demonstrated that preschool children engage in more conflicts with their friends than with neutral associates. These differences are best understood by recognizing that friends spend much more time actually interacting with each other than do nonfriends. Hartup and his colleagues also reported qualitative differences in how preschool friends and nonfriends resolve conflicts and in what the outcomes of these conflicts are likely to be. Friends, as compared with nonfriends, make more use of negotiation and disengagement, relative to standing firm, in their resolution of conflicts. In conflict outcomes, friends are more likely to have equal resolutions, relative to win or

lose occurrences. Also, following conflict resolution, friends are more likely than neutral associates to stay in physical proximity and continue to engage in interaction.

In summary, preschoolers behave differently with friends than nonfriends. Preschoolers engage in more prosocial behaviors as well as more conflicts when interacting with friends than with nonfriends. These conflicts are most likely to be resolved through negotiation, and the outcomes are usually equitable. These differences suggest that preschoolers view friendship as a unique context, separate and qualitatively different from their experiences with nonfriends.

### **Groups**

Many researchers have found that the social dominance hierarchy is an important organizational feature of the preschool peer group (e.g., Hawley, 2002; Vaughn, 1999; Vaughn, Vollenweider, Bost, Azria-Evans, & Snider, 2003). And, in keeping with a central tenet of the ethological perspective, researchers have argued that dominance hierarchies develop naturally in groups to serve adaptive functions. In the case of preschool-aged children, dominance hierarchies appear to reduce overt aggression among members of the group. Observations of exchanges between children in which physical attacks, threats, and object conflicts occur reveal a consistent pattern of winners and losers. And children who are losers in object struggles rarely initiate conflict with those who have proven “victorious” over others or who have been victorious over them (Strayer & Strayer, 1976).

### **Summary**

Even in early childhood, one can identify children who are more or less skilled in manipulating their peers or in meeting their interpersonal goals. Dominance hierarchies reflect primarily differences in children’s success in struggles over objects. However, achieving the acquisition of desired objects is only one of many interpersonal goals that preschool children may have. Consequently, it remains unknown whether preschool children who have risen to the top of the preschool dominance hierarchy are those who develop and maintain positive relationships with their peers, not only in preschool, but thereafter as well.

As noted earlier, new statistical techniques are now allowing researchers to examine the quantity, composition, and stability of networks in the peer group. In a series of studies, van den Oord and colleagues demon-

strated that, as early as the preschool period, children’s groups comprise individuals who are behaviorally similar (van den Oord, Rispens, Goudena, & Vermande, 2000; Vermande, van den Oord, Rispens, & Goudena, 2000). Aggression is the most important determinant of social clustering in the preschool classroom: A researcher can best predict the peer group composition for aggressive children—a finding that repeats itself in older groups of children (see following).

### **Middle Childhood and Early Adolescence**

The school-age years represent a dramatic shift in social context for most children in Western cultures. During this time, the proportion of social interaction that involves peers increases. Whereas approximately 10% of the social interaction for 2-year-olds involves peers, the comparable figure for children in middle childhood is more than 30%. Other changes include: the size of the peer group (which becomes considerably larger) and how peer interaction is supervised (it become less closely supervised by adults). Thus, in the years leading up to adolescence, children are brought into contact with a more diverse set of peers, although generally with those who are similar to them in age.

The settings of peer interaction also change. Preschool children’s peer contacts are centered in the home and in day-care centers, whereas school-age children come into contact with peers in a wide range of settings. Although the settings for peer interaction in middle childhood have not been well described, there are some key studies. Zarbatany, Hartmann, and Rankin (1990) reported that the most frequent contexts for peer interaction, among middle class young adolescents include, in order of their frequency, conversing, “hanging out,” being together at school, talking on the telephone, traveling to and from school, listening to TV and records, and noncontact sports. Boys and girls differed on only one of these activities—more peer interaction took place during phone conversations for girls than for boys. In terms of their perceived *importance*, this sample of early adolescents viewed noncontact sports, watching TV or listening to records, conversing, talking on the telephone, physical games, parties, and “hanging out” as the most important contexts for peer interaction. An important aspect of this research is that these contexts were associated with different types of peer interaction. Noncompetitive activities facilitated socializing and the development of relationships, whereas competitive ac-

tivities provided opportunities for identifying unique aspects of the self. According to Zarbatany et al. (1990), the full range of activities is necessary for early adolescents to derive broad benefits from peer experiences.

### Interaction

During middle childhood, verbal and relational aggression (insults, derogation, threats, gossip) gradually replace direct physical aggression. Further, relative to preschoolers, the aggressive behavior of 6- to 12-year-olds is less frequently directed toward possessing objects or occupying specific territory and more specifically hostile toward others (Dodge, Coie, & Lynam, Chapter 12, this *Handbook*, this volume). With regard to positive social behavior, Eisenberg, Fabes and Spinrad (Chapter 11, this *Handbook*, this volume) report the levels of generosity, helpfulness, or cooperation that children direct to their peers increases somewhat during the primary and middle school years.

The frequency of “pretend” or “nonliteral” aggression, or R&T play fits a U-shaped developmental function (Pellegrini, 2002). Rough-and-tumble play comprises approximately 5% of preschoolers’ social activities. In early elementary school, the frequency of R&T ranges from 10% to 17%, thereafter declining in middle childhood and early adolescence to 5% (Humphreys & Smith, 1987). Interestingly, it has been proposed that the primary function of R&T, especially among early adolescent boys, is to establish dominance status and thereby delimit aggression among peers (Pellegrini, 2002). Finally, by middle childhood, increases are found in the frequencies of games with or without formal rules. In these latter activities, children’s interactions with peers are highly coordinated, involving both positive (cooperative, prosocial) and negative (competitive, agonistic) forms of behavior.

Children’s concerns about acceptance in the peer group rise sharply during middle childhood, and these concerns appear related to an increase in the salience and frequency of *gossip* (Kuttler, Parker, & La Greca, 2002). Gossip, at this age, reaffirms children’s membership in important same-sex social groups and reveals, to its constituent members, the core attitudes, beliefs, and behaviors comprising the basis for inclusion in or exclusion from these groups. Thus, gossip may play a role in fostering friendship closeness and in promulgating children’s social reputations. Kuttler et al. (2002) recently reported that preadolescents label most talk about a non-present other as gossip and consider it to be inappropriate,

are more skeptical of gossip than of first-hand information, and are likely to assume that gossipers spread false information out of jealousy.

Two additional forms of interaction have received specific attention in the recent literature. Dishion, McCord, and Poulin (1999) coined the term *deviancy training* to refer the processes of praise, encouragement, imitation, and expectancy by which children increase the level of *aggression* or *antisocial behavior* in their peers. Essentially, deviancy training occurs when children model and reward aggressive behaviors in each other; the process by which these exchanges take place is thought to increase individual tendencies in aggressiveness and to strengthen ties to aggressive and substance-abusing friends and delinquent peer groups. In this regard, deviancy training “hits” at all levels of the social enterprise.

A form of interaction that affects *internalizing* problems has been identified also. Rose (2002) has shown that in the interactions of close friends, especially in the friendships of early adolescent girls, there can be a pattern of interaction described as “co-rumination” in which negative thoughts and feelings are shared and discussed. This joint focus on worries and negative experiences appears more often in the friendships of young adolescent girls than boys and is associated with internalizing problems for 12- to 14-year-olds, but not for 8- to 10-year-olds. Ruminative thoughts in individuals and shared rumination among peers may play a role in sustaining or exacerbating problems of an internalizing nature, thus this topic seems ripe for additional study.

Yet another form of interaction emerging fully blown during middle childhood and early adolescence is *bullying* and *victimization* (Espelage, Bosworth, & Simon, 2000). Bullying refers to acts of verbal and physical aggression on the part of an individual that are chronic and directed toward particular peers (victims). Bullying accounts for a substantial portion of the aggression that occurs in the peer group (Olweus, 1978, 1993). The dimension that distinguishes bullying from other forms of aggressive behavior is its specificity—bullies direct their behavior toward only certain peers, comprising approximately 10% of the school population (National Institute of Child Health and Human Development Early Child Care Research Network, 2001; Olweus, 1984). Research on bullying suggests that bullies are characterized by strong tendencies toward aggressive behavior, relatively weak control over their aggressive impulses,

and a tolerance for aggressive behavior (1978, 1993). Further, Perry, Perry, and Kennedy (1992) noted that bullies are most likely to use force unemotionally and outside of an ongoing flow of conflict or interaction. Also, bullies generally do not experience much resistance to their aggressive acts.

Children who are greatest risk for victimization are those who have elevated scores on measures of aggression or social withdrawal. Nearly every study that has assessed the association between aggressiveness and victimization has revealed a positive correlation (e.g., Camodeca, Goossens, Terwogt, & Schuengel, 2002; Hanish & Guerra, 2004; Hodges, Malone, & Perry, 1997; Snyder et al., 2003). These findings appear to be culturally universal; thus victimization and aggression have been found to be positively associated in North American, Southern Asian (Khatri & Kupermidt, 2003) and East Asian (Schwartz, Farver, Chang, & Lee-Shin, 2002) samples. When bullies direct their aggression to other aggressive children, it facilitates a transactional relationship that appears to facilitate the stability of aggression in the bully victim partners (Camodeca et al., 2002; Kochenderfer & Ladd, 1997; Kochenderfer-Ladd 2003). Finally, there is evidence that anxious and socially reticent children are victims of bullying behavior (Hanish & Guerra, 2004; Kochenderfer-Ladd 2003; Olweus, 1993).

As implied by Graham and Juvonen (2001) and Schafer, Werner, and Crick (2002), victimization may occur at multiple levels of social complexity, such as the dyad (Crick & Nelson, 2002) or the group (Bukowski & Sippola, 2001). There are at least two explanations for the observation that aggression and social withdrawal are associated with victimization. One explanation notes that a withdrawn child is likely to be victimized because she or he is an easy and nonthreatening prey who is unlikely to retaliate when provoked (e.g., the construct of “whipping boy”; Olweus, 1978, 1993); alternatively, an aggressive child is victimized because his or her behavior is irritating and likely to provoke victimization from others (“the provocative victim”; Hodges et al., 1997; Olweus, 1993). According to this view different mechanisms underlie victimization for different types of children. Another view uses a single model to explain victimization. It claims that children victimize peers who do not promote the basic group goals of coherence, harmony, and evolution. According to this view, aggressive and withdrawn children do not

promote these positive aspects of group functioning and as a result they are victimized.

### *Relationships*

The period of middle childhood and early adolescence brings marked changes in children’s understanding of *friendship*. To chart these changes, researchers have asked children questions such as “What is a best friend?” or “What do you expect from a best friend?” (Bigelow, 1977). Although children of all ages indicate that a reciprocal “giving-and-taking” is necessary for friendship (Hartup & Stevens, 1997), researchers have shown that young children’s conceptions of a friend are anchored in the here and now, and not easily separated from social activity itself. Early school-age children have friendship concepts that transcend any specific activity, and imply the continuity of relationships over time. Nevertheless, during the early school years, children can still be instrumental and concrete in what they view as a friendship or appropriate friendship behavior. For example, Bigelow’s (1977) findings show that children’s friendship conceptions at the start of middle childhood (7 to 8 years) involve rewards and costs—friends are individuals who are rewarding to be with, whereas nonfriends are individuals who are difficult or uninteresting to be with. For children of this age, a friend is someone who is convenient (i.e., who lives nearby), has interesting toys or possessions, and shares the child’s expectations about play activities. This conception evolves during middle childhood and early adolescence. By about 10 to 11 years, children recognize the value of shared values and shared social understanding. Friends at this age are expected to stick up for and be loyal to one another. Later, at 11 to 13 years, children acquire the view that friends share similar interests, are required to make active attempts to understand each other, and are willing to engage in self-disclosure.

According to Berndt (1996), children do not abandon initial notions about play and mutual association when they eventually recognize the importance of intimacy and loyalty. In support of this view, school-age children’s drawings of their friends show clearly that friends are perceived as being similar to each other in many observable ways while at the same time, they show their loyalty and closeness to each other (Pinto, Bombi, & Cordoli, 1997). Moreover, even school-age children appear to recognize that while friends may share objective experiences in their friendships they may be differ-

ent from each other in their subjective experiences (Little, Brendgen, Wanner, & Krappman, 1999).

Children draw sharper distinctions between the supportiveness of friends and nonfriends with increasing age (Berndt & Perry, 1986). Moreover, children's descriptions of their friendships indicate that loyalty, self-disclosure, and trust increase with age (Berndt, 2002), although these trends are more likely to be observed in girls than in boys (Berndt & Perry, 1986; Strough, Swenson, & Cheng, 2001). Older children of both sexes also possess more intimate knowledge of their friends, describe their friends in a more differentiated and integrated manner, and see their friendships as more exclusive and individualized (Berndt, 2002; Smollar & Youniss, 1982).

Significantly, there is little cross-cultural research on children's *understanding* of friendship. Keller (2004a) has recently questioned whether the notion of emotional intimacy that so characterizes friendship in Western cultures during the later years of childhood and beyond is also typical in non-Western societies. She notes that in some cultures, especially in those that have subsistence economies, a primary function of friendship is instrumental aid and not emotional support (see also Beer, 2001). Moreover, in comparing such Western countries as Germany and the United States with non-Western China, Keller found that children in that latter culture emphasized moral issues and the importance of altruism in their understanding of close friendships. Children in the Western countries were more likely to emphasize relationship intimacy (Keller, 2004b). Given these significant differences in conceptions of friendship, it behooves researchers to examine cultures beyond those investigated by Keller and colleagues. Indeed, it would seem important to study within-cultural/ethnic differences as well (e.g., Way & Chen, 2000).

Changes in the understanding of friendship are accompanied by changes in the patterns and nature of involvement in friendships across middle childhood. Children's friendship choices are more stable and more likely to be reciprocated in middle childhood than at earlier ages, although it is not clear that either the reciprocity or stability of friendship increases during middle childhood (Berndt & Hoyle, 1985). *Stability* of friendships is thought to derive from the positive qualities of, and the positive interactions between, children. Friendships that are high in relationship quality are more likely to persist over time (Berndt, 2004), and this

is also true in early childhood. For example, Ladd, Kochenderfer, and Coleman (1996) found higher levels of positive friendship qualities (e.g., validation) and lower levels of negative friendship qualities (e.g., low conflict) in stable friendships of kindergarteners, relative to unstable friendships. Furthermore, stable friendships in middle childhood and early adolescence are more likely to comprise dyads in which the partners are sociable and altruistic; friendships that dissolve during the course of a school year are more likely to comprise partners who are aggressive and victimized by peers (Hektner, August, & Realmuto, 2000; Wojslawowicz, Rubin, Burgess, Booth-LaForce, & Rose-Krasnor, in press). In addition, children's liking for, and friendship involvement with, *opposite-sex* peers drops off precipitously after 7 years of age (Leaper, 1994).

Friendship dissolution may have a serious impact on children's adjustment. For example, disruptions of close peer relationships have been associated with depression, loneliness, physiological dysregulation, guilt, and anger (e.g., Laursen et al., 1996; Parker & Seal, 1996). In addition, friendship loss in *preadolescence* (typically defined as the late years of middle or junior high school) may be particularly painful, due to the special role of friends' loyalty during this developmental period (Buhrmester & Furman, 1987). Recently, for example, Wojslawowicz et al. (in press) reported that 10- and 11-year-old children who had a best friend at the beginning of the school year but who lost that friendship and failed to replace it by the end of the school year were at increased risk for victimization by peers. Thus, it may be that if a dissolved best friendship is not replaced, the "advantages" of once having a best friend may quickly vanish.

Significantly, researchers have found that the lack of a best friendship, whether at a given point in time or chronically, can be accompanied by numerous risks. Friendless children are more likely to be lonely and victimized by peers (Boulton, Trueman, Chau, Whitehand, & Amatya, 1999; Brendgen, Vitaro, & Bukowski, 2000; Kochenderfer & Ladd, 1997). *Chronic friendlessness* during childhood has been associated contemporaneously with social timidity, sensitivity, and the lack of social skills (Parker & Seal, 1996; Wojslawowicz et al., in press), and predictively with subsequent internalizing problems (Ladd & Troop-Gordon, 2003). Relatedly, investigators have demonstrated that friendship can be an important buffer for children; for example, Hodges and colleagues (Hodges, Boivin, Vitaro, & Bukowski,

1999) found that peer victimization predicted increases in internalizing and externalizing problems during the school year *only* for those children who lacked a mutual best friendship.

The protective function ascribed to friendship is consistent with the view that close relationships function as security systems (e.g., Sullivan, 1953). Hodges, Malone, and Perry (1997), for example, showed that children who are at risk for victimization because of their own personal characteristics (i.e., being aggressive and/or withdrawn) are less likely to experience victimization in the peer group if they are also befriended rather than friendless. In such studies, it is argued that individual differences in victimization are associated with personal characteristics but that these associations are heightened by the lack of a friendship.

With respect to the *features* of children's friendships in middle childhood and early adolescence, Newcomb and Bagwell (1995) reported that children are more likely to behave in positive ways with friends than nonfriends or to ascribe positive characteristics to their interactions with friends. Although the effect size of this difference may, in some cases be small (Simpkins & Parke, 2002), this pattern of findings is observed across a broad range of studies using a variety of methods, including direct observations (e.g., Simpkins & Parke, 2002), interviews (Berndt, Hawkins, & Hoyle, 1986), and hypothetical dilemmas (Rotenberg & Slitz, 1988). More important, Newcomb and Bagwell's (1995) meta-analysis showed that the expression of affect varied considerably for pairs of friends and nonfriends during middle childhood and early adolescence. In their interactions with friends, relative to interaction with nonfriends, children show more affective reciprocity and emotional intensity, and enhanced levels of emotional understanding. Moreover, young adolescent friends use distraction to keep their friends from potentially harmful rumination about social attributions that may induce guilt or shame (Denton & Zaratany, 1996). In this regard, friendship is a socially and positive relational context, and it provides opportunities for the expression and regulation of affect (Salisch, 2000). Consistent with the aforementioned views of Sullivan (1953), it has been found that these friend-nonfriend differences are stronger during early adolescence than during either middle childhood or during the preschool years.

One of the few dimensions of interaction in which there are no differences between friends and non-

friends is that of *conflict*. Research has shown repeatedly that after early childhood, pairs of friends engage in about the same amount of conflict as pairs of nonfriends (Laursen et al., 1996). There is, however, a major difference in the conflict resolution strategies that friends and nonfriends adopt. Friends are more concerned about achieving an equitable resolution to conflicts. More specifically, researchers report that friends are more likely than nonfriends to resolve conflicts in a way that will preserve or promote the continuity of their relationship (see Laursen et al., 2001, for a recent review). Consistent with these findings, friendship motives related to conflict resolution have been observed to be associated with lower levels of anger and more constructive forms of behavior (B. Murphy & Eisenberg, 2002). However, the beneficial effects of friendship are qualified by the characteristics of the best friend: Young adolescents with aggressive friends, compared with those who have nonaggressive friends, adopt increasingly aggressive solutions to social conflicts; young adolescents who are nonaggressive and who have nonaggressive friends use more prosocial solutions to conflicts (Brendgen, Bowen, Rondeau, & Vitaro, 1999). In this respect, experience in a best friendship is linked to the development of social competence; in the best friendship, children and adolescents show a concern for a balance between individual and communal goals.

There appear to be consistent *qualitative* differences in boys' and girls' best friendships in the middle childhood and early adolescent years. For example, the friendships of girls are marked by greater intimacy, self-disclosure, and validation and caring than those of boys (Leaper, 1994; Rubin, Dwyer, et al., 2004; Zaratany, McDougall, & Hymel, 2000). Ironically, it is because of the intimacy of girls' best friendships that they appear to be less stable and more fragile than those of boys (Benenson & Christakos, 2003; Hardy, Bukowski, & Sippola, 2002). Males' best friendships are characterized by physical activities that do not require the exchange of personal information. According to Benenson and Christakos, intimate disclosure between female friends may become hazardous when best friends have a conflict. In such cases, the conflicting friends can divulge personal information to outsiders (Crick & Grotpeter, 1995). Moreover, girls' close friendships are more likely to occur in isolation, whereas boys' friendships are more likely to occur in a larger social network (Baumeister & Sommer, 1997). Conflict resolution may

be aided by third party mediators and allies in the larger group context.

As noted earlier, girls also report more co-rumination (e.g., negative dwelling on emotionally charged and intimate everyday occurrences and feelings), in their friendships than do boys (Rose, 2002). Significantly, when children's peer activities are marked by communal rather than competitive/agentive activities, friendship intimacy is higher. And when boys' best friendships are with girls rather than boys, intimacy is higher, thus suggesting that there may be two different "worlds" of relationships defined by context and activity (Zarbatany et al., 2000).

Thus far we have examined how children think about friendship and how they interact when with their best friends. We have also described the stability of best friendships during the middle childhood/early adolescent period. But who is it that children are attracted to? And with whom do they form best friendships? Just as is the case with young children, older children and young adolescents are drawn to others who are like them. Throughout this age period, children are attracted to and become best friends with those who resemble them in age, sex, ethnicity, and behavioral status (Hartup & Abecassis, 2002). For example, it has been reported that children and young adolescents are attracted to peers whose behavioral tendencies are similar to their own (Rubin, Lynch, Coplan, Rose-Krasnor, & Booth, 1994). Hamm (2000), for example, showed that similarity on a particular dimension varied across children largely due to the importance the child ascribed it. Similarity to their friend on academic performance was highest among children who saw academic performance as important.

Researchers in both Western and Eastern cultures have reported that greater behavioral similarities exist between friends than nonfriends, and children share friendships with other children who resemble themselves in terms of prosocial and antisocial behaviors (e.g., Haselager, Hartup, van Lieshout, & Riksen-Walraven, 1998; Liu & Chen, 2003; Poulin & Boivin, 2000), shyness and internalized distress (e.g., Hogue & Steinberg, 1995; Rubin, Wojslawowicz, Burgess, Booth-LaForce, & Rose-Krasnor, in press), sociability, peer popularity, and academic achievement and motivation (Altermatt & Pomerantz, 2003; Liu & Chen, 2003). Children also dislike those who are different from themselves and terminate relationships with those who are behaviorally unlike themselves (Poulin

& Boivin, 2000). As Hartup and Abecassis (2002) put it: "No evidence exists to suggest that opposites attract" (p. 291).

Finally, as noted earlier, researchers have begun to study enmity and mutual antipathies. Abecassis et al. (2002) have shown that rates vary across classrooms, with the frequencies of dyadic enmity being as high as 58% in some classrooms. Although mutual antipathies are experienced by all children, they are most common among rejected children and they are more common among boys than girls, especially during middle childhood compared with adolescence (Rodkin & Hodges, 2003). But it is important to note that enmity is not simply due to elevated levels of rejection. The specific characteristics of particular pairs of "enemies" appear to be connected to attachment-related experiences (Hodges & Card, 2003). Children whose attachment-related coping styles are incompatible (e.g., one has an avoidant style and the other is preoccupied) are more likely to become enemies than are other children.

The developmental significance of mutual antipathies is unclear. Children in such relationships tend to be more depressed than are other children, and the presence of a mutual antipathy appears to exacerbate the effect of other negative experiences. Nevertheless, participating in the process of mutual disliking may be one means by which young people develop a clearer sense of self as they identify the characteristics that they like and dislike in others.

Many issues related to the study of mutual antipathies require further exploration. Perhaps the most important concerns the issue of how we define and measure the concept of enemy. Just as mutual liking is simply the minimum criterion for friendship, mutual disliking must be considered the minimum criterion for the presence of enmity. To paraphrase the important discussions provided by Hartup and Abecassis (2002), having an enemy implies warfare. Consequently, researchers would do well to examine whether children who nominate each other as "Someone I do not like," actually interact. It may be that mutual antipathies merely capture an affective dimension, not an interactional one. "True" enemies may be proactive about their relationship. They may spread gossip about one another and engage in relational or other forms of aggression. They may be members of different identifiable groups, each of which exclude the other (research on peer exclusion may be particularly relevant, e.g., Horn, 2003; Killen &

Stangor, 2001; Killen, Stangor, Horn, & Sechrist, 2004; Killen et al., 2002). At present, there are virtually no data indicating how and whether those who mutually nominate each other as "Someone I do not like" actually have a clearly defined relationship. As a result, researchers must be careful about how they define and measure the presence of enmity.

### Groups

During the upper elementary school and middle school years, the structure of the peer group changes from a relatively unified whole to a more differentiated structure. In this new structure, children organize themselves into social groups, clusters, networks, or cliques (Bagwell, Coie, Terry, & Lochman, 2000; Degirmencioglu, Urberg, Tolson, & Richard, 1998). Peer networks and cliques are voluntary, friendship-based groups, and stand in contrast to the activity or work groups to which children can be assigned by circumstance or by adults. Cliques generally include three to nine same-sex children of the same race (Chen, Chang, & He, 2003; Kindermann, McCollom, & Gibson, 1995). By 11 years of age, children report that most of their peer interaction takes place in the context of the clique, and nearly all children report being a member of one.

With respect to group size, boys, compared with girls, show a preference for larger groups (Benenson, Apostoleris, & Parnass, 1997). It may be that this sex difference has functional significance. Specifically, interaction in smaller groups is less likely than experience in large groups to promote competitiveness and self-criticism (Benenson, Nicholson, Waite, Roy, & Simpson, 2001). Because girls are more likely than boys to have experience in small groups, they may have fewer experiences with competition than boys have. This difference could explain why girls tend to be less competitive than boys (Roy & Benenson, 2002) and why they feel less comfortable with competition (Benenson et al., 2002). This avoidance of competition in favor of more egalitarian strategies may explain why girls experience greater fragility in their same-sex friendships (Benenson & Christakos, 2003).

Peer networks, whether identified observationally (e.g., Gest, Farmer, Cairns, & Xie, 2003) or via peer reports (e.g., Bagwell et al., 2000), or whether identified in or out of school (Kiesner, Poulin, & Nicotra, 2003), are typically organized to maximize within-group homogeneity (Rodkin, Farmer, Pearl, & Van Acker, 2000).

Thus, in recent studies of preadolescents conducted in both Western (e.g., Canada, Finland, United States) and Eastern (e.g., China) cultures, group membership has been found to comprise children similar with regard to the following characteristics: aggression (Espelage et al., 2003; Gest et al., 2003; Kiesner et al., 2003; Xie et al., 1999), bullying (e.g., Salmivalli, Huttunen, & Lagerspetz, 1997), attitudes about bullying (Espelage et al., 2003; Salmivalli & Voeten, 2004), and school motivation and performance (e.g., Chen et al., 2003; Kindermann, 1993; Liu & Chen, 2003; Ryan, 2001; Sage & Kindermann, 1999).

Apart from cliques, the other primary organizational feature of children's groups in middle childhood and early adolescence is the popularity hierarchy. There have been recent attempts to distinguish between *sociometric* popularity and *perceived* popularity. In the case of sociometric popularity or peer acceptance, the questions asked of children are "Who do you most like?" and "Who do you most dislike?" (see following for details about assessment). In the case of perceived popularity, the child is asked who he or she believes is the most popular in the classroom, grade, or school (Parkhurst & Hopmeyer, 1998; LaFontana & Cillessen, 1998, 2002). Unwittingly, these efforts follow Northway's (1946) assertion that being accepted and being popular are different phenomena that have different antecedents and different consequences. Whereas being liked or accepted occurs at the dyadic level (i.e., one person has affection for someone else), the perception of someone as being popular in a classroom or school reflects a group level of analysis (i.e., the person is perceived according to her/his position in the group). Thus, in the study of peer group relationships, the word (and traditional measurement of) *acceptance* is most properly taken as a direct assessment of the extent to which a child is liked by her/his peers, whereas the word *popularity* refers to a child's perceived standing or status in the group.

Recently, researchers have focused on the study of the peer relationship correlates of such negative characteristics such as aggression, bossiness, and untrustworthiness to clarify the distinction between the meanings and measurement of peer acceptance and perceived popularity. Thus, for example, in contradiction to the general finding that aggression impedes a child's *acceptance* among peers, aggression appears to promote a child's perceived *popularity* (Buskirk, Rubin, Burgess, Booth-LaForce, & Rose-Krasnor, 2004; Hawley, Little,

& Pasupathi, 2002; Lease, Kennedy, & Axelrod, 2002). Research regarding the association between aggression and popularity is approached according to basic aspects of group process such as dominance, resource control, and regulation of retaliatory gestures between group members (Hawley, 2003). Findings show that children whose level of aggression is moderately above the mean and who use aggression for instrumental reasons are *perceived* as more popular in their groups than are children who are low in aggression or whose aggression is high and undifferentiated (Hawley, 2003; Little, Jones, Henrich, & Hawley, 2003; Prinstein & Cillessen, 2003; Vaughn et al., 2003).

Although the association between aggression and popularity may be seen even during the preschool period (Vaughn et al., 2003), this association appears to be stronger during early adolescence (Cillessen & Mayeux, 2004; Prinstein & Cillessen, 2003). Whereas aggression is positively associated with measures of popularity during early adolescence (Cillessen & Mayeux, 2004; LaFontana & Cillessen, 1998, 2002; Parkhurst & Hopmeyer, 1998), it is not related to acceptance (Buskirk et al., 2004). Moderately aggressive children may be given status and power in the peer group; however, this does not mean they are adjusted or that they will receive or benefit from the affection or kindness from their peers.

These findings are consistent with ideas about how groups function and how groups reward persons who promote the group's functioning (see Bukowski & Sippola, 2001). Whereas the main reward that one can provide at the level of the dyad is affection, the main rewards that can be provided at the level of the group are power, attention, and status. And whereas group members victimize peers who impede the group's evolution and coherence, groups give power, attention, and status to group members who promote the group's well-being. Given that group leaders may, at times, have to be forceful, strong, assertive, indeed Machiavellian, their behavior may include a larger coercive or aggressive component than is seen among other children. This tendency to ascribe power and status to moderately aggressive individuals may be more pronounced in adolescence when aggression is seen as a more normative entity than among younger children (Moffitt, 1993). As a result, status, leadership, and aggression may often go together especially for young adolescents (Prinstein & Cillessen, 2003).

Three final points must be made. First, consistent terminology is a prerequisite for learned discussion. As the distinction between how much a child is liked and how popular a child is becomes more frequent, the clarity of the terms used to refer to these constructs becomes increasingly important. The word *acceptance* should be used to refer to a direct assessment of the extent to which a child is liked by her/his peers, whereas the word *popularity* should be used to refer to a person's place in the peer group. The meaning of *acceptance* captures the essence of the construct it refers to (i.e., the extent to which a person is received with favor or approval by others). The word *popularity* is also ideally suited to the construct it is used to represent. Popularity, by definition, refers to someone's position or status among the people. In this respect it is essentially a group-oriented construct.

Second, the "traditional" measures of popularity have been sociometric measures. Sociometry refers to the attractions and repulsions between individuals. To the extent that a measure of perceived popularity is neither a measure of attraction nor repulsion, it is not a sociometric measure. Third, most of the research on acceptance and popularity has been empirically driven. Because researchers have been largely interested in identifying the different correlates of these constructs, little direct attention has been devoted to understanding the conceptual differences between these constructs by their psychological or functional significance. Lease and her colleagues have gone furthest in discussing the link between popularity and power in the peer group (Lease, Kennedy, et al., 2002; Lease, Musgrove, & Axelrod, 2002). Their discussions of how power and status are fused in the construct of popularity provide a strong base for further exploration of how peer groups function and of how their dynamics are controlled by particular peers.

## Adolescence

### Interaction

The trend of spending increasingly substantial amounts of time with peers that begins in middle childhood continues in adolescence (Larson, Brown, & Mortimer, 2002). For example, during a typical week, even discounting time spent in classroom instruction, high school students spend almost one-third (29%) of their waking hours with peers, an amount more than double

that spent with parents and other adults (13%; Csikszentmihalyi & Larson, 1984). Moreover, adolescent peer interaction takes place with less adult guidance and control than peer interaction in middle childhood, and is more likely to involve individuals of the opposite-sex (Brown & Klute, 2003). These phenomena are largely consistent across cultural groups.

### Relationships

As they enter adolescence, both boys and girls already understand a great deal about the reciprocal operations and obligations of friendship, about the continuity of friendships, and about the psychological grounds that evoke behavior. During *early* adolescence, friendship can be seen in overly exclusive terms in the sense that relationships with third parties are inimical to the basic nature of friendship commitment. During adolescence, however, youngsters begin to accept the other's need to establish relationships with others and to grow through such experiences. In particular, perhaps in parallel to their struggles for independence from their parents, adolescents recognize an obligation to grant friends a certain degree of autonomy and independence. Thus, their discussions of friendship and friendship issues show fewer elements of possessiveness and jealousy, and more concern with how the relationship helps the partners enhance their respective self-identities (Berndt & Hoyle, 1985).

During adolescence, friendships are best maintained when the partners have similar attitudes, aspirations, and intellect (e.g., Smollar & Youniss, 1982). Based on this perspective, it appears that children who are different from the other boys and girls in the group are those who are less likely to have a friend. Nonetheless, same-sex friends account for an increasingly larger proportion of adolescents' perceived primary social network, and friends equal or surpass parents as sources of support and advice to adolescents in many significant domains (e.g., Buhrmester, 1998; Furman & Buhrmester, 1992). Moreover, the friendships of adolescents are relatively stable (Berndt, Hawkins, et al., 1986).

One hallmark of friendship in adolescence is its emphasis on intimacy and self-disclosure. Studies consistently indicate that adolescents report greater levels of intimacy in their friendships than do younger children (Buhrmester & Furman, 1986). Furthermore, observations of adolescent friends indicate that intimate self-disclosure is a highly salient feature of friendship

interaction. Unlike at earlier ages, self-disclosure during adolescence prompts lengthy and sometimes emotional discussions about the nature of the problem and possible avenues to its resolution.

During adolescence, boys and girls have clear conceptions of the properties that distinguish *romantic* relationships from friendships (Collins, 2003; Connolly, Craig, Goldberg, & Pepler, 2004). Whereas romantic relationships are conceived in terms of passion and commitment, other-sex friendships are largely characterized by affiliation. Although even the youngest of adolescents distinguish between romantic relationships and other-sex friendships, distinctions between these relationships increase with age and with experience in romantic relationships. The study of adolescent romantic relationships by developmental psychologists is a surprisingly new enterprise with nearly all research on this topic stemming from the past 10 years. Relevant research is organized around three questions: (1) When do these relationships first emerge and for whom do they occur? (2) What are the characteristics of these relationships and what accounts for individual differences in their quality? (3) How do romantic relationships affect development?

With regard to developmental timing, romantic relationships are first seen during early adolescence with approximately 25% of 12-year-olds claiming they have had a romantic relationship during the past 18 months (Carver, Joyner, & Udry, 2003). This frequency increases in a largely linear fashion during adolescence with roughly 70% of boys and 75% of girls making this claim at age 18 (Carver et al., 2003; Seiffge-Krenke, 2003). The average duration of a romantic relationship has been observed to be 3.9 months at age 13, and 11.8 months at age 17 months (Seiffge-Krenke, 2003).

Dating and romantic relationships appear to follow a developmental sequence. Connolly et al. (2004) showed that affiliation in mixed-sex groups and dating were qualitatively different phenomena that were sequentially organized. This sequential order followed a path that started with same-sex friendships and moved through an affiliative period of mixed-sex group activities and mixed-sex festive occasions (e.g., parties), followed by dating and being involved in a romantic dyad.

There are large differences between those adolescents who do and do not participate in romantic relationships. These differences vary during the adolescent

period and they are often characterized by complex patterns (Collins, 2003). *Early* involvement in romantic relationships has been linked to problem behaviors and emotional difficulties during adolescence (e.g., Davila, Steinberg, Kachadourian, Cobb, & Fincham, 2004), although this difference appears to be strongest among boys and girls who are unpopular among their same-sex peers (Brendgen, Vitaro, Doyle, Markiewicz, & Bukowski, 2002). It has been reported also that early daters show lower levels of scholastic achievement (Seiffge-Krenke, 2003), especially among girls (Brendgen et al., 2002). Among older adolescents, however, participation in romantic relationships is associated with positive experiences among same-sex peers and emotional and behavioral well-being (Seiffge-Krenke, 2003). Connolly, Furman, and Konarski (2000) reported that being part of a small group of close same-sex friends predicted being involved in other-sex peer networks, which, in turn, predicted the emergence of future romantic relationships. The observation that involvement in a romantic relationship is linked to acceptance with same-sex peers resembles prior findings regarding same-sex acceptance and other-sex friendship. These findings, however, have shown that participation in friendship with other-sex peers is linked to same-sex acceptance in a linear and a curvilinear manner in which children who are most liked by same-sex peers, and those who are least liked, have other-sex friends (Bukowski, Sippola, & Hoza, 1999; Kovacs, Parker, & Hoffman, 1996). There is evidence also that the quality of a child's same-sex friendships predicts the quality of their concurrent and subsequent romantic relationships (Connolly et al., 2000). Future research needs to clarify whether this pattern of findings regarding romantic relationships is equally valid for hetero- and homosexual youth.

Although there appears to be some inter-relatedness between romantic relationships and other relationship experiences, this association is often complex. Using an attachment framework, Furman, Simon, Shaffer, and Bouchey (2002) studied adolescents' internal working models for their relationships with parents, friends, and romantic partners. Adolescents' perceived *support* in relationships with their parents tended to be related to their perceived support in romantic relationships and friendships; support in friend and romantic relationships, however, were not related to each other. Nevertheless, self and other *controlling* behaviors in friendships were related to corresponding behaviors in romantic re-

lationships. Perceived *negative interactions* in the three types of relationships were also significantly associated with each other. This pattern of results indicates greater generalizability of negative than positive features across relationship types.

Romantic relationships also appear to have both positive and negative effects on development although the literature on these matters is not yet clear. Whereas there is evidence that participation in romantic relationships can be associated with elevated levels of depressed mood, higher levels of conflict, and emotional lability (Joyner & Udry, 2000), these findings appear to be the result of breakdowns of romance rather than of romance per se. On the positive side, being involved in a romantic relationship indirectly affects the adolescent's sense of well-being via its direct effects on his or her sense of romantic competence (Kuttler, La Greca, & Prinstein, 1999).

### Groups

As in middle childhood, cliques are readily observed in adolescence, and membership in cliques is related to adolescents' psychological well-being and ability to cope with stress (Hansell, 1981). Also, as in middle childhood and early adolescence, group membership comprises individuals who are similar with regard to school achievement (Kindermann, 1995), substance use (cigarettes and alcohol; Urberg, Degirmencioglu, & Pilgrim, 1997), and delinquency (Kiesner et al., 2003). Nevertheless, Shrum and Cheek (1987) reported a sharp decline from 11 to 18 years of age in the proportion of students who were clique members and a corresponding increase with age in the proportion of children who had ties to many cliques or children whose primary ties were to other children who existed at the margins of one or more cliques. These authors concluded that there is a general loosening of clique ties across adolescence, a process they label "degrouching." This interpretation meshes well with data suggesting that both the importance of belonging to a group and the extent of intergroup antagonism decline steadily during high school years (Gavin & Furman, 1989). It is consistent also with the observations of ethnographers, who report a dissipation of clique boundaries and a sense of cohesiveness among senior high school class members (Larkin, 1979).

Whereas cliques represent small groups of individuals linked by friendship selections, the concept of peer subcultures, or "crowds" (Brown & Klute, 2003), is a

more encompassing organizational framework for segmenting adolescent peer social life. A crowd is a reputation-based collective of similarly stereotyped individuals who may or may not spend much time together. Crowds are defined by the primary attitudes or activities their members share. Thus, crowd affiliation is assigned through the consensus of the peer group and is not selected by the adolescents themselves. Brown (1989) listed the following as common crowd labels among American high school students: jocks, brains, eggheads, loners, burnouts, druggies, populars, nerds, and greasers. Crowds place important restrictions on children's social contacts and relationships with peers (Brown, 1989); for example, cliques are generally formed within (versus across) crowds. Crowd labels may also constrain adolescents' abilities to change their lifestyles or explore new identities by "channeling" them into relationships and dating patterns with those sharing the same crowd nomenclature or classification (Eckert, 1989).

Crowd membership is an especially salient feature of adolescent social life and children's perceptions of crowds change in important ways with age. For example, between the ages of 13 and 16 years, adolescents alter the ways that they identify and describe the crowds in their school (O'Brien & Bierman, 1987). Whereas young adolescents focus on the specific behavioral proclivities of group members, older adolescents center on members' dispositional characteristics and values. This observation reflects broader changes that characterize developmental shifts in person perception between the childhood and adolescent years.

The stigma that is placed on members of a particular crowd channels adolescents into relationships and dating patterns with those sharing a similar crowd label. This may prevent adolescents from the exploration of new identities and discourages a shift to other crowd memberships. There is recent evidence that the stigma associated with some large peer groups or crowds influences the judgments that adolescents form about their peers (Horn, 2003). Consistent with findings from research focused on children's aggressive reputations and social cognitions (e.g., Dodge, 1986), Horn (2003) found that adolescents are biased in their use of reputational or stereotypical information about particular *groups*, particularly when presented with ambiguous situations. It is likely that these crowd-specific evaluations help to perpetuate group stereotypes and the structure of peer groups in a school.

The percentage of students who are able to correctly identify their peer-rated crowd membership increases with age (Brown, Clasen, & Neiss, 1987). An abbreviated list of crowds (populars, jocks, brains, burnouts, nonconformists, and none) used by Prinstein and La Greca (2002) revealed that self-nominations to groups overlapped strongly with findings from peer assignments.

Despite the differences that exist in the structures of peer groups, all of them inevitably disintegrate in the late adolescent years. This is largely due to the integration of the sexes that accompanies this period. To begin with, mixed-sex cliques emerge. Eventually, the larger groups divide into couples, and by late adolescence, girls and boys feel comfortable enough to approach one another directly without the support of the clique. Another contributing factor to the decline in importance of crowds results from adolescents creating their *own* personal values and morals. In this regard, they no longer see it as necessary to broadcast their membership in a particular social group and are therefore content to be separate and apart from particular crowds.

## Conclusion

In this section, we have outlined developmental differences that mark the changing nature of social interactions and peer relationships from infancy to adolescence. Hopefully, this review will prove sufficient to provide a normative basis for the discussion that follows concerning the development of individual differences in children's social behaviors and peer relationships.

The nature of children's peer experiences changes with age because of a complex mix of developments with regard to intrapersonal (i.e., changes in interpersonal understanding and concerns), interpersonal (changes in the frequency or forms of specific behaviors), dyadic (changes in qualities of friendships or patterns of involvement in friendships), and group (changes in configurations of and involvement in cliques and crowds) factors. Furthermore, these different factors are not orthogonal; rather, they interlock in complex ways.

## SOCIAL BEHAVIORS, INTERACTIONS, RELATIONSHIPS, AND GROUPS: ASSESSMENT ISSUES

The perspective we have adopted for this chapter assumes that children's experiences with peers occur at

several orders of social complexity—from interactions to relationships to groups. Implied in such a formulation is that these levels of analyses provide separate windows on the adjustment of individual children with peers: To the extent that individual differences exist in children's adaptation or success with peers, such differences will be reflected in their (a) social interactions, (b) abilities to develop and sustain friendships, and (c) acceptance in peer groups. We examine procedures by which researchers assess peer interactions, relationships, and groups in this section.

### Children's Behaviors and Interactions with Peers

Although parents, clinicians, and archival data have all served as sources of information about the valence and nature of children's peer interactions, the most common sources are the reports of other children or teachers or structured observations.

#### Observations of Behavior

There has been a long tradition of observing children in either naturalistic or laboratory-based play groups and then coding their behavior to reflect particular constructs. For example, *observational procedures* have been used to index the frequency with which individuals engage in particular behavioral styles (e.g., aggression, sociodramatic play, reticence/social wariness, or sharing), adopt particular roles in relation to their partners (e.g., dominant versus submissive roles), or demonstrate social competence (e.g., are successful at entering play-groups). Several well-known coding systems have been developed for these purposes, and discussions of these techniques can be found elsewhere (e.g., Bierman, 2003). These coding schemes have been used profitably to reliably distinguish between children along a variety of behavioral dimensions. For example, Rubin (2001) developed the *Play Observation Scale* (POS), a norm-based time-sampling procedure to assess free play behaviors in early and middle childhood. During free play or unrestricted activity time (in a classroom, on a playground, or in a laboratory playroom), behaviors with and without peers are coded on a checklist that includes the cognitive play categories of functional-sensorimotor, exploratory, constructive, dramatic, and games-with-rules behaviors *nested* in the aforementioned social participation categories of solitary, parallel, and group activities (e.g., Coplan, Gavinski-Molina, Lagace-Seguin, & Wichmann, 2001; Guralnick, Hammond, &

Conner, 2003). In addition, overt and relational aggression, R&T play, unoccupied and onlooker behaviors, and conversations with peers are recorded. Observational procedures such as the POS are useful in targeting children whose behaviors (e.g., different forms of aggression and social withdrawal) deviate from age-group norms. Such procedures can be used to validate peer and teacher assessments of children's social behavior.

Additional observational protocols assess appropriate and inappropriate behavior (e.g., M. L. Lewin, Davis, & Hops, 1999), social competence (e.g., Vaughn et al., 2003), peer group entry (e.g., Putallaz & Gottman, 1981), multiple forms of aggression (e.g., Bierman, Smoot, & Aumiller, 1993), how existing peer dyads respond to newcomers (Zarbatany, Van Brunschot, Meadows, & Pepper, 1996), adolescent conversation and discussion (e.g., Hops, Albert, & Davis, 1997), and group planning (Englund, Levy, Hyson, & Sroufe, 2000).

Although observational methods offer many advantages over the assessments discussed next, they also have specific limitations. First, observations are time-, energy-, and money-consuming. Whereas peer and teacher assessments can be conducted in minutes or hours, observations can require weeks or months of data collection. Second, as children get older, it becomes increasingly difficult to observe them during "free play" (although recent advances in remote audio-visual recording allow observations of children's conversations and interactions from afar; Atlas & Pepler, 1998). Third, situational demands strongly influence the types of behaviors displayed and their frequency. Unless researchers carefully consider or control how subjects' behavior is being influenced by setting demands, observation methods can lead to false conclusions of the willingness of certain individuals to engage in behaviors of interest. Fourth, observations may be reactive; for example, children who are aware that they are being observed may behave in atypical manners, perhaps suppressing negative behaviors or increasing the production of prosocial behaviors. Finally, it should be mentioned that observational strategies have been used rarely to study peer interactions and relationships from a cultural and cross-cultural perspective.

#### Peer Assessments of Social Behavior

In lieu of direct observations, researchers have often relied on children for information about who it is in the peer group that behaves competently or incompetently, or has qualitatively good or poor relationships. Hymel

and Rubin (1985) noted the following advantages of peer informants. First, as “insiders,” peers can identify characteristics of children and relationships that are considered relevant from the perspectives of those who ultimately determine a child’s social status and integration in the peer group. Second, the judgments of peers are based on many extended and varied experiences with those being evaluated. For example, peers may be able to consider low frequency but psychologically significant events (e.g., a punch in the nose or taking someone’s valued possession) that lead to the establishment and maintenance of particular social reputations. These latter events may be unknown to nonpeer “outsiders.” Third, peer assessments of children’s behaviors and relationships represent the perspectives of many observers with whom the target child has had a variety of personal relationships. The chance that error will be introduced by some idiosyncratic aspect of any single reporter’s experience with the child is therefore correspondingly reduced.

In most peer assessment techniques, children are given a set of target behaviors or personality descriptions and asked to nominate peers on the basis of a variety of behavioral roles or character descriptions (e.g., “is a good leader,” “gets into fights,” or “likes to play alone”). Nominations received from peers are summed in various ways to provide indices of a child’s typical social behavior or reputation in the peer group, whether that group comprises a classroom or school grade.

Two commonly used peer assessment techniques are the *Revised Class Play* (Masten, Morrison, & Pellegrini, 1985) and the *Pupil Evaluation Inventory* (PEI; Pekarik, Prinz, Liebert, Weintraub, & Neale, 1976). Factor analysis of children’s nominations using these two measures has yielded three similar behavioral factors. For the PEI, the factors obtained were Likeability, Aggression, and Withdrawal. The factors obtained for the Revised Class Play are labeled Sociability-Leadership, Aggressive-Disruptive, and Sensitive-Isolated.

Recent advances in the use of peer assessments have provided a more refined articulation of the dimensions underlying children’s social behavior. Thus, Zeller, Vannatta, Schafer, and Noll (2003) computed a confirmatory factor analysis for the Revised Class Play and discovered that the model that best fit the data needed to be substantially more differentiated than a simple three factor model would imply. In a sense, this result is not surprising given previous analyses that have distinguished between different forms of social withdrawal

(e.g., Bowker, Bukowski, Zargarpour, & Hoza, 1998; Rubin & Mills, 1988) and between different forms of aggression (Crick & Bigbee, 1998; Poulin & Boivin, 1999). In the case of aggression, peer assessment procedures to distinguish between physical aggression (fighting, kicking, hitting), verbal aggression (threats, teasing), and relational aggression (spreading rumors, excluding from play) have been developed. Recently, Burgess and colleagues (Burgess, Wojslawowicz, Rubin, Rose-Krasnor, & Booth, 2003) developed a reliable and valid extension of the Revised Class Play to distinguish between forms of social withdrawal, as well as to measure sociability, prosocial/altruistic behavior, and victimization. Embedded items assess peer acceptance, perceived popularity, and rejection.

Like the Revised Class Play, the PEI (Pekarik et al., 1976) has undergone revision. Pope, Bierman, and Mumma (1991) condensed the original scales and added items describing inattentive/immature and disruptive/hyperactive behaviors. By so doing, Pope et al. provided an instrument that could distinguish aggressive children who are rejected from those who are accepted by peers.

Peer behavioral assessment assumes that children’s impressions of one another are established over time. Indeed, it has long been assumed that a major advantage of this technique is that it permits researchers to identify children who engage in behaviors that are salient to other children but too infrequent or too subtle for researchers to observe with any reliability. But a disadvantage of peer assessments is that once behavioral reputations consolidate they can be resistant to change (Hymel, 1986). Thus, even though a child’s behavior may have changed, their reputation for this behavior persists with peers. As such, the data reaching the researcher may not fully reflect the current state of “reality.” In addition, reputations are probably unduly influenced by infrequent but salient events (e.g., embarrassing social gaffs or poignant aggressive outbursts). Although characteristic of the child, the child’s reputation for this behavior may overstate the frequency with which it appears in his or her social interchanges. Relatedly, there is evidence that children’s recall of their peers’ abilities and behavior is affected by their own behavioral reputation, level of peer status, age, and liking for the target; situational factors; and the target’s gender, age, and sociometric status (e.g., Hymel, 1986). Finally, a main challenge to the study of peer assessments is the potential variance across cultural contexts in the

organization of social constructs (see Bukowski & Sippola, 2001). Because social demands and practices may vary across cultures, children's representations of social constructs may vary also. The cross-cultural research of Chen and colleagues is particularly relevant in this regard and is discussed later (e.g., Chen, Cen, Li, & He, 2005; Chen, Rubin, Li, & Li, 1999; Chen et al., 2004).

### ***Teacher Assessments***

Teachers can provide useful data concerning low frequency social exchanges that may contribute toward the quality of a child's peer relationships. One advantage of teacher assessments over peer assessments is that the collection of data is more efficient and less time consuming. A second advantage is that, because they themselves are not members of the peer group, teachers may be more objective in their assessments of social behavior. However, teachers may bring with them an "adultomorphic" perspective that carries with it value judgments about social behaviors that might differ from those of children. Furthermore, teachers may carry with them biases that influence the ways in which they react to their pupils; such teacher reactions may strongly influence children's peer preferences and judgments (White & Kistner, 1992).

Teacher *referrals* are one source of data on children with behavioral difficulties. Many objections might be leveled against this approach, however. In the first place, teachers refer children for academic behaviors (e.g., learning disabilities or motivational problems) that may have only minor implications for social difficulties with peers. Second, even when problematic behavior toward peers is the basis for referral, it is not clear that such referrals will take place when the behavior is not also disruptive of classroom routines and academic progress.

Many standardized measures presently exist and an excellent review of teacher ratings of child behavior may be found in Bierman (2003). Generally, these measures can be broken down into several socioemotional clusters or factors that fall along dimensions of sociability/likeability/leadership, aggression/hostility/conduct disorder, hyperactivity/impulsivity, and anxiety/fearfulness/withdrawal.

### ***Agreement among Sources***

Achenbach, McConaughy, and Howell (1987) reported that the correlations between reports of children's behavioral problems average about .60 between similar informants seeing children under generally similar

conditions (e.g., pairs of teachers; pairs of parents); .28 between different types of informants seeing the child under different conditions (e.g., parents versus teachers); and .22 between children's self-reports and reports by others, including parents, teachers and mental health workers. Age, sex, and the specific topography of the behavior under consideration have all been shown to be important factors influencing agreement. For example, agreement between teachers and peers concerning social withdrawal appears to increase with age from early to late childhood (Hymel, Rubin, Rowden, & LeMare, 1990), primarily because social withdrawal takes on increased salience to peers (but not teachers) with increasing age. Thus, it would appear as if no single source can substitute for all the others. The goal is not to determine which assessment procedure yields the singular truth about the child but to use what each one reveals about the child's functioning in particular areas or contexts.

### ***Children's Relationships with Friends***

Friendship is a subjective relationship and an inherently dyadic construct. Children perceive their friendship partners in particularized rather than role-related ways. They stress the uniqueness of the relationship and reject efforts to treat particular friendship partners as interchangeable with others. Researchers and other observers may note commonalities in personalities or behavioral tendencies across the friendships of a focal child, but the focal child him- or herself is likely to be impressed by the distinctions and diversity among his or her individual partners and relationships.

These subjective and reciprocal properties are challenges to understanding and require special caution in assessment. In early childhood, it is common to ask parents or teachers to identify whether a child is a friend of another child (Howes, 1988). Typically, researchers do not give these informants specific criteria by which the presence of a friendship should be determined. Instead, it is often simply assumed that these informants share the researcher's definition of friendship, which may or may not always be the case. In the assessment of the friendships of older elementary school-age children, the focal child's perceptions of his or her circle of friends must be sought and aligned with independent evidence of reciprocity of affection obtained directly or indirectly from each of these implicated individuals (Asher et al., 1996; Bukowski & Hoza, 1989). Typically, preschoolers and elementary school-age children are

presented with a roster or a set of pictures of their same-sex *classmates* (or some other functionally similar group) and asked to circle or otherwise indicate which members are their best or close friends. Researchers who study middle-schoolers may use classroom lists or they may simply ask children to write down the names of their best friends. The pattern of choices is then examined to identify children who nominate one another. Less often, investigators have used reciprocated high ratings as an index of friendship, either alone or in conjunction with friendship nominations (Bukowski, Hoza, & Newcomb, 1994). Both procedures are consistent with the definition of friendship that we presented earlier—friendship requires reciprocity, refers to a free choice on the part of the two children involved, and is predicated on affectional concerns rather than instrumental issues.

Evidence of reciprocity of affection alone may be insufficient to presume or substantiate claims of friendship. Children may enjoy each other's company in school but never spend time together outside of school or in other ways have experiences together that lead them to think of each other as friends. Indeed, sometimes children have only limited direct contact with other children they report liking. For example, children can admire another child from a distance, can be grateful to someone who is only an acquaintance, or have affection for someone whose leadership facilitates group's functioning (Parker, Saxon, et al., 1999). Yet, friendship generally implies that the individuals involved in the relationship not only like or admire one another but also label their relationship a friendship, have some shared history together, are committed to one another, and are comfortable being perceived as a pair of friends by others. Normally, friendship cannot be presumed unless children have been expressly asked whether the relationship in question is a friendship.

One problem that can limit the validity of friendship measures is whether one has adequately assessed the entire domain of a child's peer relationships. Although the peer group at school is typically a child's most salient peer group, it is almost always the case that children have friends outside of school—in their neighborhood or in connection with sports or recreational activities. In this regard, the sole use of school-based data underestimates the extent of children's friendship relations. This problem is further exacerbated if assessments allow only for the nomination of classmates—friendships with children in other classrooms at school are overlooked. This is a particular problem in schools in which children do

not spend their school time in a single class comprising the same group of peers. In North American middle and high schools, for example, it is often the case that students take different courses with different classmates. In this regard, the use of classroom nominations makes little sense. One would fare better by asking all children in a given grade to list their best friends in that particular grade. With increasing age, however, it may also make sense to ask children to nominate their best friends in the given school.

To solve the problem of identifying friendships in a given classroom or school, some researchers have begun to use diary data: They ask children in late middle school (junior high school) or high school to keep a log of who it is they spend time with when they are not at school (e.g., Laursen, Wilder, Noack, & Williams, 2000; Laursen & Williams, 1997). These logs or diaries allow children to indicate the length of time and quality of their interactions with friends.

A second problem occurs when children are permitted only a limited number of friendship nominations (e.g., three choices). This practice may arbitrarily restrict the number friendships a child may have. Furthermore, when the number of choices is specified, children who have one or two classroom friends may feel compelled to add to their list the names of children who are not actually their best friends. This creates the possibility for overestimating the actual number of friendships these children have.

A central benefit of friendship may also be one of its challenges. Whereas friendship may help protect children from inadequacies in their families, the interface between friendship and family may present difficult demands on children. As French (2004) has shown, in cultures that ascribe considerable power or authority to the family system, the significance and meaning of friendship may differ substantially from the meaning of friendship in Western cultures. It is conceivable that friendship may even be seen as a threat to the expected structure and influence of the family. Accordingly, peer research needs to be increasingly sensitive to the cultural variations in the way that friendship is constructed and in the role that friendship is given in children's lives.

### ***Friendship Quality***

In addition to determining whether a child has a close dyadic friendship, investigators have shown an increasing concern with the characteristics or qualities of children's relationships with their best friends. Given that

children's understanding of friendship changes with age, it is not surprising that there are age differences in the properties of children's friendships. And considering the wide variations in individual characteristics that children bring with them to their friendships, it is reasonable to expect that not all friendships will be alike. The most common approach involves assessing the features of children's friendships through children's own reports (e.g., Berndt & Perry, 1986; Furman & Buhrmester, 1992; Parker & Asher, 1993). Furman (1996) has noted that assessments of this type are usually conducted with questionnaires or interview procedures and are predicated on the belief that a child's impression of a relationship is the best index of this relationship for the child. Drawing from theoretical accounts of friendship (e.g., Sullivan, 1953), the dimensions typically assessed relate to (a) the *functions of friendship* (e.g., provision of companionship, level of intimate disclosure, degree of helpful and advice), (b) *conflict and disagreements*, and (c) the *affective properties* of the friendship (e.g., the affective bonds between friends).

Observational techniques have also sometimes been used to study friends' behavior with one another (e.g., Dunn, Cutting, & Fisher, 2002; Lansford & Parker, 1999), although far less frequently than self-reports. Part of the reluctance of researchers to use observational approaches may stem from the formidable task of isolating the contributions of individual members to the observed patterns of dyadic interaction (Hinde & Stevenson-Hinde, 1987). This is a real concern, but some promising observational methods for describing interdyad variation are available (e.g., Howes, 1988; Simpkins & Parke, 2002; Youngblade, Park, & Belsky, 1993). Presumably, any interpersonal behavior between friends may be amenable to observational assessments. Researchers have generally been interested in dimensions of behavior that relate to the putative functions of friendship (e.g., provision of companionship, level of intimate disclosure, degree of helpful and advice) or address the affective properties of the relationship (e.g., the affective bonds between friends). Children's conflict and disagreement with friends have also been of interest.

### Children's Peer Acceptance

Much of the dramatic increase in interest in children's peer relationships during the past 25 years can be traced to advances in *sociometry*. Techniques for measuring popularity, especially a procedure developed by Coie,

Dodge, and Coppotelli (1982), gave researchers a means by which to represent the extent to which a child is liked and disliked by peers. Much of the activity regarding sociometry is aimed at the challenge of developing valid and efficient measures of the two fundamental sociometric forces, specifically acceptance and rejection, and the measures that derive from them. *Acceptance* refers to how much a child is liked by peers; *rejection* refers to how much a child is disliked. The challenge of creating categorical measures results from the lack of independence between acceptance and rejection. These measures are neither the opposite of each other nor are they unrelated. Accordingly, a child high in acceptance is not necessarily low in rejection and a child high in rejection is not always low in acceptance. Some children could be high on both dimensions or low on both dimensions.

To account for these different patterns of association, derivative scores can be computed to index a child's general likeableness (i.e., sociometric *preference*) and the child's "visibility" in the peer group (i.e., sociometric *impact*). These scores have been used in various ways, most notably to make categorical assignments to the following sociometric groups: (a) *popular*—children who are high in acceptance and low in rejection (i.e., high impact, high preference); (b) *rejected*—children who are low in acceptance and high in rejection (i.e., high impact, low preference); (c) *neglected*—children who are low in both acceptance and rejection (i.e., low impact, mid-range in preference); (d) *average*—children who are average in acceptance and rejection (i.e., mid-range on both variables), and (e) *controversial*—children who are high in acceptance and rejection (i.e., high impact, mid-range on preference). Note well that in the case of sociometric classifications, the term *popular* is used as a synonym for accepted rather than as an index of social prestige or status. Discussions of the stability of sociometric scores and classifications can be found in Cillessen, Bukowski, and Haselager (2000), and in our previous *Handbook* chapter on children's peer interactions, relationships, and groups (Rubin, Bukowski, & Parker, 1998). Discussion of the conceptual, methodological, and potential ethical problems with sociometric techniques classification can be found in Rubin et al. (1998) and Bukowski and Cillessen (1996).

### Assessments of the Peer Group

Typically, groups have been studied for three reasons. First, investigators have sought to determine whether

and how a child is embedded into a naturally and spontaneously formed group structure. Two techniques, *Social Network Analysis* (SNA; Richards, 1995) and the *Social Cognitive Map* (SCM; Cairns, Gariepy, & Kindermann, 1989) are often used to identify peer networks. Social Network Analysis is based on friendship nominations. Children are asked to list the friends with whom they hang out most often in the school. Group members, liaisons, dyads, and isolates based on patterns of friendship links and the strengths of the links are identified (Richards, 1995). *Group members* are those individuals who belong to a rather exclusive social group that comprises at least three individuals who are linked with other members in the same group and who are connected by paths entirely in the group. *Liaisons* are individuals who have friendships with group members, but are not group members themselves. *Dyads* comprise individuals who have one reciprocated friendship. They do not belong to a group per se, but have mutual friendships. Finally, *Isolates* are children who have no reciprocated friendships. Given that SNA is based on friendship (either reciprocal or nonreciprocal) nominations, groups identified through the program represent *friendship networks*.

Compared with SNA, the SCM technique, developed by Cairns et al. (1989), assesses peer groups more directly. Children are asked, "Are there people in school who hang around together a lot? Who are they?" To ensure that the respondents include themselves, a follow up question is asked "What about you? Do you hang around together a lot with a group? Who are these people you hang around with?" Children are expected to report on groups about which they are most knowledgeable. Based on the reports of all participants, a matrix is constructed from the number of occasions that any two persons co-occurred in the same group. Specifically, each participant's group-membership profile is first generated based on the frequencies of nominations of group-membership with every other child in the class. Then a profile similarity index is derived by correlating pairs of individual group-membership profiles.

Second, following the determination that a child is a member of a group, a researcher can assess the group's structural properties. These properties typically consist of (a) group size, (b) the position of the group in the broader community of peer groups, and (c) the patterns of association in the group. *Size* refers simply to the number of children in the group. The *position of the group* in the broader peer group refers to how many links the group has to other collectives in the general

community of peers. And *group structure* refers to how many links there are between group members. In a *dense* group, most members would be linked to others; in a *loosely organized* group, some members would have no links to others at all.

Finally, a third goal is to assess the psychological characteristics of children's groups. Examples of this approach can be seen in the work of Chen and colleagues (Chen, Chang, & He, 2003), Gest et al. (2003), and Kindermann et al. (1995). In their research, group profiles are schematized, representing the interest and characteristics that its members share. Kindermann and colleagues, for example, have shown that groups vary considerably in their emphasis on academic performance.

Whereas group clustering techniques have been used to account for differences between groups that comprise the larger peer system, they may be an excellent way to capture differences between the structures of the peer group in different cultures. One would expect that, for example, in collectivist cultures, peer groups might be larger in that there might be more links in and between groups than one would see in individualistic cultures. This is an untested empirical question.

## THE PROXIMAL CORRELATES OF CHILDREN'S PEER RELATIONSHIPS

The understanding of the origins and correlates of individual differences in children's experiences with peers comprises the largest corpus of peer relationships research in the past 25 years. Much of this research has focused on the processes and variables that either provide the basis for, or are correlated with children's acceptance or rejection by the peer group; a much smaller proportion of the research extant is focused on the correlates and antecedents of individual differences at the level of the dyad (e.g., friendship).

The literature on individual differences in popularity and friendship can be divided into two domains. First, the largest concentration of investigations center on the *individual* characteristics associated with (a) acceptance or rejection in the peer group at large, (b) the ability to make and keep friends, and (c) the quality of friendship. Most of this work focuses on either the display of particular forms of social behavior or the ways that children think about their social environments and relationships.

A second body of research is concerned with the associations between peer acceptance and rejection and friendship and both the child's family relationship expe-

riences and the social environments in which the child functions. This literature deals with the *distal* correlates of peer acceptance and friendship. Although researchers appear to have their own preferences with regard to whether they examine proximal or distal correlates, these factors are truly interdependent; indeed, the study of the links between proximal and distal factors has become the central theme of much contemporary research.

### Proximal Correlates—Peer Acceptance

Over 20 years ago, researchers set out to develop a behavioral explanation of peer acceptance and rejection. Studies were conducted using several approaches and designs most notably involving play groups (e.g., Coie & Kupersmidt, 1983) and peer-assessment techniques (Newcomb & Bukowski, 1983). In these investigations, researchers typically examined differences between children who had been classified as sociometrically *popular*, *rejected*, *neglected*, *controversial* and *average*. Literally, hundreds of studies were conducted, making sociometric studies the bread and butter of peer research throughout much of the 1980s.

A thorough review of the literature on the concomitants of popularity was presented in the previous version of this chapter (Rubin et al., 1998). Whereas some reviews of research serve as renaissances that renew the study of a topic, the reviews of the sociometric classification studies served as a requiem. Although many of the basic questions of sociometric classification remain unanswered, research on the differences between children in the five sociometric groups has waned. Here we provide a cursory discussion of what this literature has informed us.

#### Popular Children

“Popular” children are high in acceptance and low in rejection. Keep in mind that whereas the term *popular* has been traditionally used to refer to these children, this usage varies with the more recent trend to use the word “popular” to refer to children who are high in status and prestige in the group. The children traditionally known as “sociometrically popular” have been shown to have the following characteristics. Relative to other children, those of popular status are skilled at initiating and maintaining qualitatively positive relationships. When entering new peer situations, popular children are more likely than members of other sociometric status groups to consider the frame of reference common to the ongoing

playgroup and to establish themselves as sharing in this frame of reference (Putallaz, 1983). Popular children are also less likely to draw unwarranted attention to themselves when entering ongoing playgroups: They do not talk exclusively or overbearingly about themselves and their own social goals or desires, and they are not disruptive of the group's activity (Dodge, McClaskey, & Feldman, 1985). In addition, when entering the ongoing play of both familiar and unfamiliar children, popular children speak clearly, respond contingently to their prospective playmates, and otherwise demonstrate communicative competence that allows the maintenance of connected, coherent interaction (Black & Hazan, 1990). They are seen as cooperative, friendly, sociable, and sensitive by peers, teachers, and observers (e.g., Coie et al., 1982; Newcomb & Bukowski, 1983, 1984; Parkhurst & Hopmeyer, 1998). Specifically, popular children are more likely to be helpful, to interact actively with other children, to show leadership skills, and to engage in constructive play (e.g., Pakaslahti, Karjalainen, & Keltikangas-Jarvinen, 2002). When involved in conflict, sociometrically popular children believe that negotiation and compromise will help them get what they want while simultaneously maintaining positive relationships with peers (e.g., Hart, DeWolf, Wozniak, & Burts, 1992).

Sociometrically popular children do not differ from average children on all aspects of aggression. In a meta-analysis of research on popularity, Newcomb et al. (1993) distinguished between assertive/agonistic behaviors and behaviors that reflected disruptiveness. Popular children did not differ from others on the former category of behavior whereas they did on the latter. Popular children, it appears, can engage in some forms of assertive behavior, but they rarely engage in behaviors that are likely to interfere with the actions and goals of others.

#### Rejected Children

The most commonly cited behavioral correlate of peer rejection is aggression, regardless of whether aggression is indexed by peer evaluations, teacher ratings, or observations (e.g., Crick, Casas, & Mosher, 1997; Haselager, Cillessen, van Lieshout, Riksen-Walraven, & Hartup, 2002; McNeilly-Choque, Hart, Robinson, Nelson, & Olsen, 1996). The association between rejection and aggression appears to be rather broad; Newcomb et al. (1993) revealed that rejected children, relative to average popular and neglected children, showed elevated levels on three forms of aggression—

specifically, disruptiveness, physical aggression, and negative behavior (e.g., verbal threats). A small number of studies provide evidence of a causal link between aggression and rejection. Two of these are the groundbreaking playgroup studies of Dodge (1983) and Coie and Kupersmidt (1983). In these cleverly designed investigations, the interactions between *unfamiliar* peers in small groups were observed in a laboratory context over several days. Each child's behavior was observationally coded; in addition, each child was assessed in a sociometric interview at the end of each play session. Gradually, some of the children became popular and others became rejected. The behavior that most clearly predicted peer rejection was aggression.

However, aggression is not the only factor linked to rejection. Detailed analyses indicate that aggressive children comprise only between 40% to 50% of the rejected group (Bierman, Smoot, & Aumiller, 1993; Cillessen, van IJzendoorn, van Lieshout, & Hartup, 1992). Indeed, with increasing age, it appears as if aggression becomes decreasingly associated with rejection, especially among boys (e.g., Sandstrom & Coie, 1999). Also, the data extant indicate that aggression may not lead to rejection if it is balanced by a set of positive qualities (e.g., social skill) that facilitate links with other children (Farmer, Estell, Bishop, O'Neal, & Cairns, 2003).

Researchers have found that there is a high level of heterogeneity among the behavioral tendencies of rejected children. For example, children who are highly withdrawn, timid, and wary comprise between 10% to 20% of the rejected group (e.g., Cillessen et al., 1992; Parkhurst & Asher, 1992). Another perspective on this latter statistic is that when extremely withdrawn children are identified, approximately 25% of them fall into the sociometrically rejected group (e.g., Rubin, Chen, & Hymel, 1993).

Finally, victimization has been observed to be associated with peer rejection, either as a correlate (Kochenderfer-Ladd, 2003; Schwartz, 2000), as a mediator that explains the association between withdrawal and victimization, or as a moderator that increases the stability of victimization (e.g., Hanish & Guerra, 2004).

### ***Neglected Children***

Few, if any, discrete behaviors have been found to be distinctive of sociometrically neglected children (see Newcomb et al., 1993). Sociometric neglected status is relatively unstable, even over short periods, and in that light, the fact that there are few strong associa-

tions between neglected status and specific behaviors is unsurprising.

### ***Controversial Children***

Sociometrically, this group is unique in that controversial children are high on both acceptance and rejection. Accordingly, controversial children appear to have many of the characteristics of both popular *and* rejected children. Coie and Dodge (1988), for example, reported that controversial boys, like rejected boys, were aggressive and disruptive, socially withdrawn, prone to anger and rule violations, and highly active. Alternatively, they reported that controversial boys were like popular boys in that they showed high levels of helpfulness, cooperation, leadership, and, in some instances, social sensitivity.

### ***Summary***

General conclusions can be drawn as to the features that distinguish sociometrically popular, rejected, neglected, controversial, and average children from one other. These differences generally fall along a positive/negative continuum. Sociometrically rejected children show high levels of negative behaviors and low levels of positive behaviors, whereas the opposite pattern is characteristic of popular children. Average children show moderate amounts of positive and negative behaviors, neglected children demonstrate low levels of each form of social behavior, and controversial children show high levels of both positive and negative behaviors. It should be remembered that the conclusions regarding differences between sociometric groups are based on consistencies across studies. Nevertheless, these general conclusions do not always represent powerful effects. Accordingly one cannot conclude that all aggressive children will be sociometrically rejected and one should not be surprised to discover that some aggressive children are actually liked by their peers. The next wave of research on acceptance, rejection, and children's individual characteristics needs to sort out why some features lead to rejection in one case and acceptance in another.

Recent research has provided some guidance as to what the next set of studies should be like. One direction would be to give further attention to the interactions between variables. Hawley (2003), for example, has shown that aggression is linked with competence when it co-occurs with prosocial tendencies. Alternatively, Prinstein and Cillessen (2003) have pointed to the importance of studying nonlinear effects such as examining whether the association between aggression and

competence with peers is best represented as curvilinear. As we noted earlier, several researchers have made the distinction between traditional sociometric dimensions of acceptance and rejection and the conceptualization of *perceived* popularity as an index of a child's status in the group (e.g., Parkhurst & Hopmeyer, 1998).

### **Variations in the Behavioral Correlates of Popularity: Sex, Group, and Cultural Differences**

Groups have norms, or standards, regarding the "goodness" of particular acts. The acceptability of a behavior, and of the child who displays that behavior, is determined by whether the behavior conforms to the group's norms. If a behavior is universally valued, it should correlate with peer acceptance; if the normalcy of a behavior varies across groups, the extent to which the behavior is linked to popularity should vary across these groups also. It is this logic that has provided the basis for much of the research on group variations in the correlates of popularity.

#### ***Sex Differences***

Given the widespread concern with sex differences in the literature on child development, it seems surprising to discover how little work exists on the topic of sociometric peer acceptance. Typically, researchers have failed to examine whether general findings are equally valid for boys and girls. For that matter, much of the early work focused solely on boys (e.g., Coie & Kupersmidt, 1983; Dodge, 1983) despite published calls for the examination of sex differences in the causes, proximal and distal correlates, and prospective outcomes of peer acceptance and rejection (e.g., Rubin, 1983). Further, sex differences have been neglected despite (a) the long-standing view that the relationships formed and maintained by females are qualitatively distinct from those of males (Leaper, 1994) and (b) the evidence that some aspects of social behavior may be differentially normative for boys and girls (e.g., Humphreys & Smith, 1987).

Sex differences do exist when behavior that is typical for a gender is considered. For example, in an observational study of 8- and 10-year-olds, Moller, Hymel, and Rubin (1992) distinguished styles of play that were engaged in more frequently by females from styles of play that were engaged in more frequently by males. The children were also administered a sociometric rating. The authors found that the relations between the same- or

opposite-gender preferred play scores and popularity were nonsignificant for females in either age group. For males, however, the frequent demonstration of female preferred play was significantly, and negatively, associated with acceptance, not only by boys, but also by girls. And this relation held only for the 10-year-old males who frequently produced female sex-stereotyped play.

These latter data are in keeping with a study by Berndt and Heller (1986). Using scenarios in which they described a child who had chosen activities either consistent or inconsistent with gender stereotypes, the participants were asked to make judgments of the actor's popularity among peers. The authors found that 9- and 12-year-old children demonstrated a greater negative reaction to gender inconsistent behavior than did 5-year-olds. Furthermore, they found this intolerance was greater for boys than for girls in that it was more appropriate for girls to behave in a gender inconsistent manner. Taken together, the research on the correlates of popularity for boys versus girls reveals one consistent finding. Males who display female-stereotyped behavior are disliked by both same- and opposite-sex peers; females who display male-stereotyped behavior are generally accepted by both same- and opposite-sex peers. These relations appear to gain strength with increasing age in childhood. Nevertheless, the relevant data base for examining sex differences in the correlates of peer acceptance and rejection is sparse. This gap in the literature is striking and it severely compromises our current understanding of the peer system (see Ruble, Martin, & Berenbaum, Chapter 14, this *Handbook*, this volume, for further discussion).

#### ***Variations across Groups***

The argument that a child's popularity will be associated with particular peer group norms has been the central focus of a number of investigations. Wright, Giammarino, and Parad (1986) examined the differences in the correlates of popularity in groups at a summer camp for boys with behavioral and emotional problems. For highly aggressive groups of children, the correlation between peer preference and aggression was very low. In nonaggressive groups, this association between preference and aggression was of moderate strength. The opposite pattern was seen in these same groups when social withdrawal was considered. Withdrawal was strongly and negatively correlated to preference in the high aggression groups and uncorrelated to preference in the low aggression groups. Boivin, Dodge, and Coie (1995) reported that reactive aggression,

proactive aggression, and solitary play were more negatively linked to a measure of social preference when high levels of these specific behaviors were nonnormative and unrelated to preference when high levels on these behaviors were normative. Stormshak et al. (1999) also found support for the person-group similarity model. These researchers reported that for boys, social withdrawal was associated with peer acceptance in those classrooms in which withdrawal was normative; for boys, aggression was linked to peer preference in those classrooms in which aggression was more normative. Findings for girls were, complex and in some cases not supportive of the person-group similarity model. For example, in classrooms marked by high aggression, aggressive girls were not better liked than nonaggressive girls.

These studies show clearly that the association between a particular form of behavior and popularity depends on whether the behavior is normative for a group. Considering the importance of group norms as moderators of the associations between behaviors and popularity, researchers should be cautious about drawing broad conclusions about the correlates of popularity. Indeed, researchers would do well to assess the *person/group interaction and similarity* as a major determinant of peer acceptance and rejection.

Lastly, the recent study of deviancy training is germane. In this work, researchers find that children who deviate from the norm (typically insofar as their aggressive behavior is concerned) find social support in peer networks of like-behaved counterparts (Bagwell & Coie, 2004; Dishion, Spracklen, Andrews, & Patterson, 1996). It is in such groups that popularity may be determined by behavior that is dysfunctional.

### ***Variations across Culture***

Cross-cultural research on the correlates of peer acceptance and rejection has been aimed at asking whether given behaviors known to be associated with acceptance or rejection in North American samples demonstrate similar relations in other cultures. One shortcoming in this work may be that investigators have taken measures originally developed for use in a Western cultural context, and have employed them in other cultural milieus. The general conclusion from this research has been that aggression and helpfulness are associated with rejection and popularity respectively in a wide range of cultures (e.g., Casiglia, Lo Coco & Zappulla, 1998; Chang et al., 2005; Chen, Rubin, & Li, 1995; Cillessen et al., 1992; Tomada & Schneider, 1997). Alternatively, researchers

have found that among young Chinese children, sensitive, cautious, and inhibited behavior are positively associated with competent and positive social behavior and with peer acceptance (Chen et al., 1999; Chen, Rubin, & Sun, 1992). More recently, however, Hart and colleagues (2000) found that social reticence, defined as unoccupied and onlooking behavior (Coplan et al., 1994), was associated with a lack of peer acceptance, not only in young American children, but also among Russian and Chinese youngsters. Furthermore, Chang and colleagues (2005) have recently found that social withdrawal among young Hong Kong Chinese adolescents predicted the lack of peer acceptance 1.5 years hence. Relatedly, Chen et al. (2005) have reported that over the years, since the early 1990s, shy, reserved behavior among Chinese elementary school children has *increasingly* become associated with negative peer reputations. Chen and colleagues have argued that the changing economic and political climate in China is being accompanied by preferences for more assertive, yet competent, social behavior. In short, researchers would do well not to generalize findings drawn from children of one cultural group to children from another context. Moreover, changing socioeconomic climates may prove to have significant influences on that which is deemed acceptable behavior by significant peers and adults in the child's environment (Silbereisen, 2000).

### ***Summary***

We have highlighted the notion that acceptance by the peer group (typically defined by classroom composition) is driven by conformity to or deviation from *behavioral* norms. Such a view is admittedly simple conceptually and does not take into account the possibility that correlates of popularity may vary according to whether a child is acquiring or maintaining their status in a group. This latter issue seems ripe for study in the next generation of studies on patterns of liking and disliking among children.

### **Social Cognitive Correlates of Peer Acceptance and Rejection**

Those who study social cognition believe that the child's thoughts about the social universe, especially about specific children, can be evocative or inhibitory because behavioral expression is concerned. Thus, if a child has difficulty understanding the sorts of behaviors

required to make proper entry into a group or to obtain desirable objects or to avoid harassment by peers, it may be reflected in their behavior in the peer group. In short, the connection between social cognition and peer acceptance and rejection is best understood by suggesting that thoughts (and emotions for that matter) about things social and relational can evoke particular forms of behavior. In turn, these behaviors lead to acceptance or rejection by peers.

With this in mind, researchers have studied a wide range of social cognitive variables that appear to have some bearing on the child's acceptance by peers. In general, the more social-cognitively astute the child is, the more popular she or he is found to be (e.g., Slaughter, Dennis, & Pritchard, 2002). In this section, we review research in which social cognition has been associated with sociometric status.

### ***Social Information Processing***

We begin with a brief description of social information-processing models that are relevant to the study of children's skilled and unskilled social behaviors. In one model, Rubin and Rose-Krasnor (1992) speculated that, when children face an interpersonal dilemma (e.g., making new friends, acquiring a desired object from someone else, or stopping others from acting against them), their thinking follows a particular sequence. First, children select a social goal or a representation of the desired end state of the problem-solving process. Second, they examine the task environment; this involves reading and interpreting relevant social cues. For example, social status, familiarity, and age of the participants in the task environment are likely to influence the child's goal and strategy selection (Krasnor & Rubin, 1983). Third, they access and select strategies; this process involves generating possible plans of action for achieving the perceived social goal, and choosing the most appropriate one for the specific situation. Fourth, they implement the chosen strategy. Finally, it is proposed that children evaluate the outcome of the strategy; this involves assessing the situation to determine the relative success of the chosen course of action in achieving the social goal. If the initial strategy is unsuccessful, the child may repeat it or she/he may select and enact a new strategy or abandon the situation entirely.

Crick and Dodge (1994) proposed a similar social-cognitive model designed specifically to account for aggression in children (see Dodge, Coie, & Lynam, Chapter 14, this *Handbook*, this volume). This model

consists of six stages: (1) the encoding of social cues, (2) the interpretation of encoded cues, (3) the clarification of goals, (4) the accessing and generation of potential responses, (5) the evaluation and selection of responses, and (6) the enactment of the chosen response. Recently, Lemerise and Arsenio (2000) integrated *emotional* experiences into the Crick and Dodge's social information-processing model. For example, aggressive children's emotional reactions to problematic social situations might include frustration or anger; anxious/withdrawn children may react with fear. These emotions, in turn, may influence the information that is attended to and the information that is recalled. This mood-congruent information processing might reinforce aggressive children's social schemas or "working models" that the social world is a hostile one or withdrawn children's notions that the social world is fear inducing. These emotional responses may explain, in part, why aggressive and withdrawn children respond in predictable ways to negative events befalling them.

Much research on social cognition and peer relationships has focused on rejected children's deficits or qualitative differences in performance at various stages of these social information-processing models. First, rejected children are distinguished from their nonrejected counterparts on the basis of their spontaneous *motives* for social engagement. Popular children, for example, are more inclined to indicate the reason for interacting with others is to establish new, or enhance ongoing, relationships. Rejected children, however, are more likely to be motivated by goals that would reasonably be expected to undermine their social relationships, such as "getting even with" or "defeating" their peers (e.g., Rabiner & Gordon, 1992).

Second, when considering the motives or intentions of others, *rejected-aggressive* children are more disposed than their popular counterparts to assume that negative events are the product of malicious, malevolent intent on the part of others (e.g., Dodge et al., 2003). This bias is evident when children are asked to make attributions for others' behaviors in situations where something negative has happened but the motives of the instigator are unclear. In these ambiguous situations, rejected-aggressive children appear unwilling to give a provocateur the benefit of the doubt—for example, by assuming that the behavior occurred by accident. This "intention cue bias" is often suggested as an explanation for why it is that aggressive and oppositional-defiant children choose to solve their interpersonal problems in

hostile and agonistic ways (e.g., see Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002, for a recent review).

But why would aggressive children think that when negative, but ambiguously caused events befall them, the protagonist means them harm? In keeping with Lemerise and Arsenio (2000), a transactional perspective would suggest that aggressive children, many of whom are already rejected (and victimized) by their peers, believe that certain others do not like them, those others have a history of rejecting of them or acting mean toward them, and thus the negative act *must* be intentionally caused. This conclusion of intentional malevolence is posited to elicit anger and a rapid fire response of *reactive* aggression. Many researchers have found that when asked how they would react to an ambiguously caused negative event, aggressive children respond with a choice of agonistic strategies (Orobio de Castro et al., 2002). And aggressive children also regard aggression to be an effective and appropriate means to meet their interactive goals (Vernberg, Jacobs, & Hershberger, 1999). The processes leading to the enactment of aggression and the behavioral display itself no doubt reinforces an already negative peer profile.

By the elementary and middle school years, many socially withdrawn children are also rejected by their peers. Thus, one may ask whether these children view their social worlds in ways that vary from those of non-withdrawn and/or nonrejected children. To begin with, when socially withdrawn 4- and 5-year-olds are asked how they would go about obtaining an attractive object from another child, they produce fewer alternative solutions, display more rigidity in generating alternative responses, and are more likely to suggest adult intervention to aid in the solution of hypothetical social problems when compared to their more sociable age-mates (Rubin, Daniels-Beirness, & Bream, 1984).

Observational research has demonstrated that socially reticent and withdrawn children produce fewer overtures to their peers than nonwithdrawn children (Nelson, Rubin, & Fox, 2005; Stewart & Rubin, 1995). Yet, the overtures produced are typically unassertive. Despite this production of unassertive strategies, withdrawn children are more often rebuffed by their peers than are nonwithdrawn children (Nelson et al., 2005; Stewart & Rubin, 1995). This connection between peer rebuff and social withdrawal or reticence may be taken as an in vivo assessment of peer rejection.

Rubin and colleagues (e.g., Rubin, Burgess, Kennedy, & Stewart, 2003) have argued that as a result of frequent

interpersonal rejection by peers, withdrawn children may begin to attribute their social failures to internal causes; they may come to believe that there is something wrong with themselves rather than attributing their social failures to other people or situations. Supporting these notions, Rubin and Krasnor (1986) found that extremely withdrawn children tended to blame social failure on personal, dispositional characteristics rather than on external events or circumstances. These results are in keeping with recent findings by Wichmann, Coplan, and Daniels (2004) who reported that when 9- to 13-year-old withdrawn children were presented with hypothetical social situations in which ambiguously caused negative events happened to them, they attributed the events to internal and stable “self-defeating” causes. Moreover, withdrawn children suggested that when faced with such negative situations, they were more familiar with failure experiences and that a preferred strategy would be to withdraw and escape.

Some have suggested that there is a particular group of victimized children who are characterized by a socially withdrawn demeanor. For example, Olweus (1978, 1993) has referred to “whipping boys”—a group of victimized children perceived as easy marks by peers. Hodges and colleagues have referred to some victimized children as “physically weak” and “withdrawn” (Hodges, Boivin, et al., 1999; Hodges, Malone, & Perry, 1997; Rodkin & Hodges, 2003). Not surprisingly, researchers have found that children victimized by peers are also rejected by them (Kochenderfer-Ladd, 2003; Schwartz, 2000). Given the conceptual associations between social withdrawal, victimization, and peer rejection, the earlier noted findings by Wichmann et al. (2004) are reminiscent of work by Graham and Juvonen (1998, 2001). These latter researchers reported that youngsters who identified themselves as victimized by peers tended to blame themselves for their peer relationship problems. And Nolen-Hoeksema, Girgus, and Seligman (1992) have argued that self-blame can lead to a variety of negative outcomes of an internalizing nature, such as depression, low self-esteem, and withdrawal, thereby suggesting a self-reinforcing cycle of negative socioemotional functioning (see also Dill, Vernberg, & Fonagy, 2004).

Taken together, the findings reported earlier suggest that if children interpret social experiences negatively, inappropriately, and inaccurately, they may prove to be their own worst enemies. Such negative biases are likely to contribute to their already problematic social relationships. In the case of rejected-aggressive children,

demonstrated deficits in social-cognitive processing suggest that these children may have difficulty understanding the consequences of their behaviors for others and that their social failures can be attributed to internal, stable causes. In short, they may not claim responsibility for their production of agonistic social behaviors ("They made me do it!") or for their negative social reputations. Indeed, given their social-cognitive inadequacies, rejected-aggressive children may not realize that their interactive styles are perceived negatively by peers. After all, as noted earlier, they do regard aggression as an effective and appropriate means to meet their interactive goals.

Alternatively, the rejected socially withdrawn child may be able to think through interpersonal dilemmas in an adequate, competent manner. Nevertheless, when confronted by the "real-life" social world, withdrawn children may be less able to meet their social goals than are their nonwithdrawn peers. The experience of peer noncompliance noted earlier is likely to have an unfortunate outcome for the sensitive, wary, withdrawn child. It is this type of sensitive rejected child who would attribute social failures to internal, stable characteristics, and who would respond to peer rebuff by expressing (a) loneliness, (b) self-blame, (c) dissatisfaction with his or her social relationships, and (d) negative self-appraisals of social skills.

### Self-System Correlates of Peer Acceptance and Rejection

An important repercussion that has been ascribed to the experiences with peers is their effect on the self-concept. In the foundational ideas of Sullivan and of the symbolic interactionists, peer relationships were described as a critical source of the self. Specifically, boys and girls were said to use their peer relationships as important sources of information about themselves. Most *positive* experiences were believed to provide a strong sense of validation that reinforced the perception that one is well-functioning and grounded. Accordingly, research on peer relationships has often addressed theoretically derived hypotheses about the effects of peer experiences on aspects of the self.

Researchers have consistently reported that it is mainly *rejected-withdrawn* children (also variously described as submissive, sensitive, wary) who believe they have poor social skills and relationships (Hymel, Bowker, & Woody, 1993). *Rejected-aggressive* children do not report thinking poorly about their social compe-

tencies or their relationships with peers (Zakriski & Coie, 1996). These findings are in keeping with the results of studies concerning withdrawn and aggressive children conducted in Western cultures; it is only the former group that reports having difficulty with their social skills and peer relationships (Rubin, Chen, & Hymel, 1993).

Given rejected-withdrawn children's negative perceptions of their social competencies and relationships, and given their negative experiences in the peer group, it is not surprising that these children report more loneliness and social detachment than popular children or children who are rejected but aggressive (e.g., Gazelle & Ladd, 2003). These relations have been reported throughout childhood and early adolescence (e.g., Crick & Ladd, 1993; Parkhurst & Asher, 1992).

A further distinction between rejected children is the chronicity of their peer problems. Whereas rejection is temporary for some children, it is an enduring experience for others. Ladd and Troop-Gordon (2003) showed that chronic rejection was related to subsequent views of the self and that these negative self-perceptions partially mediated the relation between peer difficulties and internalizing problems and loneliness.

In summary, although rejected children tend to report that they are less competent, less efficacious, and less satisfied with reference to their social skills and peer relationships, this conclusion appears true only for rejected children who are withdrawn, timid, or submissive. The study of the association between the self and peer relations is part of a large and enduring research tradition, which treats that self as the result of peer processes. More recent research suggests that children who are high and low in self-esteem manage and use their peer relations for different purposes. Research on the association between peer relationships and the self may benefit from the adoption of new perspectives such as the ideas from dynamic systems models of the self.

### Children's Friendships: Correlates and Individual Differences

In an earlier section, we described developmental issues pertaining to friendship, such as its understanding by children, its prevalence, features, and functions. In this section, we examine the correlates of friendship and individual differences in those aspects of friendship described earlier.

Children who lack friends may miss out on the advantages thought to be garnered by such relationships.

Furthermore, not only is the presence of friendship viewed as important, but the *quality* of the relationship is also considered significant. Qualitative dimensions of friendship include intimacy, companionship, and emotional and social support. Notably, friendship quality has been positively associated with indices of psychosocial adjustment and functioning, such as self-esteem (Berndt, 1996).

In an attempt to illustrate the distinction between peer acceptance and friendship, several researchers have examined the relation between sociometric status, friendship prevalence, and relationship quality. For example, Parker and Asher (1993) showed that while not all highly accepted children had best friends and not all children low in peer acceptance were without best friendships, highly accepted and average-accepted children were twice as likely as low-accepted children to have a mutual best friend. Additionally, low-accepted children reported qualitatively poorer friendships than the other two groups. From a dyadic perspective, Brendgen, Little, and Krappmann (2000) found that the degree of parallelism in friendship quality, or perceptual concordance, varied as a function of sociometric status. Whereas the perceptions of friendship quality of average-accepted and highly accepted children and their respective best friends were highly correlated, there was little relation between rejected children's own perceptions and their best friends' perceptions of the relationship quality, particularly concerning the extent to which they viewed the relationship as close and being fun.

Although an examination of the relation between sociometric status (group "level") and friendship (dyadic relationship "level") is important, there is also a need to describe how children's *individual* characteristics are related to the prevalence of friendship and the quality of their dyadic relationships with peers. Given that many rejected children appear to be aggressive and/or withdrawn, it is surprising to note that few investigators have examined the friendships of these children. Not all aggressive and withdrawn children and certainly not all rejected children experience later adjustment difficulties. Thus, the best friendships of these children may function protectively and buffer them from later problems. Alternately, some best friendships may actually serve to exacerbate existing problems. An example of the protective role that friendship may play for children who have difficulties in the peer group may be drawn from research by Hodges, Boivin, et al. (1999). These researchers found that peer victimization predicted

increases in internalizing and externalizing difficulties during the school year for those children who lacked a mutual best friendship. The relation between peer victimization, internalizing, and externalizing problems was nonsignificant for children who possessed a mutual best friendship, thereby suggesting that friendship may function protectively for children who are victimized by their peers.

We now compare the friendships of those children who appear at greatest risk for peer rejection (i.e., those who have been identified as aggressive or socially withdrawn) with their age-mates who have no evidence of such behavioral or psychological difficulties.

### *Friendship Prevalence and Quality*

Investigators have shown that the majority of aggressive children have a mutual best friendship and are as likely as well-adjusted children to have mutual friends (e.g., Vitaro, Brendgen, & Tremblay, 2000). Aggression, however, does seem to be negatively related to friendship stability (e.g., Hektner, August, & Realmuto, 2000), a finding that is not too surprising considering the adverse nature of aggression. Moreover, aggressive children have friends who are more aggressive and their relationships are more confrontational and antisocial in quality (e.g., Dishion, Eddy, Haas, Li, & Spracklen, 1997). High levels of relational aggression (e.g., threatening friendship withdrawal) *within* the friendship, and high levels of exclusivity/jealousy, and intimacy characterize the friendships of relationally aggressive children. In contrast, overtly aggressive children direct their overt aggression *outside* their friendship dyads, and report low levels of intimacy (Grotzinger & Crick, 1996).

The prevalence of best friendships among *young* socially withdrawn children is not significantly different from that among nonwithdrawn children (Ladd & Burgess, 1999), and approximately 60% of withdrawn 8-, 9-, and 10-year-olds have reciprocated friendships (Rubin, Wojslawowicz, Burgess, Booth-LaForce, & Rose-Krasnor, in press; Schneider, 1999). These data suggest that social withdrawal and shyness are individual characteristics that do not influence the formation, prevalence, and maintenance of friendship in childhood.

Relationship qualities have been studied in relation to different subtypes of aggression, such as relational and overt aggression (Grotzinger & Crick, 1996), and proactive and reactive aggression (Poulin & Boivin, 1999). Results from the aforementioned studies suggest that aggressive behaviors may negatively affect the qual-

ity of friendships. Recently, it has been shown that the friendships of withdrawn children are viewed as relatively lacking in fun, intimacy, helpfulness and guidance, and validation and caring (Rubin, Wojslawowicz, et al., in press). These findings suggest a "misery loves company" scenario for withdrawn children and their best friends. One may conjure up images of victimized friends coping poorly in the world of peers, images reflected in recent newspaper and television accounts of peer victimization and its untimely consequences.

There is some evidence to suggest that socially withdrawn children are more likely than their age-mates to be *chronically friendless*. In a summer camp study conducted by Parker and Seal (1996), chronically friendless children were rated by their peers to be more shy and timid, to spend more time playing alone, and to be more sensitive than children who possessed a mutual best friendship during the summer camp program. Additionally, counselors rated these friendless children as less mature, less socially skilled, and as displaying more withdrawn and anxious behaviors than children with friends. The aforementioned study is the only investigation to date of chronically friendless children, and the summer camp setting may have influenced the results in a significant fashion. If some socially withdrawn children are *shy* (e.g., Rubin, Burgess, Kennedy, & Stewart, 2003), then establishing friendships amongst unfamiliar others may prove somewhat overwhelming for many of these children. However, in a familiar setting, such as school, withdrawn children may have less difficulty forming and keeping friendships over the course of the school year. Conversely, as noted earlier, social withdrawal increases in salience with age to peers. Thus, it is possible that the negative reputation accorded socially withdrawn children may hinder friendship formation and maintenance processes. In any event, an investigation of the *consistent absence* of friendship among withdrawn and aggressive children relative to their nonwithdrawn, nonaggressive age-mates may prove illuminating.

#### **DISTAL PREDICTORS OF CHILDREN'S SOCIAL SKILLS AND PEER RELATIONSHIPS**

The quality of children's extrafamilial social lives is likely a product of factors internal and external to the

child. Drawing from Hinde (1987), for example, it seems reasonable to suggest that such *individual* characteristics as biological or dispositional factors (e.g., temperament; self-regulatory mechanisms) may influence children's peer interactions and relationships. It is equally plausible that the *interactions* and *relationships* children experience with their parents are important.

In the following section, we present a brief review of some of the distal factors that may influence children's social interactions and peer relationships. We begin with a short discussion of the role of *individual* or dispositional temperament and biological factors. Following this, we examine the association between the parent-child and child-peer *relationship* systems. We focus primarily on research conducted in the framework of attachment theory. Following our discussion of attachment theory, we examine the relevant literature on parenting beliefs and behaviors.

#### **Temperament, Social Behaviors, and Peer Relationships**

Recently, temperament has been construed as constitutionally based individual differences in emotional, motoric, and attentional reactivity and the regulation thereof (Rothbart, Ellis, & Posner, 2004). Researchers who study temperament report that individuals differ not only in the ease with which positive and negative emotions may be aroused (*emotionality*) but also in the ease with which emotions, once aroused, can be *regulated* (Rothbart et al., 2004). In some respects, a better term for emotionality is *reactivity* in that most research on the phenomenon is focused on the extent to which children react to situations or events with anger, irritability, or fear. And again, most contemporary researchers have been interested in the ways in which reactive responses can be *self-regulated*. Thus, researchers have centered on the *effortful self-control* of emotional, behavioral, and attentional processes (Sanson, Hemphill, & Smart, 2004).

The constructs of difficult temperament, activity level, inhibition, and sociability merit special attention in the study of peer interactions and relationships. *Difficult temperament* refers to the frequent and intense expression of negative affect (Thomas & Chess, 1977). Fussiness and irritability would be characteristic of a "difficult" infant or toddler. In reactivity/regulation terminology, the *difficult* child is one whose negative emotions are easily aroused and difficult to soothe or

regulate. The *highly active* baby/toddler is one who is easily excited and motorically facile. Again, these children are easily aroused—that is, highly reactive. *Inhibited* infants/toddlers are timid, vigilant, and fearful when faced with novel social stimuli; like the other groups of children, their emotions are easily aroused and difficult to regulate. Finally, children who are outgoing and open in response to social novelty are described as *sociable* (Kagan, 1999).

Each of these temperamental characteristics is relatively stable (e.g., Rothbart, Derryberry, & Hershey, 2000), and each is related to particular constellations of social behaviors that we described earlier as characteristic of either popular or rejected children. The conceptual model that “drives” much of the longitudinal research connecting temperament to peer interactions and relationships is rather straightforward. Temperament processes, such as emotional reactivity or effortful control, are posited to underpin the presentation of given social behaviors; these behaviors, in turn, are thought to predict children’s relationships with their peers (e.g., Eisenberg, 2002).

In keeping with this perspective, infants and toddlers who have been identified as having difficult and/or active temperament, or as emotionally reactive are more likely to behave in aggressive, impulsive ways in early childhood (e.g., Hay, Castle, & Davies, 2000; Rubin, Burgess, Dwyer, & Hastings, 2003). Contemporaneous and predictive connections between negative emotionality and/or difficult temperament and children’s aggressive and oppositional behavior have been discovered by researchers the world over (e.g., Keenan, Shaw, & Delliquadri, 1998; Russell, Hart, Robinson, & Olson, 2003; Vitaro, Brendgen, & Tremblay, 2002). And, as we noted earlier, undercontrolled, impulsive, and aggressive behavior is associated contemporaneously and predictively with peer relationships characterized by rejection. Indeed, negative emotionality itself has been associated with peer rejection (e.g., Eisenberg, Fabes, Guthrie, & Reiser, 2000).

Similarly, behavioral inhibition, an individual trait identified in infancy and toddlerhood predicts the display of shyness and socially withdrawn behavior in early and middle childhood (Kagan, 1999; Rubin, Burgess, & Hastings, 2002). Contemporaneous connections between behavioral inhibition and children’s shy or socially reticent behavior have been found during early and middle childhood and adolescence (e.g., Pfeifer, Goldsmith, Davidson, & Rickman, 2002). Shy, socially

reticent children display less socially competent and prosocial behaviors, employ fewer positive coping strategies, and are more likely to develop anxiety problems than their nonreticent age-mates (e.g., Coplan et al., 1994; Eisenberg, Shepard, Fabes, Murphy, & Guthrie, 1998). Moreover, reticence and social withdrawal has been found to predict peer rejection and victimization from as early as the preschool years (e.g., Gazelle & Ladd, 2003; Hart et al., 2000).

It has been suggested that dispositional characteristics related to *emotion regulation* may lay the basis for the emergence of children’s social behaviors and relationships. For example, Rubin, Coplan, Fox, and Calkins (1995) have argued that the social consequences of emotion dysregulation vary in accord with the child’s behavioral tendency to approach and interact with peers during free play. They found that sociable children whose approach behaviors lacked regulatory control were disruptive and aggressive; those who were sociable but able to regulate their emotions were socially competent. Unsociable children who were good emotion regulators appeared to suffer no ill effects from their lack of social behavior; when playing alone, they were productive engagers in constructive and exploratory activity. They were neither anxious amongst peers nor rated by parents as having socioemotional difficulties. Unsociable children who were poor emotion regulators were more behaviorally anxious and wary, more reticent than constructive when playing alone, and were viewed by parents as having more internalizing problems than their age-mates. Thus, emotionally dysregulated preschoolers may behave in ways that will elicit peer rejection and inhibit the development of qualitatively adaptive friendships. Further, this is the case for emotionally dysregulated sociable as well as unsociable children.

The results of Rubin et al.’s (1995) study are clearly in keeping with findings from Eisenberg and colleagues’ extensive research program on young children’s emotional arousal and regulation. Eisenberg and colleagues have consistently found that emotion dysregulation is a concomitant and predictor of behavioral solitude (e.g., Fabes, Hanish, Martin, & Eisenberg, 2002; Spinrad et al., 2004) and externalizing forms of behavior (e.g., Eisenberg, Cumberland, et al., 2001) in the peer group. Relatedly, researchers have found that the abilities to regulate negative emotions and to inhibit the expression of undesirable affect and behavior (regulatory control) are associated with, and predictive of, social competence and peer acceptance (e.g., Eisenberg, Pidada, &

Liew, 2001; Eisenberg, Spinrad, Fabes, Reiser, et al., 2004; Gunnar, Sebanc, Tout, Donzella, & Van Dulmen, 2003; Kochanska, Murray, & Coy, 1997), while an inability to regulate affect is associated with socially incompetent behavior (e.g., Calkins & Dedmon, 2000; Calkins, Gill, Johnson, & Smith, 1999). Importantly, these findings appear to be consistent across cultures (e.g., Eisenberg, Pidada, & Liew, 2001; Zhou, Eisenberg, Wang, & Reiser, 2004).

### ***Temperament and Friendship***

Most research associating temperament-related constructs and peer relationships have focused on peer popularity or rejection. There has been little work in which temperament has been associated with aspects of friendship. Stocker and Dunn (1990) found that sociable children were rated as having more positive relationships with friends; highly emotional children had less successful relationships with friends. Dunn and Cutting (1999), in a study of young children, found that negative emotionality was associated with the observed frequency of failed social bids and with less amity directed to the best friend; as a counterpoint, children showed less amity to friends who were inhibited or shy. More recently, in a study of young adolescents, Pike and Atzaba-Poria (2003) reported that sociability was related to positive aspects of perceived friendship quality, whereas negative emotionality was associated with friendship conflict.

### ***Summary***

In summary, researchers suggest that individual, dispositionally based characteristics may set the stage for the development of particular types of parent-child relationships and for the development of social behavioral profiles that ultimately predict the quality of children's peer relationships.

### **Parent-Child Attachment Relationships, Social Behaviors, and Peer Relationships**

According to Hartup (1985), parents serve at least three functions in the child's development of social competence and qualitatively positive peer relationships. First, parent-child *interaction* is a context in which many competencies necessary for social interaction develop. Second, the parent-child *relationship* constitutes a safety net permitting the child the freedom to examine

features of the social universe, thereby enhancing the development of social skills. Third, it is in the parent-child relationship that the child begins to develop expectations and assumptions about interactions and relationships with other people.

### ***The Parent-Child Attachment Relationship***

A basic premise of attachment theory is that the early mother-infant relationship lays the groundwork for children's understanding of, and participation in, subsequent extrafamilial relationships. And, since the quality of attachment relationships with the mother may vary, subsequent social success and relationships with peers is expected to vary as well.

The putative, proximal causes of the development of a secure attachment relationship are the expressions of parental responsiveness, warmth, and sensitivity (e.g., Belsky & Cassidy, 1995). The sensitive and responsive parent recognizes the infant's or toddler's emotional signals, considers the child's perspective, and responds promptly and appropriately to the child's needs. In turn, it is posited that the child develops a belief system that incorporates the parent as someone who can be relied on for protection, nurturance, comfort, and security; a sense of trust in relationships results from the secure infant/toddler-parent bond. Furthermore, the child forms a belief that the self is competent and worthy of positive response from others. The process by which a secure attachment relationship is thought to result in the development of social competence and positive relationships with peers may be described briefly as follows. The "internal working model" of the securely attached young child allows him or her to feel secure, confident, and self-assured when introduced to novel settings; this sense of felt security fosters the child's active exploration of the social environment (Sroufe, 1983). In turn, exploration of the social milieu leads to peer interaction and play. And as we noted earlier, peer interaction and play allow children to experience the interpersonal exchange of ideas, perspectives, roles, and actions. From such social interchanges, children develop skills that lead to the development of positive peer relationships.

Alternatively, the development of an insecure attachment relationship is posited to result in the child's developing an internal working model that interpersonal relationships are rejecting or neglectful (Bowlby, 1973). Attachment theorists have suggested also that the expectations and assumptions that infants hold about others, and the means by which they cope with these cognitions,

are internalized and carried forward into subsequent relationships. Thus, it has been proposed that, in their subsequent peer relationships, insecure “avoidant” infants are guided by previously reinforced expectations of parental rejection; hence, they are believed to perceive peers as potentially hostile and tend to strike out proactively and aggressively (Troy & Sroufe, 1987). Insecure “ambivalent” infants, alternatively, are thought to be guided by a fear of rejection; consequently, in their extrafamilial peer relationships they are posited to attempt to avoid rejection through passive, adult-dependent behavior and withdrawal from the prospects of peer interaction (Renken, Egeland, Marvinney, Mangelsdorf, & Sroufe, 1989).

### ***The Parent-Child Attachment Relationship and Children's Social Behaviors: Empirical Support***

Securely attached infants are more likely than their insecure counterparts to demonstrate socially competent behaviors amongst peers during the toddler (e.g., Pastor, 1981), preschool (e.g., Booth, Rose-Krasnor, & Rubin, 1991), and elementary school periods (e.g., Elicker, Englund, & Sroufe, 1992). Insecure babies, especially those classified as avoidant, later exhibit more hostility, anger, and aggressive behavior in preschool settings than their secure counterparts (e.g., Burgess, Marshall, Rubin, & Fox, 2003; Shaw, Owens, Vondra, Keenan, & Winslow, 1996). Insecure-ambivalent infants are more easily frustrated, and socially inhibited at 2 years than their secure age-mates (e.g., Fox & Calkins, 1993). At 4 years of age, children classified at 1 year as ambivalent have been described as fearful and lacking in assertiveness (Kochanska, 1998). Spangler and Schieche (1998) have reported that of the 16 “C” babies they identified in their research, 15 were rated by their mothers as behaviorally inhibited. As noted earlier, it has been suggested that inhibition in infancy and toddlerhood is a precursor of social withdrawal in early and middle childhood. Finally, evidence that disorganized/disoriented attachment status in infancy predicts the subsequent display of aggression amongst preschool and elementary school peers derives from several sources (e.g., Lyons-Ruth, Easterbrooks, & Cibelli, 1997).

It is also the case that secure and insecure attachments, as assessed in early and middle childhood, as well as in early adolescence are associated contemporaneously with and predictive of adaptive and maladaptive social behaviors respectively. For example, children who experience a secure relationship with their mothers (and fathers) have been found to be more sociable and compe-

tent than their insecure counterparts, whilst insecure children exhibit more aggression and withdrawal (Allen, Moore, Kuperminc, & Bell, 1998; Rose-Krasnor, Rubin, Booth, & Coplan, 1996; Schmidt, DeMulder, & Denham, 2002; Simons, Paternite, & Shore, 2001; Stevenson-Hinde & Marshall, 1999). Extensive reviews of related literature may be found in Thompson (Chapter 2, this *Handbook*, this volume).

### ***The Parent-Child Attachment Relationship and Children's Peer Relationships: Empirical Support***

If the quality of the attachment relationship is associated with, and predictive of, patterns of social interaction, it seems logical to propose a relation between attachment status and the child's standing in the peer group. In a recent meta-analysis of the extant literature on links between attachment and peer acceptance, Schneider, Atkinson, and Tardiff (2001) found a small-to-moderate effect size between these domains.

### ***Attachment and Friendship***

According to Booth, Rubin, Rose-Krasnor, and Burgess (2004), although associations between attachment security and social competence and peer acceptance are theoretically meaningful, there is an even more compelling rationale for the link between attachment security and *friendship*. From attachment theory, one would expect that the trust and intimacy characterizing secure child-parent relationships should produce an internalized model of relationship expectations that affects the quality of relationships with friends. In support of this theoretically driven expectation, Schneider et al. (2001), in a meta-analysis, found a larger effect size linking attachment security with friendship than with peer relationships more generally.

For example, Youngblade and Belsky (1992) reported that securely attached infants were less likely than insecure infants to have negative and asynchronous friendships at 5 years of age. Freitag, Belsky, Grossmann, Grossmann, and Scheurer-Englisch (1996) found that children who had positive early relationships with their parents were more likely to have a close friend at age 10. Also, secure parent-child attachment in late childhood and early adolescence is associated positively (and contemporaneously) with positive qualities of children's close peer relationships (Lieberman, Doyle, & Markiewicz, 1999; Rubin, Dwyer, et al., 2004). And Clark and Ladd (2000) have reported that parent-child connectedness, an essential element of the attachment bond, is associated with higher levels of

harmony and lower levels of conflict in the friendships of young children.

Whether specific attachment classifications predict types of friendships characteristics is, as yet, unknown. Recently, Hodges, Finnegan, and Perry (1999) have suggested that an important feature in close relationships is the balance between autonomy and connectedness. They suggested that this *relationship orientation* or *relationship stance* may be conceptualized and coded as avoidant or preoccupied: An *avoidant* child may be characterized by showing very little emotion on reunion with or on separation from the relationship partner, may avoid the partner when in a state of distress, and renounce the importance of the relationship. A *preoccupied* child may show extreme distress when the relationship partner is needed but absent, and may be acutely sensitive to the possibility of rejection by, and separation from, the partner. Hodges et al. (1999) found that relationship orientation with a best friend could be moderately predicted from the child's relationship orientation with his or her parents, a finding that is explained by attachment theory and Bowlby's (1969/1982) notion of generalized internal working models. Hodges and colleagues (1999) do not consider their measure of relationships stance to be equivalent to an attachment classification. However, their research represents an important step in the direction of matching characteristics of parent-child and friend relationships.

### Summary

There is growing evidence that the quality of parent-child attachment relationships is associated with and predictive of qualitatively good friendships. This being the case, we might expect future research to focus on relations between relationships systems and examine whether (and when) children's friendships can augment (or exacerbate) the relations between parent-child attachment and adaptation or maladaptation.

## Parenting and Children's Social Behaviors and Peer Relationships

### Parental Beliefs

Parents' ideas, beliefs, and perceptions about the development and maintenance of children's social behaviors and relationships predict, and presumably partially explain the development of socially adaptive and maladaptive interactive behaviors and peer relationships in childhood. This is true because parents' child-rearing practices represent a behavioral expression of their ideas

about how children become socially competent, how family contexts should be structured to shape children's behaviors, and how and when children should be taught to initiate and maintain relationships with others (Bugental & Happaney, 2002; Rubin & Burgess, 2002). These ideas about child rearing and about what is acceptable and unacceptable child behavior in the social world are culturally determined. Extended discussions of such cultural determination may be found in Rubin and Chung (in press).

### Parents' Beliefs about Adaptive Child Behaviors and Relationships

Parents of socially competent children believe that, in early childhood, they should play an active role in the socialization of social skills via teaching and providing peer interaction opportunities (Rubin, Mills, & Rose-Krasnor, 1989). They believe also that when their children display maladaptive behaviors, it is due to transitory and situationally caused circumstances. Parents whose preschoolers display socially incompetent behaviors, alternatively, are less likely to endorse strong beliefs in the development of social skills (Rubin et al., 1989). Furthermore, they are more likely to attribute the development of social competence to internal factors ("Children are born that way"), to believe that incompetent behavior is difficult to alter, and to believe that interpersonal skills are best taught through direct instructional means (Rubin et al., 1989).

One conclusion that may derive from these findings is that parental involvement in the promotion of social competence is mediated by strong beliefs in the importance of social skills. When a socially competent child demonstrates poor social performance, parents who place a relatively high value on social competence are likely to become the most involved and responsive. Over time, such involvement may be positively reinforced by the child's acquisition of social skills. At the same time, parents are likely to value the social skills displayed by their children, and these children will be perceived as interpersonally competent and capable of autonomous learning. Hence, parental beliefs and child characteristics will influence each other in a reciprocal manner (Rubin, Rose-Krasnor, Bigras, Mills, & Booth, 1996).

### The Child as Parental Belief Evocateur

In keeping with the perspective that the parent-child relationship reflects the contributions of both partners, it is important to understand that parental beliefs may be evoked by child characteristics and behavior (Bornstein,

2002). For example, the “problematic” child who demonstrates maladaptive social behaviors and who does not get along with her or his peers is likely to evoke different parental emotions and cognitions than the “normal” child (Bugental, 1992). When this latter group of children behaves in maladaptive or socially inappropriate manners, they may activate parental feelings of concern, puzzlement, and, in the case of aggression, anger. These parental emotions are regulated by the parent’s attempts to understand, rationalize, or justify the child’s behavior and by the parent’s knowledge of the child’s social skills history and the known quality of the child’s social relationships at home, at school, and in the neighborhood. Thus, in the case of nonproblematic children, the evocative stimulus produces adaptive, solution-focused parental ideation that results in the parent’s choice of a reasoned, sensitive, and responsive approach to dealing with the problem behavior (Bugental, 1992). In turn, the child views the parent as supportive and learns to better understand how to behave and feel in similar situations as they occur in the future. As such, a reciprocal connection is developed between the ways and means of adult and child social information processing.

But how does the socially incompetent child’s presentation of socially maladaptive behavior affect the parent? In the case of aggressive children, any hostile behavior, whether directed at peers, siblings, or parents may evoke (a) strong parental feelings of anger and frustration (Deater-Deckard & Dodge, 1997; Eisenberg, Gershoff, et al., 2001) and (b) biased attributions that “blame” the child’s noxious behavior on traits, intentions, and motives internal to the child (e.g., Strassberg, 1995). These parental cognitions and emotions, predict the use of power assertive and restrictive disciplinary techniques (Colwell, Mize, & Pettit, 2002; Coplan, Hastings, Lagace-Seguin, & Moulton, 2002). This type of low warmth-high control parental response, mediated by affect and beliefs/cognitions about the intentionality of the child behavior, the historical precedence of child aggression, and the best means to control child aggression, is likely to evoke negative affect and cognitions in the child. The result of this interplay between parent and child beliefs, affects, and behavior may be the reinforcement and extension of family cycles of hostility (Carson & Parke, 1996; Dishion, Duncan, Eddy, Fagot, & Fetrow, 1994; Granic & Lamey, 2002).

Parental reactions to social wariness and fearfulness are less well understood. Researchers have found that

when children produce a high frequency of socially wary, withdrawn behaviors their parents (a) recognize this as a problem; (b) express feelings of concern, sympathy, guilt, embarrassment, and, with increasing child age, a growing sense of frustration; and (c) are more inclined than parents of nonwary children to attribute their children’s social reticence to dispositional traits (Hastings & Rubin, 1999). Perhaps in an attempt to regulate their own expressed guilt and embarrassment emanating from their children’s ineffectual behaviors, mothers of socially withdrawn preschoolers indicate that they would react to their children’s displays of social withdrawal by providing them with protection and direct instruction (Mills & Rubin, 1998). To release the child from social discomfort, the parents of socially wary children have indicated that they would solve the child’s social dilemmas by asking other children for information desired by the child, obtaining objects desired by the child, or requesting that peers allow the child to join them in play (Rubin & Burgess, 2002).

In summary, it is suggested that parental beliefs influence parental behavior; in turn, parental behavior influences the development, maintenance, and inhibition of children’s social behaviors, which, as we noted earlier, influence the quality of their peer relationships. Consistent with this view, parents of aggressive and withdrawn children have been found to differ from those of typical children in the ways in which they think about socializing social skills and in the ways that they report reacting to their children’s maladaptive behaviors.

### ***Parenting Behaviors, Children’s Social Skills, and Peer Relationships***

Parents may influence the development of social behaviors, interaction patterns, and ultimately, the quality of their children’s peer relationships by (a) providing opportunities for their children to have contact with peers; (b) monitoring of their children’s peer encounters (when necessary); (c) coaching their children to deal competently with interpersonal peer-related tasks; and (d) disciplining unacceptable, maladaptive peer directed behaviors (e.g., Parke & O’Neill, 1999).

### ***Parental Coaching and Managing***

Research suggests that parents vary widely in the extent of their efforts to provide opportunities for peer interaction for their children and to coach their children in specific social skills. Moreover, the available evidence suggests that parents’ efforts in these areas have implica-

tions for their young children's success with peers (see Kerns, Cole, & Andrews, 1998; Mize & Pettit, 1997; Pettit, Brown, Mize, & Lindsey, 1998). Ladd and Golter (1988), for example, found that parents who actively arranged peer contacts and who indirectly supervised these contacts had preschoolers who were better liked by their peers. In addition, children whose parents relied on indirect rather than direct monitoring of their children's peer contacts were less hostile toward peers. These findings have been supported in subsequent studies (e.g., Pettit et al., 1998). In a follow-up, short-term longitudinal study, Ladd and Hart (1992) found that mothers' over- and underinvolvement in arranging and monitoring peer contacts could be detrimental to children's social success, at least among boys. Boys whose mothers were moderately involved in initiating their child's peer contacts displayed significant gains in peer status over time compared to boys with over- and underinvolved mothers. Girls made significant gains in peer status only when their own efforts to initiate contact with other children were large in comparison to those of their mothers (i.e., when their mothers were underinvolved).

Finnie and Russell (1988) found that during play with an unfamiliar age-mate, mothers of unpopular children were more likely to avoid supervising their children and to supervise their children less skillfully than mothers of more popular children. Mothers of more popular children were more active and effective in supervising their children's peer related behaviors than mothers of less well-accepted children. In a follow-up study, Russell and Finnie (1990) examined mothers' instructions to their child immediately prior to the child's opportunity to play with an unfamiliar child. Mothers of popular children were more likely than mothers of low-status (rejected and neglected) children to make group-oriented statements during both the anticipatory instruction period as well as during the play session itself. Mothers of low-status children were more disruptive of their children's play.

In summary, research indicates that when mothers are involved in effective ways in coaching their children through difficulties with peers, facilitating their children's play with peers, and providing their children with opportunities to play with peers, their children are more popular among their age-mates. However, all of the research in this area is correlational and virtually none of the extant research is focused on fathers. It is entirely possible that the observed differences between the mothers of socially popular and unpopular or competent

and incompetent children are a consequence, rather than the cause, of their children's success with peers. Thus, it would be timely to examine whether very young children identified as being relatively unpopular with peers could "shake" their early reputations if their parents (mothers and fathers) were "trained" in parental monitoring and coaching skills.

### *Parenting Behaviors*

Parents (usually mothers) of unpopular and/or peer rejected children have been reported to use inept, intrusive, harsh, and authoritarian disciplinary and socialization practices more frequently than those of their more popular counterparts (e.g., Carson & Parke, 1996; McDowell & Parke, 2000; Pettit, Clawson, Dodge, & Bates, 1996). These data seem to hold true for parents of preschoolers through elementary school children. Alternately, parents of popular children use more feelings-oriented reasoning and induction, responsivity, warm control (authoritative), and positivity during communication than their unpopular counterparts (e.g., Mize & Pettit, 1997).

In regard to the actual process that links parenting to the child's peer relationships, it is possible to consider that parenting styles may promote particular child behaviors that mark a child for acceptance or rejection. To this end, researchers have demonstrated that mothers of socially competent children are more child-centered, more feelings-oriented, warmer, and more likely to use positive verbalizations, reasoning, and explanations than mothers of less competent children (e.g., Mize & Pettit, 1997; Rose-Krasnor et al., 1996).

With regard to socially incompetent behaviors, researchers have shown consistently that aggressive children have parents who model and inadvertently reinforce aggressive and impulsive behavior, and who are cold and rejecting, physically punitive, and inconsistent in their disciplinary behaviors. In addition to parental rejection and the use of high power-assertive and inconsistent disciplinary strategies, parental permissiveness, indulgence, and lack of supervision have often been found to correlate with children's aggressive behavior (see Rubin & Burgess, 2002, and Dodge et al., Chapter 12, this *Handbook*, this volume, for recent reviews). It may not be difficult to understand these associations given that parental tolerance and neglect of the child's aggressive behavior may actually have the implication of legitimization and encouragement of aggression. Importantly, these findings appear to have

cross-cultural universality (e.g., Cheah & Rubin, 2004; Chen & Rubin, 1994; Schneider, Attili, Vermigli, & Younger, 1997).

Relative to the literature on the parenting behaviors associated with undercontrolled, aggressive children little is known about social wariness and withdrawal. Research concerning the parenting behaviors and styles associated with social withdrawal focuses clearly on two potential socialization contributors—overcontrol and overprotection. Parents who use high power-assertive strategies and who place many constraints on their children tend to rear shy, reserved, and dependent children. Thus, the issuance of parental commands combined with constraints on exploration and independence may hinder the development of competence in the social milieu. Restrictive control may also deprive the child of opportunities to interact with peers. It should not be surprising that children who are socially withdrawn are on the receiving end of parental overcontrol and overprotection (e.g., Rubin, Burgess, & Hastings, 2002; Rubin, Cheah, & Fox, 2001). These findings concerning parental overcontrol and restriction stem from very few studies, most of which center on children of preschool age. Furthermore, the contexts in which parents of socially withdrawn children display overcontrol and overprotection have not been well specified. Thus, unlike the literature on the parents of aggressive children, the socialization correlates and causes of social withdrawal are not well-known. This dearth of data represents an open research agenda for future investigation.

### ***Parenting Behaviors and Children's Social Competence: A Model***

In summary, there is some support for the contention that parental behavior is associated, not only with the development of children's social competence, but also with their peer relationships (see Ladd & Pettit, 2002, for a review). The assumption has been that parenting leads to social competence or incompetence, which leads to peer acceptance or rejection. This causal model has been tested in a number of studies.

Dishion (1990) examined the relations among grade-school boys' sociometric status, academic skills, antisocial behavior, and several elements of parental discipline practices and family circumstances. Causal modeling suggested that the relation between inept parenting and peer rejection was mediated by boys' antisocial behavior and academic difficulties: Lower levels of parental skill were associated with higher levels of antisocial behavior and lower levels of academic perfor-

mance; antisocial behavior and poor academic performance, in turn, were associated with higher levels of peer rejection.

These findings have been replicated and extended in a similar study conducted in the People's Republic of China (Chen & Rubin, 1994). The pathway from parental authoritarian, punitive disciplinary practices to child aggression to peer rejection was replicated, but the authors also found that parental warmth and authoritative control predicted social competence, which predicted peer acceptance. These latter results suggest that the pathways to peer acceptance and rejection may be generalized across cultures.

There is also the possibility that the link between parenting and child outcomes of an adaptive or maladaptive nature can be attenuated by the quality of the child's status in the peer group or the quality of his or her friendships. For example, the longitudinal relation between harsh parenting and negative outcomes of an externalizing nature is augmented when children have poor peer relationships (e.g., Criss, Pettit, Bates, Dodge, & Lapp, 2002; Lansford, Criss, Pettit, Dodge, & Bates, 2003). And Schwartz, Dodge, Pettit, and Bates (2000) found that children who experienced harsh home environments in the preschool years were more likely to be victimized by peers in the third and fourth grades; however, this correlation was stronger for those who had a lower number of friendships.

Researchers have shown that the relation between insecurity of attachment and negative outcome can be moderated by friendship quality. Thus an insecure attachment relationship may predict difficulties of an externalizing or internalizing nature, but only for those children or young adolescents who lack friendship or qualitatively rich friendship (e.g., Rubin, Dwyer, et al., 2004). Thus, in recent models pertaining to the links between parenting and adaptive or maladaptive outcome, it appears as if, by middle to late childhood, children's friendships may buffer or exacerbate the statistical associations.

### ***Summary***

The existing research supports the general conclusion that socially successful children have mothers (and, where examined, fathers) who are more feelings-oriented, more positive, more skillful, more likely to use inductive reasoning, and less negative and coercive in their interaction with their children than their socially unsuccessful counterparts. The limits that the correlational nature of this workplace on our interpretations

should be recognized, however. Although it is likely that parents' behaviors have an influence on their children's behavior and success with peers, it must be acknowledged that parental behavior may be elicited by their children's characteristics (Belsky, 1997; Putnam, Sanson, & Rothbart, 2002). Relatedly, it should be noted that, with few exceptions, research in this area focuses on the *concurrent* relations between parental practices and children's social adjustment with peers and not these relations over time. Thus, although we take this work as generally supportive of a link between early parental behaviors contributing to children's later social success, this link has not been thoroughly demonstrated.

## CHILDHOOD PEER EXPERIENCES AND LATER ADJUSTMENT

Our goal, in this section, is to provide a summary of research in which the primary focus has been to identify aspects of childhood peer relationship experiences that predict subsequent adaptation and maladaptation. The predictors we examine fall at the levels of dyadic (friendship) and group (peer acceptance) *relationships*. Although we fully recognize that social behaviors (e.g., aggression), dispositions (e.g., temperament), and interactions (e.g., interactive conflict evoked by differences of opinion) may predict adaptive and malevolent "outcomes," relevant discussions are presented elsewhere in this volume.

Significantly, the associations between the quality of peer relationships in childhood and subsequent difficulties have generally been examined in one of two ways. First, using *case-control* or *follow-back* designs, researchers have asked whether maladjusted and adjusted adolescents or adults differed as children in their adjustment with peers. Second, with the cohort, *prospective*, or *follow-up* design, researchers have asked whether popular and unpopular children differ in their incidence of later psychological and educational adaptation. We provided a lengthy overview of retrospective studies in the previous iteration of this chapter (Rubin, Bukowski, & Parker, 1998). Here, we focus only on studies in which prospective, follow-forward designs have been employed.

### Academic Adjustment

For many children and adolescents, the primary venue for their experiences with peers is the school context.

School is where many children meet peers, form friendships, and take part in groups. For friendless, rejected, or victimized children, the school must be a less-than-desirable context and certainly a place that is unlikely to promote learning or well-being. This is likely to be the case, not only for the child who was doing poorly in school to begin with, but also for the intellectually competent child who has trouble becoming part of the peer system. For these individuals, withdrawing via truancy or by dropping out may serve as the escape route to avoid constant rejection or victimization by peers. Alternatively, having a friend with whom one can share the struggles associated with acquiring new forms of academic competence may prove entirely helpful. For these reasons, peer relationships have been studied as a form of social engagement and social motivation that has wide ranging positive and negative effects on academic performance and a child's sense of belonging and adjustment (Juvonen & Wentzel, 1996).

It has been shown that adjustment to school derives from several aspects of children's relationships with peers. Wentzel and Asher (1995) found that popular children were viewed as helpful, good students. Rejected/aggressive students, relative to average and rejected/submissive children, showed little interest in school, were perceived by teachers as dependent, and were seen by peers and teachers as inconsiderate, non-compliant, and prone to causing trouble in school. Many of the problems that lead to rejection, such as the display of disruptive and aggressive behavior, make it difficult for a child to adjust to the climate of most classrooms.

These findings were consistent with longitudinal findings reported by Ollendick, Weist, Borden, and Greene (1992) who showed that children who were actively disliked by their peers were anywhere from two to seven times more likely to fail a subsequent grade than better accepted children. Similarly, Coie, Lochman, Terry, and Hyman (1992), in a 3-year longitudinal study, found that higher levels of social rejection predicted later grade retention and poorer adjustment to the transition to middle school. Likewise, based on a 4-year longitudinal study, DeRosier, Kupersmidt, and Patterson (1994) reported that the experience of peer rejection in any 1 of the first 3 years of their study placed children at significantly greater risk for absenteeism in the 4th year, even after statistically controlling for initial levels of absenteeism.

Given these longitudinal connections between peer rejection and later poor school performance and truancy, it is not surprising to learn that children who have

troubled relationships with their peers are more likely to drop out of school than are other children. For example, Ollendick and colleagues (1992) found (in a 5-year longitudinal study) that 17.5% of rejected children had dropped out of school before the end of ninth grade compared to 5.4% of popular or average children.

Factors other than peer rejection appear to be important also. Most notably *friendships* appear to influence school adjustment in many ways. In a longitudinal study with a representative sample of 475 12-year-olds, Cairns et al. (1989) found little reason to conclude that peer rejection by itself carries risk of later dropping out. Instead, the most powerful precursors of later dropping out were aggression and academic difficulties, especially when the latter were simultaneously present. They showed that many school dropouts appeared to have satisfactory social lives and, as a result, gravitate to peers who shared their negative dispositions toward school. These conditions, in turn, lead to lower academic performance and, in some cases, school drop out.

These latter findings are important because they show that peer group norms may influence academic performance. For example, Kindermann (1993) identified the subgroups that constituted the larger peer groups in the children's elementary school classrooms. Each group was assessed according to its overall level of the academic motivational orientation. He found that children typically associated with peers who had a motivational orientation similar to their own. Moreover, using a longitudinal design, he found that children's motivational orientations toward school were in accord with the initial orientation of the peer group in which they were constituents. Recently, Hymel, Comfort, Schonert-Reichl, and McDougall (2002) noted that adolescents who drop out of school are more likely than other students to have associated with peers who do not regard school as useful and important. These authors argued that the two variables from the peer system that appear to be associated with school drop out are (1) peer rejection and (2) close association with peers who place little emphasis on academic achievement and active school participation.

Similar factors seem to be important with younger children also. In a series of studies, Ladd and colleagues (Ladd, 1990, 1991; Ladd, Kochenderfer, & Coleman, 1996, 1997) demonstrated the potential influence of close dyadic relationships on academic performance. Ladd (1990) obtained repeated measures of friendship, sociometric status, and school adjustment during the

transition to kindergarten. Although children's personal attributes (mental age and prior school experience) predicted early school performance, measures of social adjustment with peers were much better predictors by comparison. Children with many friends at the time of school entry developed more favorable attitudes toward school in the early months than children with fewer friends. Those who maintained their friendships also liked school better as the year went by. Making new friends in the classroom also predicted gains in school performance. By comparison, measures of school performance at the start of the transition to kindergarten did not generally forecast gains in social adjustment. In addition, children who were rejected by peers were less likely than other children to have positive attitudes toward school and they were less likely to show a positive school performance. These findings show clearly that even during the early childhood years, friendships with and acceptance by peers are strongly linked to children's academic success. Because Ladd used a longitudinal design in which initial assessments of academic orientation and peer relationships were accounted for, his findings suggest a causal link between friendship and academic outcome.

In a subsequent study, Ladd, Kochenderfer, and Coleman (1997) examined the association between children's perceptions of best friendship quality in kindergarten and indices of scholastic adjustment (school-related affect, perceptions, involvement, and performance) in grade school (transition from kindergarten to grade school). Their main finding replicated, at the dyadic level, one of the findings observed by Kindermann (1993) at the group level. Specifically, Ladd et al. (1997) reported that children who viewed their friendships as a source of validation or aid, tend to (a) feel happier at school, (b) see their classmates as supportive, and (c) develop positive attitudes toward school.

In two studies, the effect of early adolescent friendship was demonstrated clearly and in richer ways than seen previously. Berndt, Hawkins, and Jiao (1999) showed that adjustment to junior high school was facilitated by engagement in friendships that were stable and of high quality (e.g., rated as high in closeness and support). Wentzel, McNamara-Barry, and Caldwell (2004) also examined friendship and the adjustment to a junior high school. They showed that friendless children were lower in prosocial behavior and higher in affective distress both concurrently and 2 years later. They noted that friends' characteristics can act as a form of social

motivation that can either increase or decrease an early adolescent's adjustment to school.

In summary, it appears reasonable to conclude that children's peer relationships play a central role in promoting or maintaining academic adaptation. This role occurs at several levels of peer group analysis: Peer rejection may serve the purpose of making school an unwelcome venue for children and adolescents, and the lack of friends may fail to provide the necessary support for children and adolescents to fare well in school. Alternatively, a child's peer group may actually serve to develop and reinforce poor school-related goals and behaviors. Thus, the role of the peer culture appears too significant to be dismissed in practical efforts designed to encourage promising school aspirations and performance; indeed, this is an area that requires further empirical and practical substantiation in the future.

### Psychological Adjustment

Ample evidence exists that difficulties with peers place a child at risk for developing subsequent problems of a psychological nature. Consistent with the general trends of the peer literature, research on the long-term consequences of peer experiences has focused largely on rejection and friendship.

### Externalizing Problems

Results of longitudinal studies have indicated that peer rejection in childhood predicts a wide range of *externalizing* problems in adolescence, including delinquency, conduct disorder, attention difficulties, and substance abuse. These findings are not particularly surprising given the well-established link between aggression and peer rejection, and especially given that aggressive-rejected children are more likely to remain rejected over time.

Kupersmidt and Coie (1990) reported the findings of a longitudinal study in which they followed-forward a group of fifth grade children for 7 years. Children identified as sociometrically rejected were twice as likely to be delinquent (35%) in adolescence than was the case for the sample base rate (17%). In a second study, Ollendick et al. (1992) followed sociometrically rejected, neglected, popular, controversial, and average status 9-year-old children for 5 years; at the follow-up, rejected children were perceived by their peers as less likable and more aggressive than popular and average children. Rejected children were also perceived by their teachers

as having more conduct problems, aggression, motor excess, and attention problems than their popular and average counterparts. Moreover, rejected children reported higher levels of conduct disturbance and substance abuse and committed more delinquent offenses than the popular and average children. Controversial children were similar to rejected children on most measures. For example, children in the two groups committed similar numbers of delinquent offenses.

Similar findings concerning the predictive outcomes of rejected status have been reported by Bierman and Wargo (1995) and Coie, Terry, Lenox, Lochman, and Hyman (1995). In both of these longitudinal studies, peer rejection in combination with the early display of aggressive behavior, predicted externalizing problems. More recent research has shown that *early* peer rejection provides a unique increment in the prediction later antisocial outcomes, even when controlling for previous levels of aggression and externalizing problems (Ladd & Burgess, 2001; Miller-Johnson, Coie, Maumary-Gremaud, Bierman, & Conduct Problems Prevention Research, 2002; Miller-Johnson, Coie, Maumary-Gremaud, Lochman, & Terry, 1999; Wentzel, 2003). For example, Laird, Jordan, Dodge, Pettit, and Bates (2001) followed 400 children from early childhood through to adolescence. They reported that sociometric rejection at ages 6 to 9 years predicted externalizing problems in adolescence, even when controlling for the stability of externalizing problems over this age period.

Given the less than perfect stability of rejected status, it would seem reasonable to ask whether psychological risk status is equivalent for children with chronic versus episodic and transient rejection by peers. To address this question, DeRosier, Kupersmidt, and Patterson (1994) followed 640 7- to 9-year-old children for 4 years. They found that children who were more chronically rejected over the first 3 years of the study were at greatest risk for behavior problems in the 4th year, even after controlling for initial level of adjustment. More recently, Miller-Johnson et al. (2002) showed that peer rejection in first grade added incrementally to the prediction of early starting conduct problems in third and fourth grades, over and above the effects of aggression. Similarly, Dodge and colleagues (2003) reported that peer rejection predicted longitudinal "growth" in aggression over time (controlling for original levels of aggression) from early to middle childhood, and from middle childhood to adolescence. These researchers also found a developmental pathway in which peer

rejection led to more negative information processing patterns (i.e., hostile cue interpretation), which led to increased aggression. Certainly part of the association between rejection and externalizing involves the network of peer involvement experiences by rejected children. Brendgen, Vitaro, and Bukowski (1998) showed that rejected children were more likely than other boys and girls to associate with delinquent peers and that these associations accounted for their subsequent delinquency. Consistent with expectations related to the process of deviancy training (Dishion et al., 1996), at-risk children, especially boys, who have aggressive friends appear to influence each other with reinforcements and enticements (Bagwell & Coie, 2004) so as to increase each other's aggression. These processes likely explain why gang membership is a good predictor of developmental trajectories of aggression (Lacourse, Nagin, Tremblay, Vitaro, & Claes, 2003). These mechanisms appear to account for the development of substance abuse problems also (Dishion, Capaldi, & Yoerger, 1999; Dishion & Owen, 2002).

### ***Internalizing Problems***

Results from a growing number of studies have indicated that anxious-withdrawal is contemporaneously and predictively associated with internalizing problems during the life span, including low self-esteem, anxiety problems, loneliness, and depressive symptoms (e.g., Coplan, Prakash, O'Neil, & Armer, 2004; Gest, 1997). Rubin and colleagues followed a group of children from kindergarten (age 5 years) to the ninth grade (age 14 years). They reported that withdrawal in kindergarten and second grade predicted the following outcomes in fifth grade: peer rejection, self-reported feelings of depression, loneliness, and negative self-worth and teacher ratings of anxiety (Hymel et al., 1990; Rubin & Mills, 1988). In turn, social withdrawal in the fifth grade predicted self-reports of loneliness, depression, negative self-evaluations of social competence, feelings of not belonging to a peer group that could be counted on for social support, and parental assessments of internalizing problems in the ninth grade (Rubin, Chen, McDougall, Bowker, & McKinnon, 1995). Using a follow-back design with a group of adolescents who had been classified according to clique membership, Prinstein and La Greca (2002) found adolescents' self-reports of peer crowd affiliation to be concurrently associated with self-concept and levels of internalizing distress. Their analyses of internalizing trajectories revealed that "Populars/Jocks" had experienced significant declines in internalizing

distress across adolescences whereas "Brains" showed increases in internalizing distress between childhood and adolescence.

Researchers have also recently begun to explore the *unique* role of peer rejection in the prediction of internalizing problems. For example, in a longitudinal study following 405 children from kindergarten to grade 7, Kraatz-Keily, Bates, Dodge, and Pettit (2000) reported that peer rejection predicted increases in both internalizing and externalizing problems over time. Moreover, Burks, Dodge, and Price (1995) found that chronic rejection in middle childhood predicted the subsequent development of internalizing difficulties (depression, loneliness) 6 years hence. Their results held only for boys who had been rejected for 2 consecutive years; chronicity of rejection did not predict internalizing problems for girls. The authors speculated that girls' rejection by the larger peer group is less severe than the lack of close, intimate relationships with a friend.

Relatedly, Gazelle and Ladd (2003) found that shy-anxious kindergarteners who were also excluded by peers displayed a greater stability in anxious solitude through the fourth grade and had elevated levels of depressive symptoms as compared to shy-anxious peers who did not experience peer exclusion. Indeed, Gazelle and Rudolph (2004) recently found that over the course of fifth and sixth grade, high exclusion by peers led anxious solitary youth to maintenance or exacerbate the extent of social avoidance and depression; increased social approach and less depression resulted from the experience of low exclusion.

In understanding the link between peer rejection and psychosocial adjustment, it may also be important to consider the role of children's *perceptions* of their *own* peer rejection. Children's *perceived* rejection has been associated with increases in depression over time (e.g., Kistner, Balthazor, Risi, & Burton, 1999). Moreover, Sandstrom, Cillessen, and Eisenhower (2003) demonstrated that children's self-appraisal of peer rejection was associated with increased internalizing and externalizing problems even after controlling for actual peer rejection. Thus, children's *beliefs* that they are rejected may play an influential role in the development of psychosocial maladjustment.

The majority of the research regarding *friendship* and subsequent internalizing problems has considered the effects of friendship as either a moderator or as a mediator. Hodges, Boivin, et al. (1999) examined whether friendship would moderate the associations between victimization and depressed affect. Using a longitudinal

design they showed that young adolescents with friends *and who were victimized* subsequently showed lower levels of depressed affect than did young adolescents who were friendless and victimized. Specifically, for young adolescents without a friend, being victimized at the beginning of the school year predicted increases in internalizing and externalizing behaviors from the beginning to the end of the school year, while there was no link between being victimized and adjustment for those with friends. Relatedly, Rubin et al. (2004) found that when fifth graders (10- to 11-year-olds) reported difficulties in their relationships with their mothers and fathers, having a strong supportive best friendship buffered them from negative self-perceptions and internalizing problems.

The notion that friendship may buffer rejected children from negative outcomes has been examined in a number of recent studies. However, the findings in these studies have been somewhat counterintuitive. For example, Hoza, Molina, Bukowski, and Sippola (1995) and Kupersmidt, Burchinal, and Patterson (1995) reported that having a best friend actually *augmented* negative outcomes for children who were earlier identified as rejected and aggressive. One explanation for these findings emanates from findings noted earlier that the friendship networks of aggressive-rejected children comprise other aggressive children; the existence of a friendship network supportive of maladjusted behavior may actually exacerbate the prospects of a negative developmental outcome for rejected children (Cairns et al., 1989; Tremblay, Mâsse, Vitaro, & Dobkin, 1995). Finally, Nangle, Erdley, Newman, Mason, and Carpenter (2003) examined whether the association between being well-liked by peers (i.e., being accepted) and feelings of loneliness would be explained by the *mediating* effects of friendship. In the model supported by their data, acceptance was an antecedent to friendship, which, in turn, negatively predicted loneliness and depression.

### Summary

Studies of the predictive relations between children's peer relationships and their subsequent academic and psychological adjustment generally support the notion that experiences with peers represent a risk factor for maladjustment. The extant data reveal that the types of friends a child may have, or the groups in which she or he participates, may influence individual adaptation.

Despite these conclusions, however, it is important to note that most of the longitudinal studies are typically limited in a few critical ways. First, the design of most

studies precludes conclusions about causality. An interpretation of causality is warranted only when other potential pathways between the initial peer measures and the subsequent adjustment variables have been accounted for (Kupersmidt, Coie, & Dodge, 1990). For example, the initial level of adjustment must be controlled for if an unequivocal conclusion about causal relations is to be reached. Second, the possibility of multicollinearity must be considered. We have noted that there is neither conceptual nor empirical independence between measures of peer experiences taken from different levels of social complexity. For example, measures of aggression and group acceptance are intercorrelated. One repercussion of such associations is that if researchers want to conclude that a given measure from the peer domain predicts some outcome, it is necessary to control for the other measures with which the predictor may be confounded. Third, although the growth of the literature on peer relationships was inspired by studies that followed individuals over long periods, most current studies are of a short duration.

Considering how a set of measures will function together to affect outcome will also satisfy substantive objectives as well as methodological concerns. Inherent in theoretical positions regarding the peer system is the notion that experience in one domain of the peer system may compensate for, or enhance, experience in another domain. For example, if it is true that friends influence one another, the experience of having a friend will vary according to what the friend is like. Or, as we have shown, the experience of being rejected by peers appears to be different for children who are aggressive and those who are nonaggressive. The implication of these concerns regarding the associations among measures from different domains of the peer system is that using a single factor model to understand the link between peer experiences and outcome is likely to result in both an empirical and conceptual dead end.

### CONCLUSIONS

In this chapter, we have reviewed literature concerning (a) developmental norms in children's peer interactions, relationships, and groups; (b) the developmental significance of peer interaction, discussion, and shared differences of opinion; (c) the importance of friendship; (d) the significance of social skills and social competence; (e) the assessment of children's peer experiences; (f) the proximal and distal predictors of peer acceptance; and

(g) the outcomes of qualitative differences in peer relationships histories. The study of peer relationships has never been as active or as diverse as it is now. As we have tried to show, remarkable progress has been made in describing and explaining the features, processes, and effects of children's experiences with their age-mates. A consequence of this progress is that peer research must now answer new questions and deal with new challenges. An additional repercussion of our progress is that the gaps in our understanding of the peer system become clear. We address these concerns in this concluding section. Specifically, we identify three current challenges and opportunities for peer research, and we identify three topics that deserve more attention than they have received in the past.

### Three Critical Challenges

First, we propose that the efforts to study peer relationships as a system need to be continued and intensified. The study of peer relationships has been frequently predicated on the concept that peer relationships, however construed, must be viewed as either an antecedent or consequence. Consistent with the view that development is a dynamic, multidirectional process (Sameroff & MacKenzie, 2003), the study of peer relationships needs to be understood as a complex system. Children bring various behaviors, needs, and cognitions into their peer experiences at the dyadic and group level. In turn, these individual characteristics affect the features of these experiences and the provisions that children derive from these experiences leading to changes, for better or worse, in the child's subsequent short-term and long-term functioning. Although this approach has already been widely used, the adoption of a fully integrated model such as the one we have proposed has been rare.

The study of transactional models of development has been aided by the evolution of statistical procedures (e.g., structural equation modeling, growth curve analyses, hierarchical linear modeling, and survival analyses) that allow examination of bidirectional and reciprocal influences in multivariate longitudinal data sets. Although researchers of peer relationships have used these analytic procedures for at least 20 years, the number of investigations incorporating these techniques remains lower than one might expect.

Second, the features and effects of experiences with peers need to be understood according to the larger systems in which they are embedded and according to how

they interface with other systems. Opportunities for peer interaction and relationships vary from one culture to another and different cultures ascribe different degrees of significance to them. The "content" of peer interactions and relationships is likely to vary, for example, as a function of how much power is ascribed to kinship structures and by who makes primary decisions about allowable extrafamilial relationships. Because the defining features or characteristics of what it means to be adapted to one's social context will differ across contexts, the impact on adaptation of particular characteristics of peer relationships is likely to vary also. Finally, in a culture, the effect of the peer system is likely to vary according to differences between children in provisions they obtain in their families. Indeed, a central tenet of the seminal views of Sullivan (1953) was that the developmental significance of friendship will be higher for children whose relationships with parents was less than optimal than for other children.

A third challenge concerns the development of interventions to help children who have troubled experiences with peers and to more generally promote and facilitate more positive peer experiences among children. There now exists an extensive literature addressing how to improve children's social skills (Bierman, 2003). Nevertheless, further development of techniques is needed to help children develop healthy friendships, to decrease the frequency and the effects of victimization, to regulate emotions and inhibit maladaptive behavior, and to enhance the power of the peer system as a positive factor in development. It is important to remember that intervention research provides an important assessment of the causal pathways implicated in the link between poor peer relationships and later adjustment. Specifically, through intervention, researchers can learn whether improvements in adjustment with peers also reduce children's relative risk for subsequent adjustment disturbances.

An important feature of the literature on intervention is developmental sensitivity. The role that children's peer relationships play in development appears to vary with age. For example, we have noted that children's ideas about friendship become increasingly abstract with age. Furthermore, children's friendships are posited to play an increasingly important role with age. Yet, little is known about the potential adaptive effects of friendship or about *when* it is in childhood that friendship can serve as an accelerator, promoter, or inhibitor of adaptation or as a buffer against the ill-effects of parental or peer neglect or rejection. This issue of the functional signifi-

cance of friendship may prove helpful in the planning of intervention programs for children who have poorly developed social skills and peer relationships.

### Three Questions in Search of Answers

In spite of its diversity and breadth, at least three fundamental aspects of peer interactions, relationships, and groups are nearly absent from our review. First, *what accounts for interpersonal attraction?* The question of attraction may be implied in many of the topics we have discussed; nevertheless, its explicit presence as a topic of study in the contemporary literature is, at best, weak. This gap is surprising, and regrettable, given the potential significance of interpersonal attraction as a phenomenon at the front end of the relationship process. If we are going to claim that who one befriends or is attracted to makes a difference, knowing something about the factors underlying attraction is necessary. Thus far, two sets of ideas have been proposed. Whereas one model has emphasized general patterns of attraction (i.e., children are generally drawn to helpful peers), another has emphasized the importance of similarity on a dyadic level. Similarity as an explanation of attraction has elicited some empirical scrutiny (e.g., Hamm, 2000; Rubin et al., 1994), but the model has not been pushed hard or analyzed carefully. This inattention is surprising given the ease with which similarity between peers can be studied, especially by exploiting the advantages of such statistical techniques such as multilevel modeling.

Second, *what aspects of peer interactions, relationships, and groups affect boys and girls differently?* The study of sex differences is covered sporadically throughout this chapter and is seen also in Ruble, Martin, and Berenbaum (Chapter 14, this *Handbook*, this volume). There are many exemplary studies of how peer interactions and relationships differ for boys and for girls. A central gap in the literature is the understanding of whether some aspects of peer interactions and relationships affect boys and girls differently. This question is not about whether there are differences between the features of peer interactions and relationships of boys and girls. Instead, it is concerned with potential differences in the functions and the developmental significance of peer experiences for boys and girls. Knowing if and how the peer system works differently for boys and girls would certainly add to our understanding of peer relationships; it would augment our understanding of sexual differentiation as well.

Third, *what are the provisions of peer relationships?* Friendship, acceptance, and popularity have been studied extensively. We know how to measure these constructs, and we know a good deal about their antecedents and their consequences. Yet, we know little about what it is that children and adolescents “get” from these relationships. To be sure there have been theoretical propositions about why friendship is important and how acceptance and rejection can influence child and adolescent development. But there have been few studies of the specific opportunities and experiences that are afforded by friendship, acceptance, and popularity. And there have been fewer studies of the significance of friendship and/or peer acceptance and rejection for children who vary with regard to sex, ethnicity, and behavioral characteristics. Certainly, the role of culture remains to be fully explored. This question is not simply one of description. Research on friendship, for example, is based on claims about the putative provisions of this relationship. Similar comments can be offered about acceptance and, to a lesser extent, popularity. Further inquiry into what these experiences provide for children would help us better understand the value of the theories we have relied on.

Our review is now complete. We have examined that which we know and we have attempted to raise questions about that which we must come to know in the future. There is no doubt that many interesting and important questions remain unanswered. This should not be surprising given that the modern history of peer research began only 35 years ago with Willard Hartup's 1970 chapter in this *Handbook*. But growth begets growth, and it is encouraging to realize that there is no shortage of topics for us to study.

Prosocial behavior—voluntary behavior intended to benefit another—is of obvious importance to the quality of interactions between individuals and among groups. However, scientists did not devote much attention to prosocial development prior to 1970, perhaps because

the consequences of aggression, criminality, and immorality had greater salience for society.

Prosocial behaviors may be performed for a host of reasons including egoistic, other-oriented, or practical concerns (Boxer, Tisak, & Goldstein, 2004; Eisenberg, 1986). Of particular importance is the subgroup of

---

---

Development to Richard A. Fabes. Appreciation also is expressed to Carolyn Zahn-Waxler for comments on earlier drafts of this manuscript.

prosocial behaviors labeled *altruism*. A common definition of altruism is “intrinsically motivated voluntary behavior intended to benefit another”—acts motivated by concern for others or by internalized values, goals, and self-rewards rather than by the expectation of concrete or social rewards or the avoidance of punishment (Eisenberg & Mussen, 1989). However, because it usually is impossible to differentiate between altruistically motivated actions and actions motivated by less noble concerns, it is necessary to focus on the broader domain of prosocial behaviors.

Emotion plays a particularly important role in the development of prosocial values, motives, and behaviors. Especially relevant are empathy-related emotions. Definitions of *empathy* vary; we define it as an affective response that stems from the apprehension or comprehension of another’s emotional state or condition, and which is identical or very similar to what the other person is feeling or would be expected to feel.

It is necessary to differentiate empathy from related vicarious emotional responses, particularly sympathy and personal distress. *Sympathy* is an affective response that frequently stems from empathy, but can derive directly from perspective taking or other cognitive processing, including retrieval of information from memory. It consists of feeling sorrow or concern for the distressed or needy other (rather than feeling the same emotion as the other person is experiencing or is expected to experience). *Personal distress* also frequently stems from exposure to another’s state or condition; however, it is a self-focused, aversive emotional reaction to the vicarious experiencing of another’s emotion (e.g., discomfort, anxiety; see Batson, 1991; Eisenberg, Shea, Carlo, & Knight, 1991). As discussed later, empathy and sympathy have been strongly implicated in prosocial development and action. Thus, these vicarious emotional reactions are discussed to some degree throughout the chapter.

In the initial sections of this chapter, we briefly discuss philosophical perspectives on prosocial development, as well as several grand psychological theories that have influenced the field. Then the empirical literature related to prosocial responding in children is reviewed. Because there have been few recent studies on the role of situational factors such as cost and benefits, situational skills, or mood inductions on prosocial behavior, these topics are not reviewed (see Eisenberg & Fabes, 1998, for a review). In the final

sections of the chapter, a model for integrating the factors believed to relate to prosocial responding is presented briefly, and gaps in the field and future directions are discussed.

In this chapter, we review many of the major topics in the literature on prosocial development. Due to space constraints, we have sometimes built on previously published reviews. We generally have emphasized topics of central importance to prosocial development and issues that have emerged in the past decade or two. Further, we have confined our coverage to a somewhat narrow definition of prosocial responding. For example, the literature on cooperation, the personality trait of agreeableness, or the allocation of rewards generally is not emphasized, although some investigators of prosocial behavior included cooperation as well as other types of prosocial behavior in their index of prosociality (in these cases, we sometimes have included the study with other citations, but often refer to it in listings under “also see . . .”). Again due to space limitations, we often cite the more recent studies when there are numerous reports pertaining to a given issue. Interested readers can refer to the earlier version of this chapter in the fifth edition of this *Handbook* (1998) to obtain additional citations, especially references prior to 1990.

## PHILOSOPHICAL ROOTS OF PROSOCIAL BEHAVIOR

Philosophical concepts of prosocial behavior and sympathy often have their roots in religious doctrine. The commandment “Thou shalt love thy neighbor as thyself” is a basic tenet in Judaism and Christianity. Similarly, the parable of the Good Samaritan, who pitied and helped an injured man (Luke 10:29–37), often is cited as an example for Christians. In Buddhism, the *via positiva* outlines the virtues necessary to reach *Nirvana* (ultimate happiness), including *dana* (giving), *metta* (kindness), *mudita* (sympathetic joy), and *karuna* (compassion).

Given the influence of religion in philosophy, it is not surprising that philosophers have discussed the origins of prosocial and moral behaviors for centuries. Of particular relevance, philosophers have debated whether any human action is truly unselfish and, relatedly, the doctrine of ethical egoism (i.e., whether it is unreasonable to behave in a manner contrary to one’s own self-interest). According to Thomas Hobbes (1651/1962), a

vocal advocate of egoism and self-love, selfishness might produce helping, but the motivation for such prosocial action would primarily be to relieve the helper's own distress. He also believed that the only motivation for cooperative action lay in the fear of some outside agent.

Later philosophers began to refute the doctrine of ethical egoism. Rousseau (1773/1962) believed that human nature was basically good and that humans have an innate sensitivity toward others. In his view, if individuals were able to develop this natural state of nobility and sensitivity, a strong sense of moral obligation to others and concern for the common good would develop. He believed society corrupts this innate moral nature.

Kant (1785/1956) also refuted the doctrine of ethical egoism and argued that if an action is one's duty, that is reason enough to do it, independent of one's own interests. According to Kant, prosocial and moral behavior and values involve one's will and self-control, and stem from universal, impartial principles that are totally detached from emotion.

Nagel (1970) differentiated between pure rational altruism and behavior motivated by sympathy, love, or other emotions. In his view, the involvement of affect in the helping process tainted its purity. In contrast, David Hume (1748/1975) argued that moral emotions such as sympathy, benevolence, and concern for humanity are fundamental incentives of human action and that prosocial behaviors often are based on these incentives. Susceptibility to sympathy and empathy was viewed as an innate human propensity. Similarly, sympathy and related affective responses were core elements of A. Smith's (1759/1982) moral and social system. Smith believed that sympathy was an innate endowment, instigated by the perception of others' conditions and the desire to see them happy for purely altruistic reasons. For Smith, sympathy was not solely a primitive awareness of others' suffering; it was a complex capacity influenced by awareness of aspects of the situation or the person involved.

Lawrence Blum (1980) has been particularly vocal in refuting some of Kant's ideas about the role of emotion in morality. He pointed out that rational processes do not always produce moral action and that the sense of duty (viewed by Kant as rational) is no more immune to the distorting and weakening effects of personal feelings than is sympathy for another. Blum further suggested that because emotions such as sympathy and empathy promote perspective taking and understanding

of others, they sometimes produce rationality and may, in addition, induce more and higher quality prosocial behavior than does rationality. Similarly, Slote (2001, 2004) argued that caring is a true virtue that is involved in moral judgment and that empathy is essential to the development of morally based caring about others. Relatedly, current writings on "altruistic (or compassionate) love" (which correlates with sympathy; L.G. Underwood, 2001) and *agape* (altruistic love universalized to all humanity; Post, 2001) in theology and philosophy are relevant to the notions of selfless love and to extending caring to people outside one's ingroup.

In summary, philosophers have viewed people as primarily egoistic, primarily noble and generous, or somewhere in between. Philosophical debate about the nature and existence of altruism is alive and well in contemporary psychology, particularly in social (e.g., Batson & Powell, 2003) and evolutionary (Konner, 2002) psychology. However, it is often difficult to discriminate people's motives and conceptions of their prosocial behavior. Thus, philosophical concerns are not highly salient in developmental work and are reflected primarily in work on moral judgment influenced by cognitive developmental theory.

## PSYCHOLOGICAL THEORIES

As might be expected, the grand theories that have had considerable influence on developmental psychology have affected thinking about prosocial development, particularly in the past. Thus, pertinent ideas in psychoanalytic theory, behaviorism and social learning theory, and cognitive developmental theory are discussed briefly. In addition, recent work on prosocial behavior has been influenced by minitheories such as Hoffman's theoretical contributions to understanding empathy (1982, 2000) and socialization (1970, 1983) and Grusec's (e.g., Grusec & Goodnow, 1994) and Staub's (1979, 1992, 2003) thinking about socialization. Some of these conceptual frameworks are referred to briefly later in this chapter.

### Psychoanalytic Theory

In Freud's psychoanalytic theory, children are born with innate, irrational sexual and aggressive impulses directed toward self-gratification (the id). They develop a

conscience (superego) at about age 4 to 6 years as a means of resolving the conflict between their own hostile and sexual impulses and their fears of parental hostility or the loss of parental love. The superego is the outcome of the process of identification, by which children internalize their same-sex parents' values and introject these values. Once children develop a superego, they may behave prosocially to avoid the guilt inflicted by the conscience for not doing so or based on the internalization of values consistent with prosocial behavior (e.g., Freud, 1933/1968). In many versions of psychoanalytic theory, guilt, self-destructive tendencies, and sexual strivings underlie altruism (Fenichel, 1945; Glover, 1968). Prosocial actions often are defense mechanisms used by the ego (the rational part of personality) to deal with the irrational demands of the superego.

However, Freud and other psychoanalysts sometimes have acknowledged more positive roots of altruism. Freud (1930) asserted, "Individual development seems to us a product of the interplay of two trends, the striving for happiness, generally called 'egoistic,' and the impulse toward merging with others in the community, which we call 'altruistic'" (1930, p. 134). Other theorists such as Ekstein (1978) have built on Freud's emphasis on the importance of the early mother-child relationship for the development of empathy, identification, and internalization.

Perhaps the greatest contribution of psychoanalytic work to theory on prosocial responding is the construct of identification. Social learning theorists in the 1960s and 1970s adapted this construct to refer to children's internalization of parents' norms, values, and standards as a consequence of a positive parent-child relationship (e.g., Hoffman, 1970). This theoretical perspective had a significant impact on the early work on the socialization of altruism.

### Behaviorism and Social Learning Theory

Early behaviorists posited that children learn primarily through mechanisms such as conditioning. This perspective is reflected in some of the relatively early work on the role of reinforcement and punishment in promoting prosocial behavior (e.g., Hartmann et al., 1976) and in work concerning the development of empathy through conditioning (Aronfreed, 1970).

Social learning theorists allowed internal cognitive processes to play a greater role. For example, contingencies need not actually occur; people can vicariously

learn the likely consequences of a behavior through observation and verbal behavior. Imitation is viewed as a critical process in the socialization of moral behavior and standards (Bandura, 1986).

In current cognitive social learning theory, the interplay of cognition and environmental influences in moral development is complex. According to Bandura (1986; also see Hoffman, 2000), moral rules or standards of behavior are fashioned from information from a variety of sources such as intuition, others' evaluative social reactions, and models. Based on experience, people learn what factors are morally relevant and how much value to attach to each one. Socializers provide information about behavioral alternatives, expectations, and possible contingencies for different courses of action; model moral behaviors; reinforce and punish children for various actions; and influence the development of self-evaluative reactions (e.g., guilt). Moreover, thought, behavior, and environmental events all interact and influence one another, and the individual's attentional and regulatory processes play a role in the learning of moral behavior. Moral and prosocial functioning are thought to be governed by self-reactive responses (e.g., self processes such as self-sanctions, personal agency) and other self-regulatory processes rather than by dispassionate abstract reasoning (Bandura, 2002). Additionally, the regulation of affect has an important influence on prosocial behavior. Support for this argument has been found: Perceived self-efficacy in the regulation of positive affect was related to perceptions of empathic efficacy, which in turn were related to prosocial behavior (Bandura, Caprara, Barbaranelli, Gerbino, & Pastorelli, 2003). Thus, perceived self-efficacy to manage basic affective states plays a pivotal role in the causal processes determining the likelihood of empathic responding and prosocial behavior.

### Cognitive Developmental Theory

The cognitive developmental perspective on morality, as represented by the work of Piaget (e.g., 1932/1965) and Kohlberg (e.g., 1969, 1984), concerns primarily the development of moral reasoning and other social cognitive processes rather than moral behavior. Kohlberg described moral development as an invariant, universal, and hierarchical sequence of stages progressing as a function of sociocognitive development (e.g., perspective taking). Kohlberg emphasized the contributions of cognition, particularly perspective taking, to morality

and minimized (but did not fully neglect) the contributions of emotion and socialization (Kohlberg, 1969). Moreover, because of Piaget's and Kohlberg's assumption that young children have limited perspective-taking abilities, investigators influenced by cognitive developmental work assumed for years that other-oriented prosocial behavior was not likely to emerge until the early school years.

The cognitive developmental perspective is discussed by Turiel (Chapter 13, this *Handbook*, this volume). Its primary relevance for this chapter is that Kohlberg's theory influenced Eisenberg's (e.g., Eisenberg, 1986) work on prosocial moral reasoning. However, although Eisenberg views sociocognitive development as playing an important role in the development of prosocial moral reasoning, she does not view all stages of prosocial reasoning (especially the higher ones) as universal or as involving the hierarchical integration of lower stages. Rather, environmental and emotional factors are believed to play a considerable role in the development and use of prosocial moral reasoning. Thus, Eisenberg's conception of moral reasoning differs considerably from the traditional cognitive developmental perspective.

### **Current Conceptual Emphases: Positive Psychology and Positive Youth Development**

Positive psychology and positive youth psychology are not fully developed theories, but perspectives that recently have influenced the study of prosocial behavior. Although prosocial behavior was a popular topic of study in the 1970s and early 1980s, interest declined in the late 1980s and the 1990s. Since the late 1990s, there has been a resurgence of interest in the positive aspects of human development, spurred by the positive psychology movement. This movement is an effort to counteract the focus on negative aspects of psychological functioning (e.g., problems with psychological adjustment) and highlight human strengths. As summarized by Seligman and Csikszentmihalyi (2000), the field of positive psychology concerns subjective experiences (e.g., well-being, optimism), positive personal traits (e.g., the capacity for love, interpersonal skills, forgiveness, wisdom), and "civic virtues and the institutions that move individuals toward better citizenship: responsibility, nurturance, altruism, civility, moderation, tolerance, and work ethic" (p. 1). Similarly, the positive youth development perspective is a strength-based conception of adolescence that highlights plasticity in development and the "poten-

tial for systematic change in behavior . . . as a consequence of mutually influential relationships between the developing person and his or her biology, psychological characteristics, family, community, culture, physical and designed ecology, and historical niche" (Lerner et al., 2005, p. 13; also see Lerner, Dowling, & Anderson, 2003).

Although prosocial behavior has not been a primary topic of interest for those researchers most associated with the positive psychology movement, some psychologists (Aspinwall & Staudinger, 2003a; Eisenberg & Ota Wang, 2003) have argued that interpersonal and relational strengths such as sympathy, compassion, cooperation, tolerance, and altruism are important topics of investigation for those investigators concerned with positive psychological development. In fact, prosocial and empathic development are discussed in some books on positive psychology (e.g., Aspinwall & Staudinger, 2003b; Lopez & Snyder, 2003), and the positive psychology movement has stimulated renewed interest in prosocial behavior and sympathy by including the topic in various books and conferences. Similarly, caring is viewed as one of five components of positive youth development (along with competence, confidence, connection, and character); thus, some relevant research contains measures of sympathy or related constructs (e.g., Lerner et al., 2005).

Now that the conceptual roots of work on prosocial responding have been reviewed briefly, we turn to the review of the empirical literature. We first examine theory and empirical work on developmental trends in prosocial responding, followed by discussion of the potential origins of prosocial behavior (biological, cultural, and socialization). Next we consider the sociocognitive, empathy-related, dispositional, and situational correlates of prosocial behavior. In the final sections, age and sex differences in prosocial behavior are considered.

### **BIOLOGICAL DETERMINANTS OF PROSOCIAL BEHAVIOR**

In examining the major theoretical and empirical approaches to understanding the determinants of prosocial behaviors, most efforts have been directed at identifying the situational, social, and individual factors that affect the degree to which prosocial behavior is learned and enhanced (see M.S. Clark, 1991; Eisenberg, 1986, for reviews and examples). Relatively little of the empirical

work on prosocial behavior has focused on the genetic and neurohormonal substrates of such behavior. The lack of empirical work is somewhat surprising given the attention that genetic, evolutionary, and neurohormonal factors have received in the literature on antisocial, aggressive, and criminal behavior (see Ellis & Hoffman, 1990). As noted by Eisenberg, Fabes, and Miller (1990), some of the biological factors that affect antisocial behavior are also likely to account for variations in prosocial behavior and therefore warrant consideration in any major review of prosocial behavior and development.

### Evolutionary Explanations

Prosocial actions such as helping and sharing have frequently been observed among nonhuman animals (e.g., E. O. Wilson, 1975, 1978). Various social insects (such as certain honeybees, ants, and wasps) frequently sacrifice their own lives while defending their hives or nests from intruders. Similarly, some birds give off a warning call that informs other birds of a predator's presence. The call, however, occasionally helps predators locate the call giver, thereby resulting in its capture and death.

Sharing and cooperation also have been observed among nonhuman animals (Trivers, 1971; Wilson, 1975), as have consoling behaviors and empathy among chimpanzees (Preston & de Waal, 2002). Van Lawick-Goodall (1968) reported that chimpanzees often hand over portions of their catch to other chimpanzees who beg for food. Similarly, certain wild African dogs that live in packs share the prey they catch with members of the pack who stay behind to guard the pups. Common to all these examples is that in some way one animal has improved the chances of one or more animals reaching some sort of goal (protection, feeding, care of young, etc.).

Explanations have been proposed for the prosocial actions of animals. Wilson (1975, 1978) and others (e.g., Barash, 1977) have advanced the notion of *kin selection*, which is a broadened view of natural selection. They argue that through self-sacrificing or cooperative actions, the prosocial animal increases the probability that its relatives, who share its genes, will survive and reproduce. Thus, even if the prosocial animal dies, its genes will be passed on to the next generation by its surviving relatives. The genes selected for by evolution contribute to their own perpetuation, regardless of the individual carrying the animal's genes.

The percentage of shared or common genes is hypothesized to be an important determinant of altruism dis-

played among species members—more altruism would be expected to be directed toward more closely related kin than toward distant kin or those who are unrelated (Hastings, Zahn-Waxler, & McShane, 2005). Thus, for kin selection to be effective (in an evolutionary sense), altruists must be able to distinguish between individuals who are their kin and those who are not. Rushton and associates (Rushton, Russell, & Well, 1984) proposed that there is an innate ability to recognize someone who is genetically similar. Evidence from the study of a wide variety of species supports the conclusion that certain animals may be genetically programmed to identify their own kin (Alberts, 1976; Leon, 1983). Evidence for a similar genetic predisposition in humans is much less clear-cut (Fabes & Filsinger, 1988). There is, however, evidence that humans are more willing to assist others who are genetically related to themselves (Bar-Tal, Bar-Zohar, Greenberg, & Hermon, 1977) and that the degree of biological relatedness is positively associated with willingness to help (Cunningham, 1985/1986). In addition, the more valuable the helpful act is, the more likely it is to come from kin (Borgida, Conner, & Manteufel, 1992; Essock-Vitale & McGuire, 1985). People also are likely to seek out and assist others who are similar to themselves (Eisenberg, 1983; Rushton et al., 1984). Because individuals who share proximity and who are physically similar are likely to share more genes than dissimilar others, the predisposition to help others who are similar may enhance the survival of persons likely to share genes with the altruist.

In many species (including humans), prosocial behavior also is extended toward nonrelatives. Hall and DeVore (1965) described the tendency for baboons to form alliances and fight as a unit in aggressive encounters. Female bluebirds occasionally provide foster parenting to young birds deserted by their mothers (Hayes, Felton, & Cohen, 1985).

Trivers (1971, 1983) uses the term *reciprocal altruism* to explain instances of prosocial behavior that are directed to recipients so distantly related to the organism performing the altruistic act that kin selection can be ruled out. Trivers argues that under certain conditions natural selection favors these altruistic behaviors because in the long run they benefit the organism performing them. Cleaning symbiosis is a case in point. Both host and cleaner benefit from the relationship (e.g., the host is cleaned of parasites and the cleaner is fed and sometimes protected). There also apparently has been selection for the host to avoid eating one's

cleaner (Trivers, 1971). These behaviors cannot be explained by kin selection because they are performed by members of one species for the benefit of members of another species.

Another evolutionary explanation of prosocial behavior is that of *group selection* (Wynne-Edwards, 1962). According to this view, altruism among group members may benefit the survival of the group. Thus, groups with altruistic members are less likely to become extinct than groups comprised of nonaltruistic members. This perspective, however, has not received strong support (Boorman & Leavitt, 1980). Group selection works very slowly and it would take an exceedingly long time for an entire group to become extinct. In the short run, selfish members would have a competitive edge over altruistic members (Krebs & Miller, 1985). Altruistic members would die out long before the group does. Therefore, the forces underlying group selection do not appear compatible with the evolution of a group with altruistic members.

In summary, evolutionary perspectives on prosocial behavior suggest that these behaviors result from evolutionary forces (Sober & Wilson, 1998). Prosocial behaviors may have been selected because they (a) increase individuals' survival to reproductive age, (b) increase the reproductive capacity of the individual, and (c) increase either or both of these tendencies in other members of the species that likely carry the same genes. Inherent in this argument is that evolutionary forces favoring altruistic behaviors often come into conflict with those forces that favor behaviors maximizing the survival of the individual. Out of this complex interplay of competing forces comes the potential to act prosocially and to account for individual differences in prosocial responding (Hofer, 1981).

### Heritability of Prosocial Tendencies

Twin studies have been used to examine the genetic contribution to individual differences in prosocial responding. In these studies, if the correlation between scores on prosocial responding is higher for identical twins than for fraternal twins, the difference is attributed to genetic effects to the degree that common environmental sources are assumed to be roughly equal for the two types of twins.

In twin studies involving adults' self-reports of prosocial tendencies, researchers have found that genetic factors accounted for between 40% and 70% of the

variance in twins' altruism, empathy, and nurturance (Hastings et al., in press). Most of the remaining variance was accounted for by idiosyncratic differences in the environments of the twins rather than by their shared environment (Rushton, Fulker, Neale, Nias, & Eysenck, 1986; also see Davis, Luce, & Kraus, 1994), although in one study of adults, the variance in prosocial behavior was linked primarily to shared and nonshared environment (Krueger, Hicks, & McGue, 2001). It is likely that the common shared variance decreases with age (Scarr & McCartney, 1983; Scourfield, John, Martin, & McGuffin, 2004).

W. Johnson and Krueger (2004) examined the heritability of middle-aged adults' personality traits that likely relate to prosocial qualities. Using twin data, they found that about 50% of the variance in extraversion and neuroticism was explained by genetic influences; however, this was not the case for agreeableness, openness, and conscientiousness. Agreeableness is believed to contribute to, or overlap with, prosocial tendencies (Graziano & Eisenberg, 1997). Thus, although genetics appear to contribute to children's prosocial tendencies, genetically informed studies also provide evidence for the role of the environment in the origins of prosocial behavior.

Relatively few twin studies involve children, and the strength of the heredity estimates has varied somewhat across studies. In one study of 5- to 16-year-olds, the estimate for the genetic contribution was about 52% for parental reports, but considerably higher for teachers' reports of prosocial behavior (Scourfield et al., 2004). In another study, Zahn-Waxler and colleagues (Plomin et al., 1993; Zahn-Waxler, Robinson, & Emde, 1992; Zahn-Waxler, Schiro, Robinson, Emde, & Schmitz, 2001) examined twins' behavioral reactions to simulations of distress in others. Estimates of heritability indicated a significant genetic component for empathic concern, prosocial acts, and maternal reports of prosocial acts at 14 months of age, albeit the variance accounted for was much less than 50% for all but maternal reports (indicating that environmental factors also contributed to prosocial development). At 20 months, empathic concern (sympathy) and prosocial acts continued to evidence significant genetic contributions. Active indifference also showed significant genetic influence at 14 months; however, there was no evidence of heritability for self-distress at either 14 or 20 months (Zahn-Waxler et al., 1992). Plomin et al. (1993) found no evidence of genetic influence on change in a composite

index of children's empathy from 14 to 20 months of age, although genetic factors partially accounted for stability over time in empathy.

In follow-ups in which additional twins were added to the sample, empathic concern continued to show evidence of genetic influence at 24 and 36 months, whereas prosocial acts and indifference did so only at 36 months. Mothers' reports of children's prosocial behavior showed a genetic influence only at 14 months; it was predicted by shared environmental variance at older ages (Zahn-Waxler et al., 2001). Moreover, there is evidence that heritable differences may account for toddlers' empathy-related responding toward an unfamiliar adult, whereas shared environmental influences account for concern toward the mother (Robinson, Zahn-Waxler, & Emde, 2001). The differences in the findings reported at earlier and older ages may have been due to the smaller sample in the assessments conducted in the 2nd year of life. Regardless, the magnitude of any genetic influences on these observed measures of concern generally were modest. Moreover, Robinson and colleagues found there was no significant genetic variance in children's positive reactions to others' distress at 14 months; it was moderately strong at 20 months and disappeared again at 24 months (Robinson, Emde, & Corley, 2001). Thus, there appears to be considerable variability in heritability estimates across age and measures of prosocial responding.

The role of genetic and environmental influences in children's prosocial tendencies also has been tested in other types of genetically informed studies. In a study of stepfamilies, Deater-Deckard, Dunn, et al. (2001) found that most of the variance in adults' reports of children's (mostly preschool and school age) prosocial behavior was due to environmental (not genetic) factors, especially aspects of the environment that were not shared by the children, although there was significant variance for shared environmental effects. Moreover, in a study involving only identical pre-school-age twins, Deater-Deckard, Pike, et al. (2001) obtained additional evidence of the role of nonshared environment (e.g., maternal supportive and punitive behaviors) in predicting children's prosocial behavior.

Other evidence relevant for examining the role of genetics in prosocial behavior is found in studies of children with certain genetic abnormalities. Williams syndrome, caused by a microdeletion of part of the long arm of chromosome 7, is associated with a specific personality profile that includes highly sociable, empathic,

sympathetic, and prosocial interpersonal behavior (Mervis & Klein-Tasman, 2000), perhaps even more so than for normal children or those with some other disorders such as Prader-Willi or fragile X syndrome (Jones et al., 2000; see Semel & Rosner, 2003). Thus, the highly specific and sensitive social profile of individuals with Williams syndrome suggests that hemizygous deletion of one or more genes is involved in biasing (but not determining) development toward these components of prosocial behavior.

### Neurophysiological Underpinnings of Prosocial Responding

Behavioral genetics research provides information regarding the presence and size of genetic contributions to prosocial behavior, but does not identify the conditions or processes of organism-environment interaction through which genotypes are transformed into phenotypes. Research and theory on the neurological processes may provide a mechanism for mediation between genetics and overt behavior (see Hastings et al., 2005, for a recent review). Panksepp (1986) suggested that brain opioids influence the degree to which social contact is reinforcing and that fluctuations in brain opioids and the underlying emotive systems affect altruistic behavior. Panksepp also hypothesized that during social interactions (which are affected by brain opioids), animals may become better attuned to the emotions of their conspecifics and thereby become better able to alleviate their distress when it occurs.

Panksepp asserted that all mammalian helping behavior arises from the "nurturant dictates of brain systems that mediate social bonding and maternal care" (1986, p. 44). This view is consistent with that of MacLean (1985), who argued that the basis for altruism lies in maternal behavior, affiliation, and play, which are mediated in part by the limbic system of the brain. MacLean further suggested that the prefrontal neocortex, which developed relatively recently in evolution and is most distinctive in humans, provides the basis for concern for others and a sense of responsibility and conscience.

There have been direct attempts to identify the neural roots of prosocial behavior and emotions. It has been argued that the perceptual bases of empathy may be "mirror neurons"—neurons that fire not only when a monkey executes an action but also when it observes another monkey or human performing the same action (Gallese, 2001). In addition, Decety and Chaminade

(2003) used positron emission tomography neuroimaging (i.e., PET scanning) to demonstrate that the neural structures known to be involved in emotional responding (e.g., amygdala and the adjacent orbitofrontal cortex and the insula) were activated when people listened to sad stories designed to elicit sympathy; listening to neutral stories did not cause similar neural activation. Increased neural activity was also found in the cortical regions involved in shared motor representations (e.g., dorsal premotor cortex, right inferior parietal lobule)—areas of the brain thought to be important when taking the perspective of others (Ruby & Decety, 2001).

Other researchers have highlighted the importance of frontal cortical activity in sympathetic responses. Harmon-Jones, Vaughn-Scott, Mohr, Sigelman, and Harmon-Jones (2004) found that anger provocation increased left frontal cortical activity and decreased right activity; however, high levels of sympathetic responses were found to eliminate these effects. Moreover, Eslinger and colleagues (1998; Eslinger, Eastin, Grattan, & Van Hoesen, 1996) studied individuals with front lesions and found that when the lesion was in the dorsolateral front system, deficits in cognitive aspects of empathy resulted. In contrast, when lesions were in the orbitofrontal system, deficits in the more emotional aspects of empathy resulted. Such findings suggest that complex neural responses likely are involved in prosocial actions and reactions, a conclusion that is consistent with Panksepp's (1986) assertion that it may be unrealistic to assume that functional unitary brain circuits will be discovered for global constructs such as altruism, sympathy, and prosocial behavior.

In summary, it is likely that biological factors play some role in individual differences in empathy and prosocial behavior. However, much of the relevant research on biological mechanisms comes from work with nonhumans, and existing behavioral genetics work is limited in quantity and scope. Moreover, it is unclear whether some of the aforementioned biological correlates of empathy or prosocial behavior play a causal role in individual differences among people in prosocial tendencies (e.g., they may simply be correlates or consequences of empathy). Pertinent theory is speculative and underdeveloped. Finally, there is evidence that the environment plays a critical role in prosocial development, even in the behavioral genetics research. The key to understanding human prosocial behavior lies in determining how biological factors, prior environmental influences on the child, and the current context jointly affect prosocial behavior and development (with the in-

fluence of biology being probabilistic rather than deterministic; Wachs, 1994).

## DEVELOPMENTAL TRENDS IN THE EMERGENCE OF PROSOCIAL TENDENCIES

According to both theory and empirical findings, prosocial behavior and empathy emerge early in life. In this section, we first briefly review Hoffman's theory of the development of prosocial behavior, and we then examine age changes in prosocial behavior and empathy-related responding.

### Theory

Hoffman (1982, 2000) proposed a four-level theoretical model that delineates the role of infants' and children's affect and cognitive sense of self-awareness and self-other differentiation in the emergence of prosocial behavior. Specifically, he outlined the developmental shift over time from self-concern in response to others' distress to empathic concern (i.e., sympathy) for others that results in other-oriented prosocial behavior.

In Hoffman's first stage, newborns and infants display rudimentary empathic responses that are manifested as "global empathy." Hoffman argues that the young infant has not acquired a sense of self-other differentiation (at least in regard to emotional states) and experiences empathic distress through one or more of the simpler modes of empathy (e.g., based on reactive crying, conditioning, mimicry). Because young infants cannot differentiate their own distress from that of another, they often experience self-distress in response to another's distress, as evidenced in their reactive crying in response to the sound of another's cry (viewed as a simple form, or precursor, of global empathy). Beginning around the end of the 1st year of life, infants experience *egocentric empathic distress* and are thought to seek comfort for themselves when exposed to others' distress. At this level, infants have begun developing a sense of self as separate from others; however, this sense is quite immature (i.e., they cannot fully differentiate between their own distress and that of another). Thus, the infant is likely to respond to empathic and actual distress situations in the same way.

Early in the 2nd year of life, toddlers begin to make helpful advances toward a victim of distress (i.e., patting, touching). Around the same age, they may intervene by hugging, giving physical assistance, or getting

someone else to help (Zahn-Waxler & Radke-Yarrow, 1982). Hoffman labels this level *quasi-egocentric empathic distress*. According to Hoffman (2000), toddlers in this developmental period can differentiate between self and other, although they still do not distinguish well between their own and another's internal states. Nonetheless, toddlers can experience empathic concern for another, rather than solely seek comfort for themselves. They also can and sometimes do try to comfort another person, but such prosocial behavior is likely to involve giving the other person what the toddlers themselves find comforting. Empathy at this level differs from the previous stage because toddlers are not purely egocentric and are more likely to respond with appropriate empathic affect.

Stern (1985) has argued that young children develop a subjective self capable of recognizing the subjectivity of the other earlier than stated by Hoffman (2000). Although this issue has not been resolved, the affect attunement ("a recasting or restatement of a subjective state," p. 161) or emotional resonance between parent and child discussed by Stern—albeit believed to be largely out of the child's conscious awareness—may foster the early development of affective empathy, especially if parents are empathic in their interactions.

Sometime during the 2nd year of life, children enter the period of *veridical empathic distress*. According to Hoffman (1982, 2000), this stage marks the period in which children are increasingly aware of other people's feelings and are capable of understanding that other people's perspectives and feelings may differ from their own. Thus, prosocial actions reflect an awareness of the other person's needs (versus the egocentric empathy of the previous stage), and children can be more accurate in their empathic responses and help others in less egocentric ways. Moreover, with the development of language, children are able to empathize and sympathize with a wider range of emotions than they previously could. However, according to Hoffman, children's empathic responses are restricted to another's immediate, or situation-specific, distress.

As children develop more sophisticated perspective-taking skills and the ability to think abstractly, the ability to experience empathic responses even when the other person is not physically present (e.g., if they hear or read about someone in distress) emerges (Hoffman, 1982). Moreover, by mid to late childhood, children can empathize with another person's general condition or plight. Further, the adolescent is capable of comprehending and responding to the plight of an entire group

or class of people, such as the impoverished or the politically oppressed. Thus, Hoffman (1982) proposed that with increasing cognitive maturation, children are better able to respond with concern to others' distress.

### **Empirical Studies of the Development of Prosocial Behavior**

In this section, we review empirical studies that provide insight into the development of prosocial tendencies. To organize these, we review them according to the ages of the participants in the study.

#### ***Infancy and Childhood***

Compared with research in older children, adolescents, and adults, research examining prosocial behavior in young children is relatively limited. Nonetheless, there is some empirical support for Hoffman's theory. There is evidence that newborn infants exhibit some form of global empathy as displayed by their reactive crying in response to the cries of another infant (Martin & Clark, 1982; Sagi & Hoffman, 1976). Of particular interest, infants exhibit more distress in response to another infant's crying than to their own (Dondi, Simion, & Caltran, 1999), suggesting that they are biologically predisposed to experience a rudimentary form of empathy. However, some researchers have questioned the interpretation of these findings (Eisenberg & Lennon, 1983); for example, infants may simply find a novel cry to be more aversive than their own cry.

Around 6 months of age, infants will sometimes respond to the cry of another infant by crying, but they frequently ignore it or merely orient toward the peer (Hay, Nash, & Pederson, 1981). By 38 to 61 weeks of age, infants sometimes react to others' distress by orienting and distress cries, but they occasionally display positive affect, such as smiling or laughing (Zahn-Waxler & Radke-Yarrow, 1982).

Thus, it appears that infants are responsive to others' emotional signals. In a study in which mothers expressed sadness or joy in view of their 9-month-old infants, the infants displayed more negative emotional expressions and tended to avert their gaze away from their mothers in the sadness condition and expressed more joy when they viewed their mothers' expressions of joy (Termine & Izard, 1988). Moreover, studies of social referencing show that infants not only are responsive to others' emotional signals, but also make use of them to guide their own behavior in an ambiguous situation (see Saarni, Mumme, & Campos, 1998; Saarni

et al., Chapter 5, this *Handbook*, this volume). During the 2nd year of life, toddlers display the ability to discuss their own and others' emotions and show significant improvements in this skill between 18 and 36 months of age (Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986). These findings demonstrate that very young children are affected by the emotions they observe in others.

Around 12 to 18 months of age, infants clearly react to others' negative emotions (often with orienting and distress reactions) and sometimes react to others' distress with concerned attention and prosocial behavior, including positive contact and verbal reassurance (Zahn-Waxler, Robinson, et al., 1992). These patterns have been found in interactions with mothers (Zahn-Waxler, Robinson, et al., 1992), siblings (Dunn, 1988), peers (Denham, 1986; Howes & Farver, 1987), and strangers (Johnson, 1982).

In one of the earliest studies of children's sympathy and prosocial behavior, Lois Murphy (1937) found that preschool children reacted to another's distress in a variety of ways. Children's responses ranged from sympathy and prosocial initiations to egocentric and unsympathetic reactions, such as laughing, aggression, or ignoring. These findings have been replicated in other samples with young children (Radke-Yarrow & Zahn-Waxler, 1984; Zahn-Waxler & Radke-Yarrow, 1982; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). Moreover, researchers have found that responsiveness to peers' distress in naturalistic settings is relatively infrequent among toddlers and preschoolers (Caplan & Hay, 1989; Howes & Farver, 1987; Phinney, Feshbach, & Farver, 1986). In a naturalistic study examining toddlers' responses to peers' distress in day care, Lamb and Zakhireh (1997) found that toddlers responded to a peer's distress with prosocial behavior in only 11 out of 345 incidents. Factors that appear to relate to children's prosocial responding include whether a peer's distress persists for a long period or if the particular peer is one who infrequently becomes distressed (Caplan & Hay, 1989).

As proposed by Hoffman (1982, 2000), prosocial behaviors have been associated with indices of cognitive development. Toddlers who display evidence of self-recognition (indicating a self-other distinction) tend to be relatively empathic and are likely to display prosocial behaviors (Bischof-Koehler, 1991; Johnson, 1982; Zahn-Waxler, Radke-Yarrow, et al., 1992; Zahn-Waxler, Schiro, et al., 2001). Further, children's perspective taking (as indexed by their hypothesis testing [e.g.,

attempts to label or understand why the other is distressed] or social referencing) in the 2nd year of life and at age 4 to 5 years has been positively related to their prosocial behaviors (Kiang, Moreno, & Robinson, 2004; Zahn-Waxler, Cole, Welsh, & Fox, 1995; Zahn-Waxler, Robinson, et al., 1992). Similarly, preschool children's emotion knowledge has been positively related to prosocial behavior toward adults who express negative emotion (Denham & Couchoud, 1991) and toward younger siblings (Garner, Jones, & Palmer, 1994).

Other types of prosocial behavior besides sympathetic or comforting responses to others' distress have been examined in young children. The tendency to give objects to other people is common in early childhood, and young children have been observed sharing objects with parents, other adults, siblings, and peers (Hay, 1994). Object sharing seems to emerge around 8 months of age and is increasingly evident during the next year (Hay & Rheingold, 1983). In general, prosocial behavior has been found to increase in the early years of life (Zahn-Waxler & Radke-Yarrow, 1982; Zahn-Waxler, Schiro, et al., 1992, 2001). For example, Zahn-Waxler, Schiro, et al. (1992, 2001) and Robinson et al. (2001) studied toddlers' empathy-related responding to an experimenter and the mother feigning injuries at 14, 20, 24, and 36 months of age. They found an increase with age in empathic concern, hypotheses testing, and prosocial behavior. Van der Mark, van IJzendoorn, and Bakermans-Kranenburg (2002) also found an increase in empathy/prosocial responding (combined) from 16 to 22 months when toddlers' mothers were distressed. Further, Lamb and Zakhireh (1997) found that age was positively related to toddlers' prosocial behavior toward peers.

Moreover, nonempathic responses (e.g., self-oriented distress reactions) seem to decrease in the second and 3rd year of life (Zahn-Waxler, Radke-Yarrow, et al., 1992; Zahn-Waxler et al., 2001). Toddlers' indifference toward another's distress has been found to decline from 14 to 20 months of age and then increase between 24 and 36 months (Zahn-Waxler et al., 2001). Nonetheless, with increasing age, preschoolers are more likely to respond to others' distress with empathy and prosocial behaviors (Hastings, Zahn-Waxler, Robinson, Usher, & Bridges, 2000; Lennon & Eisenberg, 1987; Phinney et al., 1986).

Although many empirical studies have demonstrated the hypothesized increase in prosocial behavior over time, Hay (1994; Hay, Caplan, Castle, & Stimson, 1991) proposed a developmental model which predicted that prosocial action would emerge in the 2nd year of life and

*decline* after that. She argued that after the age of 2, prosocial action becomes more regulated such that it is shown to some but not to all potential recipients (e.g., prosocial actions become increasingly differentiated based on gender and personality). In one study with girls and boys in three age cohorts (18 to 24 months, 24 to 30 months, and 30 to 36 months), Hay found the hypothesized decline in sharing with peers between 18 and 24 months of age; however, the trend was not reliable thereafter. In addition, the tendency to share was more stable with older toddlers (24- to 36-month-olds) than with younger toddlers (18- to 24-month-olds; Hay, Castle, Davies, Demetriou, & Stimson, 1999). The fact that Hay and colleagues studied sharing with only familiar peers—and in fact “best friends”—may have contributed to the pattern observed; most studies have not involved this type of sharing context. Additionally, the meaning of prosocial behavior may differ across childhood. At young ages, children may exchange toys as part of simple play or to communicate with their friend about the objects they are using (e.g., to show the peer something about a toy or to interest the peer in it).

To bring coherence to the many studies of age-related change in prosocial behavior, Eisenberg and Fabes (1998) conducted a meta-analysis of relevant studies. Overall, there were significant increases in prosocial behavior within both the infant (less than 3 years of age) and the preschool (3 to 6 years) age groups (effect sizes = .24 and .33). In addition, there were increases in prosocial behavior when comparing the preschool group with either the childhood or adolescent age groups. However, there was no difference between the infancy and preschool periods, perhaps due to the relatively small number of studies that compared these age groups ( $n = 11$ ). In addition, school-age children were higher in prosocial behavior than preschoolers (effect size = .30).

In the meta-analysis, prosocial behavior generally increased across the preschool and school years (also see Benenson, Markovits, Roy, & Denko, 2003). However, some of the findings were based on relatively small samples, particularly for comparisons of the youngest children in these samples. We also recognize that the findings of our meta-analysis were based largely on cross-sectional data and on aggregations of data from studies that varied greatly in their quality and methodologies.

Despite possible age-related changes in children's prosocial behavior, there appears to be considerable interindividual stability in children's levels of prosocial responding. Côté, Tremblay, Nagin, Zoccolillo, and Vi-

taro (2002) examined the continuity of trajectories for helpfulness across early elementary school (measured annually from age 6 to age 12 years). Generally, children who entered kindergarten with specific levels of helpfulness finished primary school at similar levels. The observed degree of stability in these trajectories was impressive considering that ratings of helpfulness were provided by independent raters (i.e., different teachers at different years).

### *Adolescence*

**Age Trends.** Prosocial tendencies appear to increase from childhood into adolescence. According to Eisenberg and Fabes's (1998) meta-analysis, adolescents tend to be higher in prosocial behavior than children aged 7 to 12 years, albeit on sharing/donating, but not instrumental helping or comforting. Both young adolescents (13 to 15 years) and older adolescents (16 to 18 years) were higher than elementary school students in their prosocial tendencies (Fabes, Carlo, Kupanoff, & Laible, 1999). Thus, adolescents exhibit more prosocial behavior than do younger children; however, this pattern was noted only for particular types of studies. Although there was not an overall increase in prosocial responding across adolescence (from age 12 to 17 or 18), prosocial behavior increased in adolescence for the few studies of sharing/donating (but not helping), and in experimental/structured studies (but not naturalistic/correlational studies; see Eisenberg & Fabes, 1998; also see Jacobs, Vernon, & Eccles, 2004). Moreover, helping of victims of aggression may actually decline across adolescence (Lindeman, Harakka, & Keltikangas-Jarvinen, 1997; also see Pakaslahti, Karjalainen, & Keltikangas-Jarvinen, 2002).

In the meta-analysis, prosocial behavior directed toward adults did not change with age in adolescence. This finding may primarily reflect findings in the family setting. Investigators have found nonlinear age-related changes or no consistent change in adolescents' and parents' reports of adolescents' parent-directed prosocial behaviors (e.g., Eberly & Montemayor, 1998, 1999; also see Keith, Nelson, Schlabach, & Thompson, 1990), as well as a decline in helpfulness toward parents between fifth and ninth grades (Eberly, Montemayor, & Flannery, 1993).

Based on Hoffman's theory, one would expect an age-related increase in empathy-related responding during adolescence, especially in situations in which empathy or sympathy is directed toward abstract groups (e.g., deprived groups). In studies conducted before about

1986, findings regarding age trends in empathy-related responding in adolescence were inconsistent, although there was some evidence of an increase from childhood into adolescence (e.g., Saklofske & Eysenck, 1983; see Lennon & Eisenberg, 1987). Since 1987, there has been additional longitudinal evidence of an increase in empathy-related responding from 9th to 10th grade, especially for sympathetic concern, and of a decline in personal distress (Davis & Franzoi, 1991). In a cross-sectional study, Strayer and Roberts (1997b) also found that both reported empathic sadness and facial concerned reactions to evocative videotapes (perhaps indicative of sympathy) increased with age from childhood into adolescence (although there was no age difference in affective matching of the emotion in the film). However, some investigators who have conducted cross-sectional studies have obtained mixed evidence of sympathy increasing between 6th and 12th grade (Olweus & Endresen, 1998) or have found little change in sympathy or personal distress from 8th to 11th grades (Karniol, Gabay, Ochion, & Harari, 1998). Finally, a longitudinal study (Eisenberg, Cumberland, Guthrie, Murphy, & Shepard, 2005) did not find change in sympathy from age 15 to 16 into the 20s, although personal distress declined with age. Thus, there may be a modest increase in sympathy with age, especially in early to mid-adolescence, although it is not clear that sympathy increases in mid- and late-adolescence.

**The Potential Effects of Adolescents' Participation in Prosocial Service.** A type of prosocial behavior that appears to be much more common in adolescence than at younger ages is volunteering. Approximately half of all adolescents engage in some type of community service or volunteer activity (National Center for Education Statistics, 1997). Volunteerism is an interesting type of prosocial behavior because it generally is sustained over some period of time (rather than performed only once) and is expected to have some enduring effect on youths' prosocial, civic, and personal development.

Although motives for volunteering vary and are sometimes self-related rather than altruistic (Clary & Snyder, 1999), investigators have found that high school students who volunteer appear to benefit from the experience. Of these studies, few have used random assignment (for an exception, see Allen, Philliber, Herrling, & Kuperminc, 1997), although most have included a comparison control group or a pre/post design (see Moore &

Allen, 1996; Yates & Youniss, 1996a). In general, researchers have found volunteering is associated with increases in adolescents' self-esteem and self-acceptance, moral development, and belief in one's personal responsibility to help (Conrad & Hedin, 1982; see Switzer, Simmons, Dew, Regalski, & Wang, 1995, for similar results for a required helping program), as well as concern for social issues and future intended service (Metz, McLellan, & Youniss, 2003).

In a panel design of youth volunteers and nonvolunteers in which the initial levels of variables correlated with volunteering were controlled, volunteering was related to gains in subsequent intrinsic work values and the anticipated importance of community involvement (Johnson, Beebe, Mortimer, & Snyder, 1998). There is also evidence that service participation (voluntary or not) is related to decreases in course failure, truancy, suspension from school, school dropout, disciplinary problems, and pregnancies, as well as with improved reading skills (see Allen, Kuperminc, Philliber, & Herre, 1994; Allen et al., 1997; Calabrese & Schumer, 1986; Moore & Allen, 1996; Switzer et al., 1995; also see Eccles & Barber, 1999). Finally, in a prospective longitudinal study, volunteer work negatively predicted subsequent arrests, even when controlling for the effects of antisocial propensities, prosocial attitudes and behavior, and commitment to conventional lines of action (Uggen & Janikula, 1999). Quality of the program (e.g., allowing adolescents autonomy and choice, being challenging and enjoyable), length of the program (programs 12 weeks or more tend to be more successful than shorter programs), and age of adolescents (in some programs, older youth benefited more) all appear to affect potential benefits of volunteering (Moore & Allen, 1996). Thus, participation in service activities—a common adolescent activity—is related to both prosocial and other developmental outcomes.

### **Moderators of Age Trends across Childhood and Adolescence**

Viewed more generally, the extant literature appears to support the conclusion that as children get older, they exhibit more sympathy and prosocial behavior. This trend does not hold, however, for children of all ages or for all measures of prosocial behavior (see Radke-Yarrow, Zahn-Waxler, & Chapman, 1983; Zaratany, Hartmann, & Gelfand, 1985). In fact, in the previously mentioned Eisenberg and Fabes (1998) meta-analysis,

age differences in prosocial behavior sometimes varied as a function of study characteristics. These differences did not vary as a function of type of prosocial behavior for studies conducted with young children; moreover, across the remaining age group comparisons (involving older children), the magnitude of age differences was relatively constant in size when the type of prosocial behavior was sharing, comforting, or an aggregated index. In contrast, the magnitude of the age-related effect size for instrumental helping varied more across the older age group comparisons. The magnitude of this effect size was relatively high when the type of prosocial behavior was instrumental help for the childhood versus preschool and within-childhood comparisons and relatively low for the adolescent versus childhood and the within-adolescence comparisons.

The magnitude of the effect sizes differed significantly by the method of data collection (e.g., observation, self-report, other-report) only for childhood/preschool, childhood/childhood, and adolescent/childhood comparison groups. For both the childhood/preschool and childhood/childhood age comparison groups, effect sizes for age differences were significantly higher when prosocial tendencies were measured with observations or self-reports than when assessed with reports obtained from other people. For the adolescent versus childhood comparisons, effect sizes were significantly higher when measured with observational or other report methods rather than with self-report methods.

For all age-comparison groups, effect sizes were greater in experimental/structured designs than in naturalistic/correlational designs (although the difference was not significant for infant/infant and preschool/preschool comparisons). Finally, the magnitude of the effect size differed significantly by the target of the prosocial behavior, but this was true only for childhood/preschool, childhood/childhood, and adolescent/adolescent comparison groups. In the first two age comparison groups, effect sizes were larger when the target was an adult and lowest when the target was unknown/unspecified (with child targets in between). In contrast, for the adolescent/adolescent comparison, the effect size was greater when the target was a child compared with an adult.

There also were differences in the procedures used to measure prosocial behavior in different age groups. Instrumental help was relatively unlikely to be used as a measure of prosocial behavior with children under 7

years of age. Moreover, naturalistic/correlational designs were relatively likely to be used with very young children, whereas experimental/structured designs were more often used with older children. Additionally, adults were likely to be used as targets of children's prosocial behavior in studies with the youngest and oldest age groups, whereas children were likely to be the potential recipients of prosocial behavior for children not at the age extremes. Thus, age-related differences in prosocial behavior may have varied as a function of differences in study characteristics that differed across age groups.

To explore this possibility, we examined age differences in prosocial behavior while controlling for study characteristics (through hierarchical regression analyses). Age differences in prosocial behavior were found to be smaller as the mean age of the sample increased, as the sample size increased, and in studies published more recently. Moreover, although type of prosocial behavior was related to effect sizes for age prior to controlling for study characteristics, effect sizes were not affected by type of prosocial measure (instrumental help, sharing/donating, aggregated, comforting) after partialling out other study characteristics. However, after controlling for study characteristics (and not before), a larger increase in prosocial behavior with age was found when prosocial behavior was measured with self- or other-reports rather than with observations.

In brief, the findings of our meta-analysis suggested that age differences in prosocial behavior differed in magnitude as a function of the specific age comparison, the measure of prosocial behavior, and the type of analysis. However, combining across all studies and study characteristics, we still found a significant, positive effect size for age differences in prosocial behavior. Thus, our data support the conclusion that as children get older, prosocial behaviors generally are more likely to occur, although there may be variation within age groups and for various measures and methods.

### **Processes Potentially Related to Changes with Age in Prosocial Responding**

For some theorists, the primary source of the increase in prosocial and altruistic behavior across age is sociocognitive development, including understanding and decoding others' emotions, evaluative processes (evaluating behaviors and situations in terms of moral standards), and planning processes (Krebs & Van Hesteren, 1994).

Aspects of socioemotional responding (e.g., moral emotions, regulatory capacities) also partially account for age-related changes in prosocial behavior (Hart, Burock, London, & Atkins, 2003).

### *Sociocognitive Processes*

As noted by Krebs and Van Hesteren (1994) and Hoffman (1982), attention to the needs of others transforms egoistic affect to other-oriented affect, rendering it increasingly altruistic. Throughout infancy and childhood, children develop an increasingly refined understanding of others' emotional states and cognitive processes, and are better able to decode other people's emotional cues (see Eisenberg, Murphy, & Shepard, 1997, for a review). As is discussed later, such perspective taking and related sociocognitive skills are associated with prosocial responding. Moreover, with age, children are more likely to have the social experience necessary to perceive another's need in social contexts in which overt cues of distress are ambiguous or subtle (see Pearl, 1985), and to distinguish real versus apparent emotional states (Gosselin, Warren, & Diotte, 2002). In addition, younger children appear to weigh costs to the self more than do older children when deciding whether to assist others (see Eisenberg, 1986) and are less attuned to the benefits of prosocial behavior (Lourenco, 1993; Perry, Perry, & Weiss, 1986). These age-related differences in the analysis of costs and benefits likely contribute to age-related differences in prosocial behavior.

Moreover, numerous researchers have suggested that the quality of children's motivation for assisting others changes with age (e.g., Eisenberg, 1986; Erdley & Asher, 1999; Krebs & Van Hesteren, 1994). Bar-Tal, Raviv, and Leiser (1980) proposed that children's helping behavior develops through six stages that differ in quality of motivation. The first three stages involve helping behaviors that are compliant and in which the child anticipates the gain of material rewards (or the avoidance of punishment). The next two stages involve compliance with social demands and concern with social approval and generalized reciprocity. The final stage represents true altruism in which helping is an end in itself.

Bar-Tal and colleagues found some support for their hypothesized developmental changes in children's motives for helping. For example, older children tend to assist more often than do younger children in contexts in which the effects of compliance and rewards or costs are minimized (Bar-Tal, Raviv, et al., 1980; see Bar-Tal, 1982; Eisenberg, 1986). Although Bar-Tal and col-

leagues sought to delineate a developmental sequence in prosocial motivation, the data concerning this issue are inconclusive (i.e., it is unclear whether all their proposed stages actually emerge in the specified order; see Eisenberg, 1986). Nonetheless, children's reported motives for their prosocial behavior change in ways that generally are consistent with Bar-Tal's stages. Although even preschoolers sometimes give simple other-oriented and pragmatic reasons for their peer-directed prosocial actions (Eisenberg, Lundy, Shell, & Roth, 1985; Eisenberg, Pasternack, Cameron, & Tryon, 1984), researchers generally have found a decrease with age in self-oriented, hedonistic reasons for helping and an increase in other-oriented, internalized, and altruistic motives and reasons for prosocial behavior (e.g., Bar-Tal, Raviv, et al., 1980; see Bar-Tal, 1982; Eisenberg, 1986; cf. Hertz-Lazarowitz, 1983).<sup>1</sup> Thus, in general, the evidence of developmental change in children's motives for assisting others is relatively compelling (see Eisenberg, 1986).

Like Bar-Tal (1982), Krebs and Van Hesteren (1994) proposed age-related forms of altruism, ranging from egocentric and exchange stages (e.g., egocentric accommodation and instrumental cooperation, Stages 1 and 2, respectively), to concern with others' evaluation and behaving in a socially acceptable manner (Stage 3), to altruism motivated by the desire to fulfill an internalized sense of social responsibility (e.g., conscientious altruism, Stage 4). The higher level adult stages are motivated by the desire to uphold self-chosen, internalized utilitarian values (e.g., maximizing benefits to all; autonomous altruism, Stage 5), the goal of fostering maximally balanced and integrated social relationships (e.g., upholding the rights of all people, including the self; integrated altruism, Stage 6), and the goal of universal love stemming from a cosmic feeling of oneness with the universe and a selfless ethic of responsible love, service, and sacrifice that is extended to others without regard for merit (universal self-sacrificial love, Stage 7). Of course, children or adolescents would not be expected to obtain the higher level stages. Although Krebs and his colleagues have not explicitly tested the validity of their stages, their position is supported in the data collected

<sup>1</sup> Here and throughout the chapter, the abbreviation "cf.," meaning "compare with," signifies "contrast with." It indicates that contrary findings were obtained in a study. "Also see" generally indicates that the results in the listed studies are also relevant to discussion of the issue at hand.

by other investigators concerned with the development of moral reasoning, prosocial behavior, and empathy.

Age-related changes in children's evaluative processes and prosocial-relevant goals are reflected in children's prosocial moral reasoning (i.e., reasoning about moral dilemmas in which one person's needs or wants conflict with those of others in a context where authorities, laws, rules, punishment, and formal obligations play a minimal role). In research on prosocial moral reasoning, individuals typically are presented with hypothetical moral conflicts (e.g., about helping an injured child rather than going to a social event), and their reasoning about the conflicts is elicited.

Based on both cross-sectional and longitudinal research, Eisenberg and her colleagues have identified an age-related sequence of children's prosocial reasoning. Preschool and early elementary school students tend to use primarily hedonistic reasoning or needs-oriented (primitive empathic) prosocial reasoning. Hedonistic reasoning decreases sharply in elementary school and increases slightly in adolescence. Needs-oriented reasoning increases until mid-childhood and then levels off in use. In elementary school, children's reasoning begins to reflect concern with others' approval and enhancing interpersonal relationships, as well as the desire to behave in stereotypically "good" ways. However, such reasoning (particularly approval-oriented reasoning) appears to decline somewhat in high school.

Beginning in late elementary school or thereafter, children begin to express reasoning reflecting abstract principles, internalized affective reactions (e.g., guilt or positive affect about the consequences of one's behavior for others or living up to internalized principles and values), and self-reflective sympathy and perspective taking. Thus, although children and adolescents sometimes verbalize immature modes of reasoning, children's moral reasoning becomes more abstract, somewhat less self-oriented, and increasingly based on values, moral principles, and moral emotions with age (Carlo, Eisenberg, & Knight, 1992; Carlo, Koller, Eisenberg, DeSilva, & Frohlich, 1996; Eisenberg, Carlo, Murphy, & Van Court, 1995; Eisenberg-Berg, 1979; also see Hart et al., 2003; Helwig & Turiel, 2003). As discussed later, these age-related changes are linked to prosocial behavior; thus, the processes reflected in children's moral reasoning likely play some role in the age-related increase in quantity and quality of prosocial behavior. However, these processes may include age-related changes in goals and values, as well as in the sociocog-

nitive skills required for high-level moral reasoning (see Eisenberg, 1986).

Sociocognitive processes may underlie the development of children's prosocial behaviors, but engaging in these processes does not ensure the enacting of prosocial actions. Eisenberg and Fabes (1992) suggested that individuals who are well regulated are relatively likely to engage in costly, other-oriented prosocial behavior. Because regulatory capacities likely increase with age (Eisenberg, Smith, Sadovsky, & Spinrad, 2004), we would expect older children, relative to younger ones, to be more likely to respond sympathetically and with prosocial behavior in emotionally evocative situations. Support for the hypothesized relations between children's prosocial tendencies and their behavioral and emotional regulation is discussed later.

### *Age Changes in Empathy-Related Responding*

Developmental change in both children's emotion regulation and in their sociocognitive skills (e.g., Hoffman, 1982, 2000) would be expected to contribute to age-related changes in prosocial behavior, in part by influencing children's tendencies to respond empathically or sympathetically. Lennon and Eisenberg (1987), in a review of the literature, found that age differences in empathy varied with the specific index of empathy used. In general, self-report of empathy/sympathy was positively associated with age in preschool and elementary school years. Facial/gestural indices appeared to be either inversely related or unrelated to age in the early school years, perhaps due to increases with age in children's ability to mask their emotions. As discussed, more recent studies show some evidence (albeit mixed) for increased empathy-related responding in adolescence.

Eisenberg and Fabes (1998) conducted a separate meta-analysis of age differences in empathy (rather than prosocial behavior) in studies published since 1983 and found an overall unweighted effect size of .24 (favoring older children). Moreover, they found that effect sizes in empathy varied significantly by method; they were significant and larger for observational and self-report indices than for nonverbal (facial/physiological) or other-report measures (for which the effect sizes were not significant).

Vitaglione and Barnett (2003) found evidence that empathic anger on behalf of a victimized person motivates desires to help. As children develop the ability to empathize with others, empathic anger may increasingly motivate prosocial behavior.

### *Changes in Experience-Based Competence*

Developmental changes in children's experience-based competencies also affect their ability to engage in prosocial behavior. Peterson (1983) found that when children were specially trained on relevant tasks, age-related increases in helping evaporated. The data in our meta-analysis (see Eisenberg & Fabes, 1998) also suggested that experience-based developmental competencies may contribute to age-related differences in prosocial behavior. For example, age differences in prosocial behavior were relatively pronounced when the index of prosocial behavior was instrumental helping. Older children may provide more direct, instrumental assistance because they possess greater physical and social competence than do younger children.

### *Summary*

Developmental changes in prosocial behavior are complex and are influenced by methodological factors. Moreover, the precise developmental mechanisms involved in producing these changes are not yet fully explicated and likely involve cognitive, social, motivational/emotional, and physical processes and capabilities. The next wave of research should include studies devoted to identifying when and how age-related changes in the sociocognitive, emotional, and regulatory capabilities jointly affect prosocial responding.

## **CULTURAL DETERMINANTS OF PROSOCIAL BEHAVIOR**

Research on the cultural bases of prosocial responding provides insights into the role of the social environment—in contrast to strictly biological factors—in prosocial development. People in different cultures may differ somewhat genetically from one another, but these differences are unlikely to fully account for any large cultural differences found in human social behavior.

Research in non-Western cultures suggests that societies vary greatly in the degree to which prosocial and cooperative behavior are normative, and such differences appear to affect prosocial development. In field studies of individual cultures, some writers have described societies in which prosocial and communal values and behaviors are (or were in the past) highly valued and common, such as the Aitutaki (a Polynesian island people; Graves & Graves, 1983), the Javanese (e.g., Mul-

der, 1996; Williams, 1991), and the Papago tribe in Arizona (Rohner, 1975; see Eisenberg & Mussen, 1989). In contrast, other social and behavioral scientists have described cultures in which prosocial behaviors were rare and cruelty or hostility was the norm, such as the Ik of Uganda (Turnbull, 1972) or the Alorese (on an island east of Java; Rohner, 1975). Moreover, societal experiments such as the communally oriented kibbutzim in Israel (see Nadler, Romek, & Shapira-Friedman, 1979) support the view that subcultural variations can have a substantial impact on prosocial values and behavior.

The perceived practical value of prosocial behavior varies across cultures; such differences may affect even early socialization. It has been reported that in some cultures such as in West Africa, prosocial behavior is encouraged as early as infancy (e.g., infants are offered objects and then encouraged to return the gifts) to foster sharing and exchange norms believed to bind the social group together (Nsamenang, 1992).

In many cases, reports of cultural differences in prosocial responding are based on single-culture studies and qualitative data (or mere observation/inference). Empirical studies of prosocial behaviors and values sometimes include only one culture, sometimes more. Although the results of the empirical research generally are consistent with qualitative cultural studies in highlighting the importance of culture in prosocial development, little is known about cross-cultural differences in actual (rather than reported) prosocial actions directed toward those who are not part of the child's family or community. Nor is it clear what factors mediate or moderate the cultural factors that have been found.

### **Laboratory or Adult- and Self-Report Studies**

Much of the work on cross-cultural and subcultural variation in prosocial behavior is embedded in the research on cooperation, competition, and reward-allocation behavior. In many studies, the measure of cooperation involved overt self-gain; this work is not reviewed. However, researchers consistently have found that children from traditional rural and semi-agricultural communities and from relatively traditional subcultures (e.g., Mexican American children) are more cooperative than children from urban or Westernized cultures (see Eisenberg & Mussen, 1989).

In other studies, children were asked to make a series of choices concerning the distribution of objects (i.e., chips) to the self and a peer when giving the peer more

chips did not change the child's own yield. Brazilian children (Carlo, Roesch, Knight, & Koller, 2001) and Mexican American children generally give more to the peer than do Euro-American children (Kagan & Knight, 1981; Knight, Nelson, Kagan, & Gumbiner, 1982), and the difference for Mexican Americans increases in magnitude from age 5 to 6 years to age 8 to 9 years (Knight & Kagan, 1977b). Sometimes, however, there have been no significant differences between Mexican or Mexican American children and Euro-American children in the selection of options in which the peer could receive more chips than the child (e.g., Kagan & Knight, 1981; Knight, Nelson, Kagan, & Gumbiner, 1982). The tendency to choose more for the peer than for the self is stronger in second- than in third-generation Mexican American children (Knight & Kagan, 1977a), suggesting that acculturation is associated with a decline in prosocial tendencies. Consistent with the latter finding, de Guzman and Carlo (2004) found that acculturation was negatively related to Hispanic adolescents' self-reported prosocial behavior.

In another variation on allocation tasks, some of the choices allow children to give more to the peer at a cost to the self. Mexican American or Mexican children still tend to give more prize chips overall to a peer than do Euro-American children (e.g., Knight, Kagan, & Buriel, 1981). Mexican American children with a stronger ethnic identity have been found to display more concern with others' outcomes on this type of task (Knight, Cota, & Bernal, 1993). On a similar task, Cook Island Polynesian children were more generous than were New Zealand city and rural children of European origin (Graves & Graves, 1983).

In other studies, cross-national or cross-cultural differences in sharing or helping have been examined. Few consistent differences have been found among Western, industrialized countries such as Germany, Russia, Australia, and the United States (e.g., Kienbaum & Trommsdorff, 1999; Russell, Hart, Robinson, & Olsen, 2003), although young Italian adolescents report more prosocial behavior than Hungarian youth, who report more than Czech youth (Caprara, Barbaranelli, Pastorelli, Cermak, & Rosza, 2001). In studies within North and South America, Mexican rural children and Euro-American city children were equally likely to help a peer in a non-competitive context (Kagan & Madsen, 1972) and Mexican American and Euro-American children did not differ in anonymous sharing of candy with an unspecified classmate (Hansen & Bryant, 1980). In contrast,

U.S. first graders shared candy more than did Colombian children of the same age, although some (but not all) of this sharing was passive (i.e., they allowed a peer to take the candies; Pilgrim & Rueda-Riedle, 2002).

More consistent cross-group differences might be found when comparing Eastern and Western cultures. Although Trommsdorff (1995) did not find a difference in German and Japanese 5-year-olds' prosocial behavior with a distressed peer, Stewart and McBride-Chang (2000) found that Asian second graders (from a range of ethnic groups) were more likely than Western Caucasian children in Hong Kong to donate gifts for participating in the study to other children in the classroom who could not participate. Similarly, Rao and Stewart (1999) found that Asian (Chinese Hong Kong and Indian) kindergartners shared more food with a peer than had been found in a sample in the United States, and Asian children were more likely to do so spontaneously and to allow the peer to take some food. Thus, in initial small studies, it appears that Asian children are more likely to engage in prosocial behavior than are Western Caucasian children. This finding may be due to the greater focus on maintaining good relationships with group members (and on the interrelatedness of self and other) in at least some Asian cultures, compared with Western cultures (Markus & Kitayama, 1991).

### Naturalistic Observational Research

Systematic observation of prosocial behavior in different cultures is rare. In the classic study by Whiting and Whiting (1975), prosocial behavior was operationalized as a composite index of offering helping (including food, toys, and helpful information), offering support, and making helpful suggestions. Cultures in which children scored relatively high on prosocial behavior (Kenya, Mexico, Philippines) tended to differ from the other three cultures (Okinawa, India, and the United States) on several dimensions. In prosocial cultures, people tended to live together in extended families, the female role was important (with women making major contributions to the economic status of the family), work was less specialized, and the government was less centralized. Further, children's prosocial behavior was associated with early assignment of chores and taking on responsibility for welfare of family members and the family's economic well-being (also see Whiting & Edwards, 1988). Similar to Whiting's data on chores and family structure, Graves and Graves (1983) found that

Aituaki (Polynesian) children, particularly girls, from urban settings performed fewer chores and were less prosocial than were children raised in traditional extended families.

Consistent with some of the aforementioned laboratory research on Asian and Western children's prosocial behavior, Stevenson (1991) found that the observed incidence of sharing, comforting, and helping in Taiwanese, Japanese, and U.S. kindergarten classes was lowest in the United States (albeit relatively high in all groups). Stevenson and others have argued that Chinese and Japanese societies generally put great emphasis on socializing children to be responsible and prosocial toward others in their group (e.g., the family, the classroom, and the society; also see Hieshima & Schneider, 1994). Privileges and social acknowledgment in the classroom are dependent on group rather than on individual accomplishments. Researchers have also suggested that Japanese mothers traditionally use empathic sensitivity in their parenting to promote their children's empathy with them and with others' needs (Lebra, 1994; Trommsdorff & Kornadt, 2003). However, parental valuing of prosocial behavior appears to have declined from the 1950s and 1960s to the 1980s in the People's Republic of China (Lee & Zhan, 1991), so it is unclear whether the findings would be replicated today in Asian countries that are undergoing rapid cultural transitions.

### **Moral Reasoning, Values, and Beliefs about Social Responsibility**

Cultural norms regarding the importance of harmony among people and social responsibility differ across cultures and subcultures. Miller and her colleagues found that Hindu Indians held a broader and more stringent duty-based view of social responsibility than did people in the United States. Hindu Indians, school-age and adult, tended to focus more than North Americans on responsiveness to others' needs when discussing moral conflicts and viewed interpersonal responsibilities as at least as important as justice-related obligations (Miller & Bersoff, 1992). In contrast, people in the United States tended to view interpersonal responsiveness and caring as less obligatory and more of a personal choice, particularly if the other's need was moderate or minor, or if friends or strangers (rather than parents and children) were potential recipients (Miller, Bersoff, & Harwood, 1990). Adults in the United States, for example, were more likely than Indian adults to report that their liking of a needy sibling or colleague affected their

moral responsibility to help that person (Miller & Bersoff, 1998). Both groups, however, reported feeling less obligation to help people on the other side of the world than those in their own town. Miller and Bersoff (1992; Baron & Miller, 2000) argued that a personal morality of interpersonal responsiveness and caring (such as that in the United States) is linked to a strong cultural emphasis on individual rights and autonomy.

The research on prosocial and caring-related moral reasoning is a body of work relevant to an understanding of cross-cultural variation in cognitions about prosocial behavior. Among industrial Western cultures, relatively few cross-cultural differences in prosocial or caring-related reasoning have been noted, although minor differences have been found (see Eisenberg, Boehnke, Schuhler, & Silbereisen, 1985; Eisenberg, Hertz-Lazarowitz, & Fuchs, 1990; Skoe et al., 1999). Moreover, the reasons that German, Polish, Italian, and American adolescents attribute to themselves for helping or not helping were somewhat similar, although some differences have been found (Boehnke, Silbereisen, Eisenberg, Reykowski, & Palmonari, 1989). In general, however, the similarities in the care- or prosocial-related moral reasoning or prosocial self-attributions of individuals from Western cultures are much greater than the differences.

The prosocial-related moral reasoning of children and adults from non-Western or less industrial cultures may differ considerably from that of people from Western cultures, especially with age; however, the pattern is not very consistent. Carlo et al. (1996) found that Brazilian urban adolescents used less internalized (i.e., higher level) prosocial moral reasoning than did adolescents from the United States, although their reasoning was similar otherwise. Kumru, Carlo, Mestre, and Samper (2003) found that Turkish adolescents scored higher than Spanish adolescents on mid-level modes of prosocial moral reasoning (i.e., needs-oriented and stereotypic), whereas Spanish adolescents scored higher on both lower (hedonistic and approval oriented) and higher (internalized) types of moral reasoning. When justifying hypothetical moral decisions involving others' needs, Ma (1989) found that English adolescents were more oriented to their own survival and less to belongingness and to affective and altruistic motives than were Chinese adolescents from Hong Kong and mainland China. However, Stewart and McBride-Chang (2000) found no differences in Western Caucasian and Asian (mostly Chinese) second graders' moral reasoning; and Japanese children's prosocial moral reasoning

resembled that of children from urbanized Western cultures (although there are some differences; Munekata & Ninomiya, 1985). In the one study of a nonindustrial, traditional sample, Tietjen (1986) found that although younger Maisen children from Papua New Guinea differed little in their prosocial moral reasoning from children in Western cultures, Maisen adults' moral reasoning was less sophisticated than that of Western adults. Maisen adults' reasoning, however, was probably appropriate for a small traditional society in which others' physical and psychological needs, costs for prosocial behavior, and pragmatic concerns are paramount to everyday life.

Making cross-cultural comparisons can be difficult because cultures differ considerably in their valuing of different types of prosocial action. Hindu Indians viewed prosocial behavior performed because of reciprocity considerations as more moral than did American adults (Miller & Bersoff, 1994). Further, Middle Eastern third graders in Israel seemed to value requested acts of consideration more, and spontaneous acts less, than did Israeli Jewish children of Western heritage (Jacobsen, 1983). Thus, Westerners may value prosocial acts that appear to be based on endogenous motivation more than do people from traditional cultures whereas people from traditional cultures value prosocial actions that reflect responsiveness to others' stated needs and reciprocal obligations.

## **SOCIALIZATION WITHIN AND OUTSIDE THE FAMILY**

Family structure, socialization within the family, and socialization by peers and in the schools may augment or counteract cultural influences. However, the existing research has limitations, including an overreliance on parents' reports of the child's prosocial proclivities and of their own socialization practices or style, the use of very brief observations to measure behavior (which may not be generalizable), and a dearth of data from fathers and from minority and non-Western populations. It is likely that the relations of aspects of parental control and punitiveness to developmental outcomes (including prosocial and moral development) vary somewhat across cultures (Trommsdorff & Kornadt, 2003). Further, most of the work is correlational; thus, causal relations cannot be ascertained. The prevailing view of socialization is that the parent-child relationship is complex, bidirectional,

and transactional in influence (Bugental & Grusec, Chapter 7, this *Handbook*, this volume), and this relation is embedded in the macro environment (e.g., family, neighborhood, culture). However, this complexity generally is not reflected in the existing empirical research on the socialization of prosocial behavior.

### **Demographic Features of Families and Family Members**

Intuitively, one might expect children's prosocial behavior to be related to the socioeconomic status (SES) of their families. Poorer children might be expected to have scarce resources or, due to increased demand for participation in caregiving chores, to be relatively helpful and likely to comfort others in distress (see Whiting & Whiting, 1975).

Findings are inconsistent about the relation of indices of socioeconomic status such as family income or parental education to most types of prosocial behavior (Laible, Carlo, & Raffaelli, 2000; see Eisenberg & Fabes, 1998). However, many of the relevant studies include relatively few study participants. In a large study in England, factors such as social support for parents, favorable housing, and fewer transitions in maternal partner relationships, in addition to higher maternal education, higher family income, and lower levels of financial problems, were associated with higher levels of mother-reported prosocial behavior for school-age children (but less so for 4-year-old younger siblings; Dunn et al., 1998). Furthermore, findings are consistent for adolescents' volunteering behavior. In a large study of volunteerism among at-risk adolescents, family poverty was negatively associated with males' involvement in volunteering and community activity (Lichter, Shananan, & Gardner, 2002); a similar relation was obtained for both sexes in another large study involving a more representative sample (Hart, Atkins, & Ford, 1998) and in other studies on volunteering in the United States (Huebner & Mancini, 2003; Lichter et al., 2002; National Center for Education Statistics, 1997; Uggen & Janikula, 1999; Youniss, McLellan, Su, & Yates, 1999) and Hong Kong (Chou, 1998). Nonetheless, most of these relations are modest in magnitude.

Findings on the relation of family structure and family size to prosocial behavior are mixed. Rehberg and Richman (1989) found that preschool boys from father-absent homes comforted (but did not help) a peer more than did girls and boys from two-parent homes. Other researchers have not found effects of father absence on

measures of prosocial responding (Call, Mortimer, & Shanahan, 1995; Dunn et al., 1998), and some researchers have found that adolescents in two-parent families volunteer more than those in one-parent homes (Huebner & Mancini, 2003; Keith et al., 1990; Lichter et al., 2002; Youniss et al., 1999). Investigators have found that family size and prosocial behavior or sympathy are unrelated (e.g., Chou, 1998; Gelfand, Hartmann, Cromer, Smith, & Page, 1975); that children in a large family volunteer more (Zaff, Moore, Papillo, & Williams, 2003); and that children with siblings are less likely to help in an emergency situation (Staub, 1971b) or to comfort a peer (Rehberg & Richman, 1989). Staub speculated that children from small families are more self-assured and, consequently, are more likely to take initiative and intervene spontaneously to help someone else. In contrast, children in larger families, perhaps due to the need to engage in chores, are particularly likely to learn everyday helping and sharing behaviors. Consistent with this reasoning, Weissbrod (1976) found that large family size was related to slower helping in an emergency but higher levels of generosity.

Findings concerning ordinal position are few and limited in scope. Firstborn children, particularly girls, have been found to be more willing than their peers to give commodities to peers (Sharma, 1988) and to intervene in an emergency (Staub, 1971b). Moreover, older siblings, compared with younger siblings, more often behave prosocially in sibling interactions (Bryant & Crockenberg, 1980; Dunn & Munn, 1986; Furman & Buhrmester, 1985; Stoneman, Brody, & MacKinnon, 1986; Whiting & Whiting, 1975), perhaps due in part to their older age (rather than ordinal position per se) and their greater engagement in chores and caregiving that provide opportunities for prosocial behavior (de Guzman, Edwards, & Carlo, 2005). Other investigators have found no relation between birth order and measures of prosocial responding (e.g., Gelfand et al., 1975; Rheingold, Hay, & West, 1976) or sympathy (Wise & Cramer, 1988), or have obtained mixed findings (Eisenberg, Fabes, Karbon, Murphy, Carlo, et al., 1996). In general, older children seem to be somewhat more prosocial, especially in their actual (rather than reported) prosocial behavior and in interactions with younger children.

### Parental Socialization Style and Practices

Many investigators have examined the relations of parenting style and a range of specific socialization prac-

tices to children's prosocial behavior and empathy/sympathy.

### *Parental Warmth and Quality of the Parent-Child Relationship*

Intuitively, it would seem that warm, supportive socializers would rear prosocial children. However, support for this assumption is mixed. In some studies, a positive relation between an index of maternal warmth/support or sensitivity (often versus negativity) and children's and adolescents' prosocial or empathic/sympathetic responding has been obtained, at least for some measures (Asbury, Dunn, Pike, & Plomin, 2003; Bryant & Crockenberg, 1980; Deater-Deckard, Dunn, et al., 2001; Dunn, Cutting, & Fisher, 2002; Eberly et al., 1993; Eberly & Montemayor, 1998; Janssens & Dekovic, 1997; Janssens & Gerris, 1992; Kiang et al., 2004; Krevans & Gibbs, 1996; Laible & Carlo, 2004; Lerner et al., 2005; Robinson, Zahn-Waxler, & Emde, 1994; Strayer & Roberts, 2004b; Zahn-Waxler, Radke-Yarrow, & King, 1979; also see Shek & Ma, 2001). In contrast, other investigators have failed to obtain evidence of a relation between parental warmth (or rejection) and children's prosocial behavior or empathy/sympathy (Eberly & Montemayor, 1999; Iannotti et al., 1992; Kienbaum, Volland, & Ulich, 2001; Koestner, Franz, & Weinberger, 1990; Stewart & McBride-Chang, 2000; Turner & Harris, 1984) or have found very different relations of parental support with children's prosocial behavior and sympathy (Carlo, Roesch, & Melby, 1998). Sometimes the relation of parental warmth to children's prosocial responding has been weak and only significant through mediation; for example, Zhou et al. (2002) found that the relation of parental warmth to elementary school students' facial and self-reported empathy was indirect through its positive relation with parental expressions of positive emotion in contexts involving others' emotions (especially others' positive emotions).

Support for the role of parental nurturance or warmth can be gleaned from several other bodies of data. Parents' report of children's helpfulness is higher for adolescents who share more time and activities with their parents (Eberly & Montemayor, 1998) and when fathers in two-parent families are more involved in child care (Bernadett-Shapiro, Ehrensaft, & Shapiro, 1996). A study in which parenting was assessed with observations (Kochanska, Forman, & Coy, 1999) found that maternal responsiveness (contingent, appropriate responding) to their infants at 9 (but not 14) months predicted higher levels of toddlers' empathy/prosocial responsiveness at 22 months

(cf. van der Mark et al., 2002). Moreover, Spinrad (1999) found that observed maternal sensitivity to their infants at 10 months was positively related to toddlers' concerned attention at 18 months of age to adults' feigned distress. Further, Clark and Ladd (2000) found that parental connectedness (including mutual parent-child positive engagement, warmth, intimacy, and happy emotional tone, as well as reciprocity) was positively related to kindergartners' teacher-reported prosocial tendencies.

There also is limited evidence that children with secure attachments to their mothers at a young age are more sympathetic at 3.5 years of age (Waters, Hay, & Richters, 1986) and display more prosocial behavior and concern for others at approximately age 5 years (Iannotti et al., 1992; Kestenbaum, Farber, & Sroufe, 1989). In a study with 22-month-old children, the relation between attachment and empathy/sympathy was positive but weak and somewhat inconsistent (Van der Mark et al., 2002). Moreover, adolescents' reports of attachment to their parents have been associated with Turkish early adolescents' empathy/sympathy/perspective taking (Kumru & Edwards, 2003), middle or late adolescents' sympathy/perspective taking and prosocial behavior (Laible, Carlo, & Roesch, 2004; Markiewicz, Doyle, & Brendgen, 2001), and parents' reports of adolescents' helpfulness (Eberly & Montemayor, 1998), albeit not in all studies (de Guzman & Carlo, 2004; Eberly & Montemayor, 1999), and not across 2 years' time (Laible, Carlo, & Raffaelli, 2000). Because securely attached offspring tend to have sensitive and warm parents, the finding of a relation between the security of children's attachments and their prosocial tendencies is indirect support for an association between parental warmth and children's prosocial development.

Why might children with warm parents and secure attachments be more prosocial? Waters et al. (1986) suggested that children with secure attachments differentially attend to their parent, are positively oriented to the parent, are familiar with and reproduce parents' actions, and are responsive to parental control and wish to avoid parental censure. These tendencies would be expected to enhance the effectiveness of parents' attempts to encourage prosocial behavior. Staub (1992) also argued that the quality of early attachments is important to the development of a sense of connection to others and positive valuing of other people—two characteristics with conceptual links to intrinsically based caring for other people (also see Oliner & Oliner, 1988). Nonetheless, in families in which the child or parent has

significant psychological problems, the link between attachment and prosocial behavior or empathy/sympathy may vary in a complex manner (e.g., Radke-Yarrow, Zahn-Waxler, Richardson, Susman, & Martinez, 1994).

It is likely that the degree of association between children's prosocial responding and parental warmth is moderated by other socialization practices. Dekovic and Janssens (1992) found that democratic parenting, involving parental warmth and support, combined with inductions, demandingness, and the provision of suggestions, information, and positive comments, was associated with Dutch children's prosocial behavior as reported by teachers and peers (also see Janssens & Dekovic, 1997). Similarly, Robinson et al. (1994) found that mothers who were relatively negative *and* controlling had children who tended to decrease rather than increase in empathy from 14 to 20 months of age (for those moderate or high in empathy at 14 months). Moreover, as discussed in the section on modeling, socializers who are nurturant *and* model prosocial behavior seem to promote costly prosocial behavior in children (e.g., Yarrow & Scott, 1972; Yarrow, Scott, & Waxler, 1973). Nurturance may serve as a background or contextual variable that enhances the child's receptivity to parental influence, including parental inductions, preachings, and moral standards (Hoffman, 1970).

### Inductions

A disciplinary practice of particular importance in the study of prosocial behavior is *parental induction* (i.e., verbal discipline in which the socializer gives explanations or reasons for requiring the child to change his or her behavior; Hoffman, 1970). Hoffman (2000) argued that inductions are likely to promote moral development because they induce an optimal level of arousal for learning (i.e., elicit the child's attention, but are unlikely to disrupt learning). Further, inductions are not likely to be viewed as arbitrary by the child and thereby induce resistance; rather, they focus children's attention on the consequences of their behavior for others, thereby capitalizing on children's capacity to empathize and experience guilt. Hoffman further suggested that over time, inductive messages are experienced as internalized because the child plays an active role in processing the information (which is encoded and integrated with information contained in other inductions) and the focus is on the child's action and its consequences rather than on the parent as the disciplinary agent. Thus, over time, children are likely to remember the causal link between

their actions and consequences for others rather than the external pressure or the specific disciplinary context.

Investigators usually have tried to assess the degree to which parents use inductions as a general mode of discipline, not simply to promote prosocial behavior (as for experimental studies on preaching). Inductions vary in their content: They can appeal to justice, including fairness of the consequences of the child's behavior for another; appeal to legitimate authorities; or provide matter-of-fact, nonmoralistic information. In addition, inductions may be focused on the consequences of the child's behavior for either the parent or for the other person involved in the situation (often called peer-oriented inductions). Hoffman (1970) argued that peer-oriented inductions are likely to be most effective because they are most apt to induce sympathy.

There is support for an association between parental use of inductions and children's prosocial tendencies, although significant findings often have been obtained for one sex, age, or socioeconomic status group, or for one measure of prosocial behavior (or empathy/sympathy), and not another. Nonetheless, positive associations have been found in studies in which the type of reasoning was not specified (Bar-Tal, Nadler, & Blechman, 1980; Dlugokinski & Firestone, 1974; Feshbach, 1978; Janssens & Gerris, 1992; Oliner & Oliner, 1988; cf. Trommsdorff, 1991), as well as in those in which parental inductions focused on peers' or others' feelings or states (Hoffman, 1975; Karylowski, 1982; Krevans & Gibbs, 1996; Stanhope, Bell, & Parker-Cohen, 1987). Victim-oriented discipline seems to enhance the level of children's interpersonal understanding (e.g., perspective taking), which is associated with higher guilt, including concern about harm to another (de Veer & Janssens, 1994). Further, inductions that emphasize how others (including the parent) react to children's behavior have been found to predict higher levels of prosocial behavior (Krevans & Gibbs, 1996). Stewart and McBride-Chang (2000) found that parental emphasis on the effects of the child's misbehavior in the family and what others think of the child was positively related to the anonymous donations of Asian children in Hong Kong.

The tone in which inductions are delivered often may contribute to their effectiveness, particularly with young children. Zahn-Waxler, Radke-Yarrow, and King (1979) noted that maternal use of affectively charged explanations, particularly those that included moralizing, was positively associated with toddlers' prosocial behavior in the second and 3rd years of life. Explanations delivered without affect were not effective, per-

haps because the toddlers were unlikely to attend or to think that their mother was serious. Similarly, Miller, Eisenberg, Fabes, Shell, and Gular (1989) found that inductions regarding peers were positively related to children's sad reactions to viewing others in distress and, when delivered by mothers with affective intensity, to low levels of facial distress (an index of personal distress rather than sympathy). However, parental inductions delivered in situations involving relatively high degrees of anger, particularly inductions that are guilt-inducing, seem to be associated with low levels of preschoolers' parent-directed prosocial behavior (Denham, Renwick-DeBardi, & Hewes, 1994).

The configuration of parenting practices appears to influence the effectiveness of inductions. They are likely to be more effective at promoting prosocial behavior or empathy when verbalized by parents who typically do not use power-assertive (punitive) techniques (Hoffman, 1963; also see Dlugokinski & Firestone, 1974) or are part of a pattern of democratic or authoritative parenting (Dekovic & Janssens, 1992; Janssens & Gerris, 1992).

Some of the inconsistency in the findings on inductions may stem from a failure by researchers to assess critical dimensions of parental messages. Grusec and Goodnow (1994) argued that internalization of parental messages likely depends on children's accurate perception of the message (including its content, the rules implied in the message, and the parent's intentions and investment in the message) and children's acceptance of it. They suggested that the clarity, redundancy, and consistency of the message, as well as its fit to the child's developmental level, influence children's accurate perception of the message. Children are more likely to accept the message if they perceive it as appropriate, find it motivating (e.g., if it arouses empathy or insecurity), and believe that the value inherent in the message is self-generated. Grusec and Goodnow also hypothesized that parental responsiveness or past willingness to comply with the child's wishes promotes the child's willingness to comply with the parent's wishes. Thus, it may be productive to examine the clarity of parents' messages and variables related to children's acceptance of the message as moderators of the relation between parental inductions and children's prosocial behavior.

### *Power-Assertive, Punitive Techniques of Discipline*

Researchers generally have found that socializers' use of power-assertive techniques of discipline such as physical punishment or deprivation of privileges is either un-

related (e.g., Janssens & Gerris, 1992; Kochanska et al., 1999; Zahn-Waxler, Radke-Yarrow, & King, 1979) or negatively related to children's prosocial behavior (Asbury, Dunn, Pike, & Plomin, 2003; Bar-Tal, Nadler, et al., 1980; Deater-Deckard, Dunn, et al., 2001; Dlugokinski & Firestone, 1974; Krevans & Gibbs, 1996), empathy (Janssens & Gerris, 1992; Krevans & Gibbs, 1996), or sympathy (Spinrad et al., 1999). Likewise, a punitive, authoritarian parenting style has been unrelated (Iannotti, Cummings, Pierrehumbert, Milano, & Zahn-Waxler, 1992; Russell et al., 2003, for mothers; also see Diener & Kim, 2004) or negatively related (Dekovic & Janssens, 1992; Hastings et al., 2000; Russell et al., 2003, for fathers) to children's prosocial behavior and sympathy, and its negative relation with sympathy may increase with age (Hastings et al., 2000). Moreover, physical abuse of children has been linked to low levels of children's empathy and prosocial behavior (Howes & Eldredge, 1985; Main & George, 1985; Miller & Eisenberg, 1988; see Koenig, Cicchetti, & Rogosch, 2004, for mixed findings).

Nonetheless, there is a difference between the occasional, measured use of power-assertive techniques in the context of a positive parent-child relationship and the use of punishment as the preferred, predominant mode of discipline. Rescuers of Jews in Nazi Europe reported that the punishment they had received from their parents was not a routine response and was linked to specific behaviors rather than used gratuitously (Oliner & Oliner, 1988). Further, Miller et al. (1989) found that maternal report of using physical techniques (including physical punishment) was positively associated with preschoolers' empathic sadness when viewing others in distress, but only for children whose mothers also used relatively high levels of inductive discipline (cf. Hoffman, 1963).

Punishment can induce immediate compliance with socializers' expectations for prosocial behavior if the socializer monitors the child's behavior (Morris, Marshall, & Miller, 1973), particularly if the contingency between lack of prosocial behavior and punishment is specified (Hartmann et al., 1976). However, these effects often extinguish when punishment is removed (Hartmann et al., 1976), and children tend to attribute prosocial behavior induced by power-assertive techniques to external motives such as fear of detection or punishment (Dix & Grusec, 1983; Smith, Gelfand, Hartmann, & Partlow, 1979). Nonetheless, social disapproval, unlike material punishment (e.g., fines for not helping), has been positively associated with children's

attributing their own donating to internal motives (Smith et al., 1979). Thus, it is possible that social disapproval (verbal punishment) can be used to enhance internally motivated prosocial behavior; indeed, maternal expressions of disappointment have been linked to greater prosocial behavior (Stewart & McBride-Chang, 2000). Although most middle-class mothers in Western cultures such as the United States rarely use punishment (especially physical punishment) to induce helping or in response to children's failure to help (Grusec, 1991; Zahn-Waxler et al., 1979), this may be less true in Asian societies (see Stewart & McBride-Chang, 2000).

### *Appropriate versus Inappropriate Parental Control*

Perhaps the critical issue when thinking about parental punishment and control is whether the degree of power asserted by the parent is perceived as excessive and arbitrary versus reasonable in the given context or culture. Parental demands and expectations for socially responsible and moral behavior (often expressed in an authoritative parenting style) have been associated with socially responsible and prosocial behavior (e.g., Dekovic & Janssens, 1992; Janssens & Dekovic, 1997; Janssens & Gerris, 1992; Lidner-Gunnoe, Hetherington, & Reiss, 1999), adolescents' endorsement of caring values (Pratt, Hunsberger, Pancer, & Alisat, 2003), and caring moral reasoning (Pratt, Skoe, & Arnold, 2004). In contrast, strict, rejecting control has been linked to low levels of sympathy (Laible & Carlo, 2004). Somewhat related, in Western cultures, parental emphasis on adolescents' autonomy also has been linked with prosocial development (Bar-Tal, Nadler, et al., 1980; Pratt et al., 2004); this relation may hold less in early childhood (Clark & Ladd, 2000). In Asian cultures that emphasize parental training and filial piety (Stewart et al., 1998), training of this sort was associated with anonymous prosocial behavior, whereas restrictive control was marginally, negatively related (Stewart & McBride-Chang, 2000). Other researchers have found a positive association between appropriate parental control (rather than leniency) and children's empathy (Bryant, 1987) or girls' (but not boys') sympathy years later in adulthood (Koestner, Franz, & Weinberger, 1990). Analogously, parental monitoring of adolescents' activities was positively related to adolescents' volunteerism in large survey research (Huebner & Mancini, 2003; Zaff et al., 2003). For middle-class families, parental demands for prosocial behavior appear to be part of a child-rearing pattern in which mature behavior is expected (Greenberger & Goldberg, 1989). In contrast, parental valuing

of mere compliance, which often may lead to arbitrary overcontrol, has been linked to low levels of children's prosocial behavior with mothers and peers (Eisenberg, Wolchik, Goldberg, & Engel, 1992).

### *Parental Emphasis on Prosocial Values*

Because parents who hold prosocial values would be expected to teach and model prosocial behavior, it is reasonable to expect a relation between parental prosocial values and children's prosocial behavior. Parents' reports of holding prosocial values have been associated with peer nominations of fifth graders' prosocial behavior (including prosocial behavior, guilt, and rule-following; Hoffman, 1975) and older adolescents' caring moral reasoning (Pratt et al., 2004; also see Eisenberg, Wolchik, et al., 1992). Although some investigators have found no evidence of a relation between parental emphasis on prosocial responding (reported or observed) and children's prosocial behavior or empathy (Turner & Harris, 1984), others have obtained mixed (Bryant & Crockenberg, 1980) or positive relations (Trommsdorff, 1991) (also see section on modeling and preachings).

Perhaps the most compelling evidence for the importance of parental prosocial values comes from studies of adults who have displayed unusual acts of altruism. Rescuers in Nazi Europe often recalled learning values of caring from their parents or the other most influential person in their lives (Oliner & Oliner, 1988; also see Hart & Fegley, 1995; London, 1970). Rescuers reported that their parents felt that ethical values were to be extended to all human beings. Interestingly, rescuers did not differ from nonrescuers in reported exposure to nonprosocial values such as honesty or equity. However, real-life moral exemplars often solidify their values or even develop new moral values in adulthood when interacting with other adults who discuss value-related issues and jointly engage in moral activities with the individual (Colby & Damon, 1992). Thus, it is likely that the socialization of other-oriented values, even if it begins in one's family of origin, is a continuing dynamic process.

### *Modeling*

Because of the importance of modeling in social learning theory (e.g., Bandura, 1986), numerous researchers have examined whether children's prosocial behavior varies as a function of exposure to prosocial versus selfish models. Much of the relevant research has been conducted in laboratory studies using strangers or brief acquaintances as models and donating as the index of

prosocial behavior. Thus, the generalizability of much of the laboratory research to real-life settings involving familiar models and to other types of prosocial actions can be questioned. The experimental laboratory literature is supplemented by a smaller body of work, often correlational in design, in which real-life situations and familiar models have been used; and similar results have been obtained in these studies.

In the prototypic laboratory study of modeling prosocial behavior, children earn prizes, tokens, or money by winning a game, view or do not view a model, and then are provided an opportunity to donate to needy children or to children who did not get to play the game. Because this topic was reviewed in considerable detail in Eisenberg and Fabes (1998) and there have been few new studies since 1998, this work is briefly summarized here. In general, children who view a generous model or helpful model are more generous or helpful than those exposed to a control condition (often a model who had no opportunity to donate; e.g., Rice & Grusec, 1975; Rushton & Littlefield, 1979; Rushton & Teachman, 1978) or a selfish model (e.g., Bryan & Walbek, 1970; Rushton, 1975). Further, multiple models may be more effective than inconsistent models for inducing precise imitation of donating (Wilson, Piazza, & Nagle, 1990).

In most laboratory studies of modeling, prosocial behavior is modeled only once; thus, it is impressive that some investigators have obtained evidence of generalization to new behaviors or settings (Midlarsky & Bryan, 1967; Rushton, 1975), although others have not (Rushton & Littlefield, 1979; Rushton & Teachman, 1978). Further, investigators have found effects of modeling days to months later (Israel & Raskin, 1979; Rice & Grusec, 1975; Rushton, 1975; Rushton & Littlefield, 1979; Wilson et al., 1990).

Adults who control valued resources (Grusec, 1971) appear to be relatively powerful models, as are models perceived as competent (Eisenberg-Berg & Geisheker, 1979). Moreover, nurturant prosocial models whom children have just met seem to promote prosocial behavior when the prosocial behavior is not costly and is something they probably want to do (e.g., help when they hear someone in distress; Weissbrod, 1976; also see Staub, 1971a). In contrast, when prosocial behavior involves self-denial (e.g., donations), short-term exposure to a warm model seems to have little effect or may even reduce donating behavior (Grusec, 1971; Midlarsky & Bryan, 1967; Weissbrod, 1976). Thus, short-term noncontingent warmth seems to disinhibit children to do as

they please, including assisting distressed others as well as keeping valued commodities for themselves. However, in the classroom context in which warmth probably is not entirely noncontingent, preschool children model the prosocial behaviors and nurturance of adults with whom they have had a relatively extended nurturant relationship (Yarrow & Scott, 1972; Yarrow et al., 1973).

In addition to the laboratory studies, investigators have examined whether children appear to model real-life socializers such as parents. In the first 2 years of life, children do not seem to consistently model maternal sharing or helping of a distressed person (Hay & Murray, 1982; Zahn-Waxler et al., 1979). However, mothers' modeling of helping behaviors (such as participation in household chores) seems to enhance the likelihood of 1- and 2-year-olds helping with similar tasks (Rheingold, 1982). Moreover, the data on real-life altruists suggest an effect of parental modeling. Youth volunteerism has been found to be related to the degree to which their parents volunteer; moreover, the types of voluntary activities chosen by youths tend to be similar to those of their parents (e.g., in providing a social service or working for a cause; Keith et al., 1990; McLellan & Youniss, 2003; National Center for Education Statistics, 1997; also see Hart & Fegley, 1995; Janoski & Wilson, 1995; Stukas, Switzer, Dew, Goycoolea, & Simmons, 1999).

Consistent with the notion that parental modeling fosters children's prosocial tendencies, sympathetic parents, who likely model sympathy, tend to have same-sex elementary school children who are helpful (Fabes, Eisenberg, & Miller, 1990) or prone to sympathy rather than to egoistic personal distress (Eisenberg, Fabes, Carlo, Troyer, et al., 1992; Eisenberg, Fabes, Schaller, Carlo, & Miller, 1991; Eisenberg & McNally, 1993; Fabes et al., 1990). In contrast, links between parental empathy (rather than sympathy) and children's empathy have been mixed, with some researchers obtaining positive relations (Barnett, Howard, King, & Dino, 1980; Strayer & Roberts, 2004b; Trommsdorff, 1991) and others obtaining no relations or inconsistent correlations (e.g., Bernadett-Shapiro, Ehrensaft, & Shapiro, 1996; Strayer & Roberts, 1989). Some parents prone to empathy may become overly aroused and personally distressed, which would be expected to lead to lower levels of helping in many contexts. Multiple mechanisms, including the heritability of emotionality related to sympathy or other characteristics, could explain the significant findings that have been obtained.

In regard to high-cost real-life helping behavior, Rosenhan (1970) found that Caucasian civil rights activists in the late 1950s and 1960s who were highly involved and committed to the cause despite considerable danger and cost reported that their parents were both nurturant and actively involved in working for altruistic and humanitarian causes. In contrast, individuals who were less involved and committed reported that their parents preached prosocial values but often did not practice altruism. Further, rescuers of Jews in Nazi Europe described their parents as having acted in accordance with strong moral convictions (London, 1970; Oliner & Oliner, 1988).

The data from studies of adult altruists are not only correlational in design but involve retrospective data. Even if people's recall of parental practices were unbiased and accurate, it is possible that their altruism stemmed from family factors other than modeling, such as optimal discipline or exposure to prosocial cultural or community values. Nonetheless, research findings on parents of prosocial offspring converge with the experimental laboratory findings that implicate modeling in the development of prosocial tendencies.

### *Preachings*

The verbalizations of adults relevant to prosocial behavior have been examined in nondisciplinary contexts (laboratory situations in which the adult is not responding to the child's misbehavior), as well as in disciplinary situations (e.g., inductions). In studies of the effects of preachings or exhortations, the preacher states what should be done (sometimes in regard to his or her own earnings that can be donated), but does not directly and explicitly direct the child to assist. Often the preacher also gives reasons that one should or should not assist. Preachers may verbalize to themselves, as if thinking through the issue (Eisenberg-Berg & Geisheker, 1979), or direct their preaching to the child (e.g., Bryan & Walbek, 1970; Rushton, 1975). Preachings often are normative in content, with the preacher stating what should be done and stating either prosocial or selfish norms (e.g., "It's a nice thing [not such a nice thing] to give to the crippled children"; Bryan & Walbek, 1970). In a neutral control group, the preacher typically would make normatively neutral statements such as "This game is fun."

Most researchers have found no effects, or inconsistent effects, of normative preachings by nonparental adults on children's donating behavior (e.g., Bryan & Walbek, 1970; cf. Zarbatany, Hartmann, & Gelfand,

1985). However, normative preachings seem to foster generosity if the preacher promoting donating is an adult who is likely to have direct power over the children (Eisenberg-Berg & Geisheker, 1979). In addition, empathy-inducing preachings that emphasize the emotional consequences of assisting for the recipients of aid have been found to elicit more donating in private than do neutral control preachings (Dlugokinski & Firestone, 1974; Eisenberg-Berg & Geisheker, 1979; Perry, Bussey, & Freiberg, 1981; Smith, 1983) or punitive, threatening preachings (Perry et al., 1981). Empathy-inducing preachings also have been found to enhance the effort and success of children in elementary school when helping a peer (Ladd, Lange, & Stremmel, 1983) and have been related to prosocial behavior in another setting or at a later date (Grusec, Saas-Kortsak, & Simutis, 1978; Smith, 1983).

Not all researchers have found effects of empathy-inducing preachings. The wording in some studies may have led the children to believe that the adult or the beneficiary would be angry at them for not helping, which might evoke reactance rather than empathy (McGrath & Power, 1990), or compliance rather than internalization. Preachings seem to work best if children feel that they have a choice of whether to assist and if the preachings highlight the positive outcomes of helping for another (Grusec, Saas-Kortsak, & Simutis, 1978; McGrath, Wilson, & Frassetto, 1995). Further, the results of one study suggest that empathic preachings are effective primarily for children who have been exposed to inductive discipline at home (rather than a relatively high degree of power assertion; Dlugokinski & Firestone, 1974).

### *Prompts and Directives*

Children who are instructed or prompted to help or share tend to do so (Gelfand et al., 1975; Hay & Murray, 1982; Israel & Raskin, 1979), and the effects of directive instructions have been found to persist over 11 days (Israel & Brown, 1979) or 4 weeks (Israel & Raskin, 1979). Direct requests for prosocial behavior may be particularly important for younger children because of their limited abilities to understand others' emotions and situational cues (Denham, Mason, & Couchoud, 1995). However, there is evidence that constraining directives are less effective with older children than with younger ones (White & Burnam, 1975), particularly over time (Israel & Raskin, 1979; cf. Israel & Brown, 1979). Highly constraining instructions may induce reactance; moreover, after the early years, children are unlikely to attribute forced behavior to internal reasons

and, consequently, may not enact prosocial behavior in an unsupervised setting (see McGrath & Power, 1990).

### *Reinforcement for Prosocial Behavior*

Consistent with learning theory, concrete (Fischer, 1963) and social (Eisenberg, Fabes, Carlo, et al., 1993; Gelfand et al., 1975; Grusec & Redler, 1980; Rushton & Teachman, 1978; cf. Mills & Grusec, 1989) reinforcements have been found to increase children's prosocial behavior, at least in the immediate context. Further, parental reports of reinforcement for children's sympathetic and prosocial behavior have been associated with girls' (but not boys') concerned or sad reactions to others in distress (Eisenberg, Fabes, Carlo, et al., 1992).

Although concrete rewards may induce prosocial behavior in the given context, the long-term effect of concrete rewards may be negative. Consistent with Lepper's (1983) notion that the provision of concrete rewards undermines intrinsic motivation (and also may induce children to attribute their prosocial actions to external motivation), Szynal-Brown and Morgan (1983) found that third-grade children who were promised tangible rewards if the younger children they tutored did well were less likely to engage in teaching activities during a subsequent free-choice period than were tutors who were not promised rewards for teaching. Those children promised rewards that were not contingent on the pupil's learning were between the aforementioned two groups in regard to teaching, but did not differ significantly from either. Further, Fabes, Fultz, Eisenberg, Plumlee, and Christopher (1989) found that the use of material rewards for school children's helping behavior undermined their subsequent, anonymous prosocial behavior during a free-choice situation, particularly for children whose mothers valued the use of rewards. Moreover, mothers who felt relatively positive about using rewards reported that their children were less prosocial than did mothers who were less enthusiastic about the use of rewards. Rewards may be salient for these children and, consequently, they may be particularly likely to attribute their initial prosocial behavior to the external reward (rather than to an internal motive).

The effects of social reinforcement may vary as a function of type of praise and the age of the child. For young children, reinforcement for prosocial behavior does not seem to increase prosocial tendencies in another setting or over time and may even undermine it (Eisenberg, Wolchik, et al., 1992; Grusec, 1991). Moreover, praise that attributes the children's positive behavior to their dispositional kindness or internal motives

(e.g., because they enjoy helping others) appears to be more effective than praise that simply labels the act as positive (Grusec & Redler, 1980; Mills & Grusec, 1989; dispositional attribution is a special type of praise and is discussed in the following subsection). Grusec and Redler (1980) found that social reinforcement for prosocial actions (without an internal attribution) increased elementary school children's prosocial behavior in the immediate context; however, it was associated with the generalization of prosocial behavior to a different, anonymous situation only for 10-year-old children (not for 5- or 8-year-olds). Grusec and Redler (1980) hypothesized that older children may interpret reinforcement for a specific action as having implications for a variety of situations, whereas younger children do not view praise for a given act as having broader relevance.

### *Provision of Attributions or Dispositional Praise*

Elementary school children are likely to behave in a prosocial manner on a subsequent occasion if they initially are induced to behave prosocially and are provided with internal attributions (i.e., dispositional praise) for their actions (e.g., "I guess you're the kind of person who likes to help others whenever you can. Yes, you are a very nice and helpful person"; Grusec & Redler, 1980). Children provided with such praise are more helpful or generous even weeks later than are children who are provided with no attribution (Grusec, Kuczynski, Rushton, & Simutis, 1978; Grusec & Redler, 1980; Holte, Jamruszka, Gustafson, Beaman, & Camp, 1984; cf. Eisenberg, Cialdini, McCreath, & Shell, 1987) or with one attributing prosocial behavior to the fact that the adult experimenter expected such behavior (Grusec, Kuczynski, et al., 1978).

The provision of internal attributions is believed to foster a prosocial self-image that then results in enhanced prosocial behavior (Grusec & Redler, 1980). However, support for this supposition is mixed (e.g., Holte et al., 1984; Mills & Grusec, 1989). If changes in children's self-concepts mediate the effects of dispositional attributions, the provision of internal attributions would not be expected to be effective until children have some understanding of personality traits and their stability. Consistent with this logic, Grusec and Redler (1980) found that the provision of internal attributions was effective in enhancing prosocial behavior both immediately and long term (e.g., a week or more later) for middle and later elementary school children, but not for kindergartners. Further, Eisenberg, Cialdini, McCreath, and Shell (1989) found that children in elementary

school who were induced to engage in prosocial behavior and provided with internal attributions were more helpful if they demonstrated the ability to label traits accurately. Thus, it is possible that an understanding of traits is essential if internal attributions are to foster children's prosocial behavior.

### *Learning by Doing (and the Foot-in-the-Door Effect)*

Children's participation in prosocial activities seems to foster prosocial behavior at a later time, although boys sometimes may exhibit some reactance in the short-term (Staub, 1992). This pattern of findings has been obtained using both experimental procedures (Staub, 1979; although effects may be stronger for older children; Eisenberg, Cialdini, et al., 1987) and in research linking prosocial proclivities to participation in household chores (perhaps particularly those that benefit others; Graves & Graves, 1983; Rehberg & Richman, 1989; Whiting & Whiting, 1975; cf. Gelfand et al., 1975). In some cultures, guided participation (Rogoff, 2003) may be a major way in which children are socialized into a variety of activities, including prosocial ones (Whiting & Whiting, 1975).

In a study of 9- and 14-year-old children, Grusec, Goodnow, and Cohen (1996) found that routine (but not requested) participation in household chores was related to youths' prosocial behavior in the family, but primarily for older youth and girls. Routine participation in chores was not related to helping strangers. Thus, if chores benefit a delimited group of individuals, any prosocial tendencies fostered may not extend to those beyond that group.

Participation in organized youth activities and non-voluntary service required by school programs also has been linked to prosocial behavior, especially subsequent volunteerism or intentions to volunteer (Metz & Youniss, 2003; Stukas, Switzer, et al., 1999; Youniss & Metz, 2004). In addition, adolescents' and young adults' participation in voluntary community service sometimes has been linked to greater feelings of commitment to helping others (Yates & Youniss, 1996b; see discussion of these programs in the section on adolescence). Of particular interest, Youniss and Metz (2004) found that required school-based service was related to increased volunteerism and intentions to volunteer for students who were less inclined to participate; it had little effect for those students who quickly completed their requirement and went on to participate in voluntary activities. In contrast, Stukas, Snyder, and Clary (1999) found that mandatory volunteerism undermined college

students' future intentions to volunteer only for individuals who otherwise would not have been volunteering (i.e., they felt that their service was solely due to external force) or for those who had the preexisting belief that they would not freely choose to engage in any volunteer activities. For most students who are not generally opposed to volunteer service activities and do not focus on external pressures to engage in such activities, mandatory service participation seems likely to increase prosocial responding.

The findings on the effects of practice and compulsory service activities are similar to those obtained by social psychologists studying compliance (i.e., the "foot-in-the-door" effect) in adulthood. Although the processes underlying the findings for adults are not entirely clear (Burger, 1999; Cialdini & Goldstein, 2004), a common explanation is that engaging in the initial prosocial behavior changes the actor's self-perceptions about his or her own prosocial disposition or the actor's attitude about helpfulness. A self-concept explanation is consistent with Eisenberg, Cialdini, et al.'s (1989) finding that the effects of an initial helping experience were primarily for children with a rudimentary understanding of trait labels (because an understanding of traits is necessary for a stable self-concept) and with Eisenberg, Cialdini, et al.'s (1987) finding that practice had an effect only for children old enough to understand consistency in personality. However, there is little direct evidence that a more sophisticated understanding of the stability of personality is necessary for the foot-in-the-door effect to be effective.

It also is possible that engaging in prosocial activities enhances subsequent prosocial behavior because the experience provides empathic rewards, helping skills, and social approval. Further, investigators have argued that service activities can promote identity formation, a sense of personal competence and civic responsibility, and the adoption of prosocial norms, as well as opportunities to learn about systems of meaning (e.g., about society, social injustice; McLellan & Youniss, 2003; Yates & Youniss, 1996a, 1996b, 1998).

### **Emotion Socialization**

Parental practices that help children to cope with their negative emotion in a constructive fashion tend to be associated with children's sympathy (rather than personal distress) and prosocial behavior. This may be partly because children who cannot adequately cope with their emotions tend to become overaroused and ex-

perience a self-focused, aversive response (i.e., personal distress) when confronted with another's distress, whereas children who can regulate their emotions tend to experience sympathy (Eisenberg, Fabes, Murphy, et al., 1994, 1996).

For example, Buck (1984) hypothesized that punitive reactions by parents when children exhibit negative emotion result in children's increased arousal when they experience negative emotion, as well as in attempts to hide such feelings. Eisenberg, Fabes, Schaller, Carlo, and Miller (1991) found that mothers who emphasized to their sons the need to control their own negative emotions (e.g., sadness and anxiety) had sons who exhibited facial and physiological (skin conductance and heart rate) markers of distress when they viewed a sympathy-inducing film, but reported low distress in reaction to the film. Thus, these boys seemed prone to experience distress when confronted with others' distress, but appeared not to want others to know what they were feeling. In contrast, same-sex parents' restrictiveness in regard to emotional displays that could be *hurtful to others* (e.g., gasping at a disfigured person) has been positively related to elementary school children's reports of dispositional and situational sympathy (Eisenberg, Fabes, Schaller, Carlo, & Miller, 1991). Parents who discourage their children from expressing emotions hurtful to others may educate their children about the effects of emotional displays on others. However, maternal restrictiveness in regard to the display of hurtful emotions was associated with distress in kindergarten girls, perhaps because mothers who were restrictive in this regard with kindergarten girls were less supportive in general. Thus, for younger children, such maternal restrictiveness may reflect age-inappropriate restrictiveness or low levels of support (Eisenberg, Fabes, et al., 1992).

Parents can also demonstrate methods of coping with emotions or encourage the use of certain means of coping. Eisenberg, Fabes, Schaller, Carlo, and Miller (1991) found that boys whose parents encouraged them to deal instrumentally with situations causing their own sadness or anxiety were relatively likely to experience sympathy rather than personal distress in empathy-inducing contexts. Further, parents' encouragement of direct problem solving as a way to cope with emotion has been associated with the amount that girls (but not boys) comfort a crying infant (Eisenberg, Fabes, Carlo, et al., 1993).

Mothers' discussions of their own and their children's emotions also seem to relate to children's vicari-

ous emotional responding. When mothers verbally linked the events in an empathy-inducing film with children's own experiences, children exhibited heightened vicarious emotional responding of various sorts (sadness, distress, and sympathy). Further, mothers' references to their own sympathy and sadness and their statements about perspective taking or the film protagonist's feelings or situation were associated with boys' reports of sympathy and sadness (Eisenberg, Fabes, Carlo, et al., 1992). In addition, mothers' reports of trying to find out why their child is feeling badly, helping their children talk about negative emotions, and listening to their children when they are anxious or upset have been associated with girls' comforting of an infant (Eisenberg, Fabes, Carlo, et al., 1993). Similarly, Belden, Kuebli, Pauley, and Kindlerberger (2003) found that mothers' questions about their children's emotional reactions, states of mind, or interpretations about the motivation for a good deed performed by their child in the past were positively correlated with children's self-reported empathy. Moreover, Denham and Grout (1992) found that preschoolers' prosocial behavior at school was positively related to mothers' tendencies to explain their own sadness, and Kojima (2000) found that young children's prosocial behaviors with their siblings were positively related to the degree to which their mothers made reference to the sibling's actions and emotional states.

The positive association between parental discussion of emotion and prosocial tendencies has not been found in all studies (Eisenberg, Losoya, et al., 2001; Garner, Jones, Gaddy, & Rennie, 1997; Eisenberg, Fabes, Schaller, Carlo, & Miller, 1991). Trommsdorff (1995) found that German and Japanese mothers who focused on their child's emotions in stressful situations by verbalizing or matching their emotions had 5-year-old daughters who were prone to experience distress rather than sympathy when exposed to another's sadness. Trommsdorff suggested that girls who experience too strong a degree of empathy from their caretaker may experience more distress in empathy-inducing contexts because of less developed self-other differentiation. Another possibility is that some mothers may overarouse their children by focusing too much on distress, with the consequence that the children do not learn to regulate their distress.

It is likely that the manner in which mothers talk about emotional events partially accounts for the degree and valence of the relation between maternal emotion-related verbalizations and children's empathy-

related and prosocial responding. Fabes, Eisenberg, Karbon, Bernzweig, et al. (1994) found that mothers' displays of positive rather than negative emotion while telling their kindergarten-age children empathy-inducing stories were associated with children's sympathy, low personal distress, and relatively high helpfulness on a behavioral task. Mothers displayed more of this positive expressiveness with kindergartners if they viewed their child as reactive to others' distresses. Thus, it appeared as if mothers were reacting to characteristics of their children (i.e., age and emotional vulnerability) and were attempting to buffer younger and vulnerable children from emotional overarousal (also see Zhou et al., 2002). In contrast, for second-grade children, helpfulness, as well as sympathy and low personal distress (assessed with physiological and facial measures), were positively associated with a maternal style that combined warmth with directing the child's attention to the stories. For older children, buffering of negative emotion may not be necessary, whereas it may be important to direct the child's attention to others in a way that does not induce reactance.

In brief, findings are consistent with the view that parental practices that help children regulate their negative emotion to avoid becoming overaroused may foster sympathy and prosocial behavior rather than personal distress. However, there may be a fine line between the parental practices that help children regulate and understand their own emotion and the practices that overly focus children's attention on negative emotion. Moreover, the effects of parental emotion-related practices likely are moderated by individual differences in children's emotional reactivity, regulation, and other aspects of temperament and personality.

### *Expression of Emotion and Conflict in the Home*

Frequency and valence of emotion expressed in the home appear to be linked to children's prosocial behavior, albeit in a complex manner. Parental expression of positive emotion in the family tends to be positively correlated with children's prosocial tendencies (Denham & Grout, 1992; Eisenberg, Fabes, Schaller, Miller, et al., 1991; Garner, Jones, & Miner, 1994), a finding that is consistent with the modest associations between prosocial behavior and parental support, warmth, and sympathy. However, researchers sometimes have found no relations between familial or maternal positive emotion and children's sympathy (Eisenberg, Fabes, Carlo, Troyer, et al., 1992) or prosocial behavior (Denham &

Grout, 1993). These weak relations may be due to the relation between parental positive expressivity and prosocial behavior or sympathy being quadratic or moderated by children's dispositional regulation. Valiente et al. (2004) found that moderate (compared with low or high) levels of parental positive expressivity were most highly, positively related to children's sympathy.

Culture also may moderate the relation between parental expression of positive emotion and children's sympathy. Unlike in the United States, Eisenberg, Liew, and Pidada (2001) did not find a relation between these two constructs in Indonesia. This finding may not be surprising given that anthropological and sociological reports indicate that the expression of high levels of emotion—positive or negative—is discouraged in that culture.

At first glance, findings about negative emotion in the home appear inconsistent and puzzling. Conflict in the family has been positively associated with prosocial behavior toward family members. Even very young children exposed to parental conflict sometimes try to comfort or help their parents, and this tendency increases with age in the early years (Cummings, Zahn-Waxler, & Radke-Yarrow, 1984). Further, siblings (but not peers) exposed to conflict between their mother and another adult seem to try to buffer the stress for one another (Cummings & Smith, 1993). Young children are more likely to respond with prosocial behavior toward a parent, as well as with anger, distress, and support-seeking, if familial conflict is frequent (Cummings, Zahn-Waxler, & Radke-Yarrow, 1981) or is physical in nature (Cummings, Pellegrini, & Notarius, 1989).

Other investigators have examined the relation of prosocial tendencies to reported prevalence of hostile, negative emotion in the home environment or maternal simulations of anger situations. Some investigators have not found significant relations between mothers' reports of dominant negative affect or their own anger directed toward the child and children's observed prosocial behaviors (Garner & Estep, 2001; Garner, Jones, & Miner, 1994; also see Hastings et al., 2000). In contrast, Denham and her colleagues found that preschoolers' real-life prosocial reactions to their peers' emotional displays were negatively related to mothers' reports of the frequency of their own anger at home (Denham & Grout, 1992) and intense maternal simulations of anger (when enacting events in a photograph; Denham et al., 1994), and were positively related to mothers' reports of the ra-

tional expressions of anger (Denham & Grout, 1992). Similarly, high levels of familial or maternal dominant negative emotion (e.g., anger) have been linked to low levels of sympathetic concern and high levels of personal distress, both in the United States (Crockenberg, 1985; Eisenberg, Fabes, Carlo, et al., 1992) and in Indonesia (Eisenberg, Liew, & Pidada, 2001).

To summarize, Cummings and his colleagues found that exposure to conflict involving one or both parents, including ongoing conflict in the home, was related to increased prosocial reactions toward children's mothers and siblings (but not peers; Cummings & Smith, 1993); whereas in other studies, reports and displays of maternal anger and externalizing emotion tend to be associated with low levels of peer-directed prosocial behavior and sympathy, as well as high levels of personal distress. Perhaps exposure to adult conflict undermines children's emotional security and induces distress, resulting in children coping in ways that are likely to minimize the stress in their social environment (see Davies & Cummings, 1994). Because children frequently cannot readily escape from conflict in the home, they may attempt to alleviate their distress by intervening and comforting family members. However, children exposed to high intensity or ongoing parental anger may become overaroused by others' negative emotions and experience self-focused personal distress in reaction to others' negative emotion (see Eisenberg et al., 1994). If this were true, they would be expected to try to escape from dealing with others' distress if possible. Exposure to high levels of anger and conflict may induce attempts by children to minimize self-related negative emotional (and physical) consequences of conflict but likely does not foster the capacity for sympathy or other-oriented (rather than self-oriented) prosocial behavior.

Another reason for the inconsistency in the general pattern of findings for parental expression of dominant (assertive) negative emotion may be that the relation between parental expression of dominant negative emotion in the family and children's sympathy appears to be quadratic, with moderate levels of expressivity being most highly associated with children's sympathy (Valiente et al., 2004). Valiente and colleagues also found a quadratic relation such that children's personal distress was higher for mean and high levels of parental negative expressivity than for low parental negative expressivity. In addition, the relation of parental negative expressivity to children's sympathy appears to be moderated by chil-

dren's regulation. Valiente and colleagues found a significant negative relation between situational sympathy and parents' negative expressivity, but only for children high in regulation. Furthermore, for children who were moderate or low in regulation, dispositional personal distress was relatively high regardless of the level of parental expression of negative emotion, whereas for well-regulated children, personal distress was low when parents expressed little negative emotion but increased with the level of parental expression of negative emotion.

Negative emotions need not always be harsh and dominant; often emotions such as sadness, fear, and loss are expressed in the home. The findings about the relation between the children's exposure to parents' softer negative emotions and their prosocial tendencies are inconsistent. In studies of children from typical families, maternal report of such submissive negative emotion has been negatively related to children's caregiving toward a younger sibling (Garner, Jones, & Miner, 1994), positively related to girls' (but not boys') sympathy in the United States (Eisenberg, Fabes, Carlo, Troyer, et al., 1992), and negatively related to Indonesian children's sympathy (Eisenberg, Liew, & Pidada, 2001). Further, preschoolers' prosocial reactions to peers' emotions have been related to mothers' low rather than high intensity enacted sadness (Denham et al., 1994). In contrast, children's peer-oriented prosocial actions have not been significantly related to frequency of mothers' reported expressions of sadness or tension at home in front of their child (Denham & Grout, 1992) or mothers' reports of experiencing internalizing negative emotions (Denham & Grout, 1993).

Findings about maternal depression are also mixed. Maternal depression has been linked to lower levels of children's prosocial behavior in general (Dunn et al., 1998), to lower mother- and, to a lesser degree, teacher-reported prosocial behavior but higher child-reported prosocial behavior (Hay & Pawlby, 2003), and to higher empathy or prosocial behavior for some children in some circumstances (Radke-Yarrow et al., 1994; Zahn-Waxler, Cummings, McKnew, & Radke-Yarrow, 1984). Perhaps what is important is whether such emotion is dealt with constructively in the home and if children learn ways to manage emotions such as sadness so that they are likely to experience sympathy rather than personal distress when exposed to others' negative emotion. Denham and Grout (1992) found that mothers' reported expressions of tension or fear and sadness at

home were positively related to children's peer-oriented prosocial behavior if mothers expressed their tension in a positive manner or explained their sadness.

### *Summary of Research on Adults' Socialization-Relevant Practices, Beliefs, and Styles*

A constellation of parental practices, beliefs, and characteristics, as well as the emotional atmosphere of the home, seems to be related to children's prosocial development. The findings generally are consistent with Staub's (1992, 2003) assertion that the development of prosocial behavior is enhanced by a sense of connection to others (e.g., through attachment and a benign social environment), exposure to parental warmth (which fosters a positive identity and sense of self as well as attachment), adult guidance, and participation in prosocial activities. Moreover, parents' coaching and other behaviors that teach children to understand and regulate their emotions also are likely related to sympathetic capacities.

Although it is likely that the social environment of children, especially their parents, has a causal effect on prosocial behavior and empathy-related responding, heredity may partially account for such relations, especially when predicting aspects of prosociality based on the experience of empathic emotion (see Caspi & Shiner, Chapter 6, this *Handbook*, this volume). It is possible that prosocial, sympathetic parents have prosocial children because of shared genetic predispositions toward regulation and emotionality. Moreover, biologically based dispositions (e.g., as partly reflected in temperament) undoubtedly play a major role in empathic and prosocial functioning. However, Plomin et al. (1993) found that nonshared (unique) environmental experience accounted for some consistency and for the substantial degree of change in twins' empathy over the early years of life. Similarly, as discussed, there is evidence of shared and especially unshared environmental variance in the prediction of empathy-related responding and prosocial behavior (e.g., Deater-Deckard, Dunn, et al., 2001; Zahn-Waxler et al., 2001). For example, differences in parenting (i.e., warmth versus harsh parenting) partly explain differences in the prosocial behavior of monozygotic twins, especially for parents who treat their twins quite differently (Asbury et al., 2003; also see Deater-Deckard, Pike, et al., 2001). Further, genetic explanations cannot account for findings in experimental studies in which parents were not involved (e.g., many of

the studies on modeling, preaching, attributions for helping, directives, and learning by doing). In brief, although biological factors, including genetics, play a major role in prosocial development, environmental factors also play an important role and undoubtedly interact with biological factors.

Most researchers who have studied socialization correlates of prosocial responding have taken into account only the effects of parental behaviors and characteristics on children; the role of the children's behavior and characteristics in the socialization process has been virtually ignored. Yet, as was demonstrated by Valiente et al. (2004), it is highly likely that children's personality and temperament interact with parental characteristics and beliefs in determining the quality of the parent-child relationship and parental socialization efforts. Consistent with the possibility of child effects, adults use more reasoning about the consequences of actions and less bargaining with material rewards to induce prosocial behavior for children who are responsive and attentive than for children who are not (Keller & Bell, 1979). The role of the child and dyadic processes (e.g., mutual parent-child responsivity) in the socialization of prosocial behaviors is a key topic for further attention.

### Other Familial and Extrafamilial Influences

People and institutions other than parents in children's environments are potential socializers of children's prosocial actions. Research on the role of nonparental influences is still in the rudimentary stages, and researchers studying environmental influences seldom have simultaneously examined multiple familial models (including multiple family members) or multiple types of potential socializers (e.g., peers and the school context). (For a discussion of the effects of television, see Huston & Wright, 1998).

### Siblings

Because siblings are familiar and relatively uninhibited with one another, they would be expected to play a considerable role in the development of children's social understanding and interpersonal skills, including prosocial behavior (Dunn & Munn, 1986). Even 1- to 2-year-old children exhibit prosocial behavior toward their siblings (Dunn & Kendrick, 1982). Preschool-age children enact relatively high rates of comforting behavior to distressed younger siblings (Howe & Ross, 1990; Stewart & Marvin, 1984), but show relatively low rates of respon-

siveness to unfamiliar younger children (Berman & Goodman, 1984).

Because older siblings often act as caregivers to younger siblings, the sibling relationship provides children with opportunities to learn about others' needs and caring effectively for others. In addition, children with supportive sibling relationships may be less preoccupied with their own feelings of distress, so that they are better able to attend to and understand the feelings and need states of others—promoting prosocial behavior and action (Sawyer et al., 2002). The link between the presence of siblings and prosocial behavior is not always consistent, and it has been argued that the quality of the sibling relationship may be more predictive of children's positive behavior than the mere presence of siblings in the home (Cutting & Dunn, 1999).

As suggested, the child's ordinal position in the sibling dyad probably affects opportunities and expectations for prosocial behavior. Older children are more likely to enact prosocial behaviors directed toward younger siblings and younger siblings accept reciprocal roles by displaying high rates of compliance and modeling (Dunn & Munn, 1986; Stoneman et al., 1986). Moreover, there is evidence that older sisters are particularly likely to engage in prosocial interactions with their siblings (Sawyer et al., 2002; Stoneman et al., 1986; Whiting & Whiting, 1975; cf. Brody, Stoneman, & MacKinnon, 1986). Due to gender roles, older girls may be expected to help, comfort, and teach younger siblings. Tucker and colleagues (Tucker, Updegraff, McHale, & Crouter, 1999) found that older siblings' personal qualities and sibling relationship experiences were related to the empathy of younger sisters, but not younger brothers. By early adulthood, people are less defensive about accepting aid from a sister, particularly from an older sister, than from a brother (especially a younger brother; Searcy & Eisenberg, 1992).

Siblings' prosocial behavior may be related in degree, although the data are sparse and inconsistent. In a study of Japanese children, siblings' prosocial behaviors toward one another were positively related (Kojima, 2000). In contrast, Dunn and Munn (1986) found little correlation between older and younger siblings' prosocial behavior (also see Bryant & Crockenberg, 1980), although younger siblings' cooperation and prosocial behavior were positively related to older siblings' giving and cooperation 6 months later. Furthermore, in that study, siblings who expressed negative affect in a high percentage of their interactions were relatively unlikely

to behave prosocially with one another (cf. Stillwell & Dunn, 1985, using a small sample).

Characteristics of siblings may affect the degree of prosocial behavior between them. For example, sibling relationships in families of children with autism were characterized by less intimacy, prosocial behavior, and nurturance than those that occurred between typically developing siblings or a typical child and a sibling with Down syndrome (Kaminsky & Dewey, 2001). Children with autism rarely seek out others for comfort, affection, or help, decreasing the likelihood that siblings respond in a helpful and affectionate way (Knott, Lewis, & Williams, 1995). Thus, when one sibling has difficulty initiating, maintaining, or promoting positive interactions, prosocial and nurturing sibling interactions are likely to be negatively affected.

Because sibling relationships are embedded in the family, it is not surprising that mothers' behaviors are linked to prosocial behavior between siblings. When mothers discussed their newborn's feelings and needs with an older sibling, the older child was more nurturant toward the infant. Further, friendly interest in the infant persisted and predicted prosocial behavior toward the younger sibling 3 years later (Dunn & Kendrick, 1982). Kojima (2000) found that Japanese mothers' references to the actions or emotional states of a sibling were positively correlated with the other child's prosocial interactions with that sibling. In another study, nurturant maternal responsiveness to young daughters' needs was positively related to younger siblings' comforting and sharing with their older sibling. In contrast, mothers' unavailability was associated with older daughters' prosocial behavior toward their younger sibling (Bryant & Crockenberg, 1980). The latter finding is similar to Brody et al.'s (1986) finding that maternal valuing of a separate life from children was associated with older siblings' helping and managing their younger sibling. Perhaps older siblings, especially daughters, are expected to take a nurturant helping role when the mother is unavailable relatively often.

Because sibling caregiving provides children with opportunities to learn about others' perspectives and emotions, children with sibling caregiving experience may develop relatively mature perspective-taking skills and therefore respond relatively appropriately and effectively in caregiving situations (see section on perspective taking). Stewart and Marvin (1984) found a positive relation between perspective taking and sibling caregiving; however, Howe and Ross (1990) did not find this re-

lation (although perspective taking was related to friendly behavior between siblings). In addition, Garner, Jones, and Palmer (1994) found that emotional role-taking skills, but not cognitive perspective taking, predicted sibling caregiving behavior. Perspective taking about emotions may be a more relevant skill for sibling caregiving than is cognitive perspective taking, although the latter has been emphasized in most studies of perspective taking and sibling interactions. A relation between perspective taking and siblings' prosocial behavior may be partly because high perspective-taking siblings are especially likely to be asked by parents to take care of younger siblings (Stewart & Marvin, 1984).

In summary, sibling interactions may be an important context for learning caregiving behaviors (particularly for older siblings) and the development of perspective taking. However, little is known about the ways in which the larger familial context moderates the development of prosocial responding in the sibling relationship.

### *Peer Influences on Prosocial Development*

Developmental theorists frequently have tied the acquisition of morality to processes inherent in social interactions with peers (Piaget, 1932/1965). These theorists have argued that because peer interactions involve the association with equals and, frequently, cooperation, reciprocity, and mutuality, peer interaction may provide an optimal atmosphere for the acquisition of concepts and behaviors reflecting justice, kindness, and concern for another's welfare (Youniss, 1980). Consistent with this view, Tesson, Lewko, and Bigelow (1987) found that prosocial themes pertaining to issues such as reciprocity, sincerity and trust, helping and solving problems, and sensitivity to others' feelings were prominent in 6- to 13-year-old children's reports of the social rules they used in peer relationships. Additionally, having at least one reciprocated friendship has been related to higher levels of prosocial behavior (Wentzel, Barry, & Caldwell, 2004).

Researchers also have found that the quality of children's prosocial behavior directed toward peers and adults differs somewhat, particularly at younger ages. When asked to give examples of kindness directed toward peers, 6- to 14-year-olds tended to cite giving and sharing, playing, physical assistance, understanding, and teaching. In contrast, they cited primarily being good or polite, doing chores, and obeying in regard to kindness toward adults (Youniss, 1980). Further, preschoolers provide more authority- and punishment-related reasons

for complying with adults' than peers' requests, and more other-oriented or relational (friendship, liking) motives for complying with peers' requests (Eisenberg, Lundy, et al., 1985). With age, children appear to be slightly more likely to define kindness toward adults in a manner similar to peer-directed kindness; that is, as involving acts demonstrating concern rather than compliance (Youniss, 1980). Thus, peer interactions may provide a context that is conducive to the development of prosocial behavior motivated by other-oriented concerns rather than compliance, particularly for prosocial actions directed toward individuals outside the family.

Other research also is consistent with the notion that peer interactions are important for the development of empathy, sympathy, and an other-orientation. According to maternal reports, infants and toddlers cry more in response to cries of peers than of adults (Zahn-Waxler, Iannotti, & Chapman, 1982). Children observed adults cry relatively infrequently, and when they did, they generally did not cry. When children cried in response to adults' distress, it usually was in reaction to angry interactions such as fights between parents. Moreover, prosocial behavior (when it occurred) was enacted more often in response to a child's than to an adult's distress.

Peers also may affect prosocial development because of their roles as models. Adolescents who volunteer are relatively likely to have friends who feel it is important to engage in activities such as sports, clubs, or school events (Huebner & Mancini, 2003), to do well in school, and to be involved in community and volunteer work (Zaff et al., 2003). In contrast, adolescents are relatively unlikely to report the intention to volunteer if they belong to a crowd that places a high value on having fun (Youniss, McLellan, & Mazer, 2001; also see Pugh & Hart, 1999). Although such data are only correlational and do not demonstrate causality, prosocial peer models sometimes have been found to be effective in eliciting prosocial behavior in the laboratory (e.g., Owens & Ascione, 1991). Familiarity and liking of peer models may be important factors in influencing children's prosocial behavior: Children may have greater identification with fellow peers and may experience more freedom to try out new behaviors with peers than they do with adults. However, findings in this regard are sparse and are not readily interpretable (see Owens & Ascione, 1991). In one study, children with a history of receiving social reinforcement from peers were more likely to model the donating behavior of a peer from whom they had re-

ceived frequent rewards than the behavior of a nonrewarding peer. In contrast, children with a history of infrequent peer reinforcement imitated the prosocial behavior of a nonrewarding rather than a rewarding peer (Hartup & Coates, 1967). Thus, characteristics of the child and the peer model influence whether children imitate peers' prosocial actions.

Peers sometimes respond in a reinforcing manner to peers' prosocial actions (Eisenberg, Cameron, Tryon, & Dodez, 1981), and such reinforcement may affect children's prosocial behavior. Eisenberg et al. (1981) found that preschool girls (but not boys) who engaged in relatively high levels of spontaneous prosocial behavior were those who received marginally more positive reinforcement for their prosocial actions from peers. However, preschoolers (especially boys) who were high in compliant (requested) prosocial actions received low levels of positive reinforcement for their compliant prosocial actions. Sociable children were relatively likely to receive positive peer reactions when they enacted compliant prosocial actions, and children who responded positively to other children's spontaneous prosocial behaviors were likely to receive positive peer reactions for their own spontaneous and compliant prosocial behavior. Thus, children who were more sociable and positive may have elicited the most peer reinforcement when they engaged in prosocial behavior. A cyclical process may occur in which socially competent children elicit more positive peer reactions for prosocial behavior, which in turn increases their prosocial behavior (with the reverse process occurring for children low in social skills).

Related to this cyclical process, Fabes, Martin, and Hanish (2002) analyzed the degree to which low- and high-prosocial children (i.e., those at least 1 standard deviation below or above the mean in teacher-reported prosociality) interacted with each other. Rarely were low and high prosocial children observed interacting with each other (about 5% of the time). Fabes et al. referred to this as a type of "prosocial segregation." Of importance, the more exposure that preschool children had to prosocial peers at the beginning of the school year, the greater the degree of positive peer interactions later in the school year. In a longitudinal extension of these analyses, Fabes, Moss, Reesing, Martin, and Hanish (2005) found that exposure to prosocial peers was related to heightened prosocial behavior 1 year later. In addition, Wentzel et al. (2004) found that students with

initially low levels of prosocial behavior relative to those of their friends improved when exposed to their more prosocial peers, and students with initially higher levels of prosocial behavior decreased their levels of prosocial behavior when exposed to their less prosocial peers. Such findings demonstrate the potential potency of peers as influences on the subsequent likelihood of prosocial and positive development.

Peer interactions seem to provide unique opportunities for prosocial behavior, and peer responses in such contexts may influence the type and degree of potential prosocial responses. The role of peer interaction in older children's and adolescents' prosocial behavior has seldom been examined and little is known about the degree to which the effects of peers are moderated by other variables (e.g., the nature of interactions with other socializers and characteristics of the child, the peer group, or the context) or the exact processes that underlie such influences.

### *School Programs*

Children likely receive considerable moral education and training in school, but little is known about the effects of school experiences on children's prosocial behavior.

One avenue for examining the potential impact of the school context on children's prosocial behavior is to assess the natural occurrence of prosocial behavior in the classroom. Hertz-Lazarowitz (1983; Hertz-Lazarowitz, Fuchs, Sharabany, & Eisenberg, 1989) found that naturally occurring prosocial behaviors in school classrooms (Grades 1 to 12) were relatively rare (only 1.5% to 6.5% of total behaviors). Similarly, researchers usually have noted low frequencies of prosocial behavior in preschool classes, although estimates vary considerably with the operationalization of prosocial behavior (e.g., Caplan & Hay, 1989; Denham & Burger, 1991; Eisenberg et al., 1981; Fabes et al., 2002; Strayer, Wareing, & Rushton, 1979). Further, in studies of preschoolers, teachers rarely reinforced (Eisenberg et al., 1981) or encouraged (Caplan & Hay, 1989) children's prosocial behavior.

Findings such as these suggest that the typical classroom environment may not be conducive to eliciting frequent prosocial interactions among children. Salient and unambiguous expectations regarding prosocial behavior may be necessary to elicit more spontaneous prosocial actions in the classroom. Moreover, structuring classes to provide children with opportunities to help others may promote prosocial behavior. Bizman, Yinon,

Mivtzari, and Shavit (1978) found that Israeli kindergartners enrolled in classes that contained younger peers were more altruistic than those enrolled in classes that were homogeneous in age. Further, elementary school Israeli students in active classrooms in which cooperation and individualized learning were emphasized helped peers more than students in traditional classrooms (Hertz-Lazarowitz et al., 1989).

Some investigators have tried to assess the effects of preschool and day care on children's prosocial development by comparing children who attend preschool with those who do not (e.g., are reared at home). Clarke-Stewart (1981) suggested that attendance at group day care has a temporarily accelerating effect on social development and found that prosocial behavior was higher for children with nonparental care. However, evidence in support of this contention is equivocal. Schenk and Grusec (1987) found that home-care children were more likely than day-care children to behave prosocially in situations involving an adult stranger, whereas the two groups were similar on helping unknown children. Other researchers have produced results indicating that out-of-home care per se does not have any reliable or consistent effects on children's emerging prosocial development (Austin et al., 1991).

Although differences between home versus group care children may be limited, quality of the caregiving situation likely moderates the degree and type of influence preschools have on children's prosocial behavior and attitudes (Love et al., 2003). Quality of the day care or preschool environment has been associated with children's self-regulation (Howes & Olenick, 1986), empathy and social competence (Vandell, Henderson, & Wilson, 1988), considerateness (Phillips, McCartney, & Scarr, 1987), and positive peer-related behaviors (including prosocial behaviors; Broberg, Hwang, Lamb, & Ketterlinus, 1989). Moreover, warm, supportive interactions with teachers have been associated with preschool children's modeling of teachers' prosocial actions (Yarrow et al., 1973), sympathetic-prosocial reactions to distress (Kienbaum, Volland, & Ulich, 2001), and positive interactions among students in the elementary school classroom (Serow & Solomon, 1979). In addition, Howes, Matheson, and Hamilton (1994) found that children classified as securely attached to their current and first preschool teachers were rated as more considerate and empathic with unfamiliar peers than were children classified as having an insecure relationship (especially

ambivalent) with their teachers. Contemporaneous teacher-child relationships better differentiated peer-related outcomes for children than did contemporaneous maternal attachment relations or day-care history. Thus, degree and type of influence exerted by school experiences, as well as durability of effects on prosocial responding, probably varies as a function of quality of care received and the child's relationship with the teacher (as well as quality of care received from parents at home).

Based on the previously described literature concerning the socialization of prosocial attitudes and behavior, some investigators have attempted to design school-based programs aimed at fostering prosocial responding. Solomon and colleagues (Solomon, Battistich, Watson, Schaps, & Lewis, 2000; Solomon, Watson, Delucchi, Schaps, & Battistich, 1988) developed a program (The Child Development Project, henceforth referred to as the CDP) in which teachers were trained to maintain positive personal relationships with their students by using a child-centered approach to classroom management that emphasized inductive discipline and student participation in rule-setting. Other aspects of the program were designed to promote social understanding, highlight prosocial values, and provide helping activities; however, these program components were viewed as playing a more limited, supportive role in the program (Battistich, Watson, Solomon, Schaps, & Solomon, 1991).

Across 5 consecutive years of implementation (kindergarten through fourth grade), students in the program classrooms, compared with control classes, generally scored higher on ratings of prosocial behavior. These patterns held when both teachers' general competence and students' participation in cooperative activities were controlled, suggesting that program effects on children's prosocial behavior were not due simply to differences in teacher-initiated cooperative interactions or to more efficiently organized and managed classrooms (Solomon et al., 1988).

Children enrolled in the program (but not children in the control group) evidenced the highest ratings for prosocial behavior and harmony in kindergarten. Thus, it appears that the impact of this program was greatest when first introduced. The degree to which program effects generalized beyond the immediate classroom environment was unclear (Battistich et al., 1991). However, the teachers in the program had only 1 year of experience in implementing the program and the effects may have been more sustained given additional time for

teachers to develop their techniques and fully integrate the program into the ongoing routine of the classroom.

In another longitudinal test of the effects of the CDP, the program was used with a cohort of students who began in kindergarten and continued through eighth grade (Solomon, Battistich, & Watson, 1993). Of particular interest, measures of prosocial reasoning and conflict resolution were obtained each year. Comparison students reasoned higher than CDP children at kindergarten, but CDP students reasoned at higher levels from first grade on, although the within-year difference was significant only in second grade. In general, CDP students also evidenced higher conflict resolution scores than comparison students (indicating consideration of others' needs and a reliance on compromise and sharing). Program effects appeared to be greater when combined across years (effects were not consistently significant within years). However, the CDP initially was implemented in schools with mostly advantaged Caucasian children. More recently, the CDP was implemented in six school districts over a 3-year period, with two additional schools in each district serving as comparison groups (Battistich, Schaps, Watson, Solomon, & Lewis, 2000; Solomon et al., 2000). For those schools that made significant progress in implementing the program, students showed positive gains in personal, social, and ethical values, attitudes, and motives, and a reduction of substance abuse and other problem behaviors (also see Battistich, Solomon, Kim, Watson, & Schaps, 1995).

Other school-based programs have been designed to promote empathy. Although some seem to have been minimally effective (e.g., Kalliopuska & Tiitinen, 1991), Feshbach and Feshbach (1982) found that empathy training significantly increased incidents of prosocial behavior in schoolchildren. Moreover, the use of cooperative educational techniques in classroom activities has been found to promote acceptance of others (Johnson & Johnson, 1975), as well as cooperation and prosocial behavior (Hertz-Lazarowitz & Sharan, 1984; Hertz-Lazarowitz, Sharan, & Steinberg, 1980).

Some researchers have developed school-based programs that include a formal curriculum component. Ascione (1992) studied the effects of a humane education program when used with first, second, fourth, and fifth graders for nearly 40 hours over the school year. There was relatively little evidence of an immediate effect for younger children, although there was an effect on humane attitudes a year later (Ascione & Weber, 1993).

Humane attitudes were enhanced for the fourth graders in the immediate posttest and for fourth and fifth graders a year later. Human-directed empathy increased for fourth and fifth graders on both the initial and 1-year posttests.

In summary, although prosocial behavior often may not be directly promoted in the classroom, quality early schooling and supportive relationships between children and their teachers have been associated with the development of prosocial tendencies. Moreover, school-based programs designed to enhance prosocial values, behaviors, and attitudes in children can be effective in fostering children's prosocial attitudes and behaviors. However, most programs have involved relatively weak and short interventions that may not be adequate for some groups of children. Variation in instruction among teachers within a treatment group often is problematic, as is the application of these programs to large and diverse samples. These issues are critical if one hopes to argue that such programs are cost-effective and impactful, especially in contexts where resources and time are limited.

### **COGNITIVE AND SOCIOCOGNITIVE CORRELATES OF PROSOCIAL DEVELOPMENT**

Numerous theorists have hypothesized that cognitive and sociocognitive skills, particularly perspective taking and moral reasoning, foster prosocial responding (Batson, 1991; Eisenberg, 1986; Hoffman, 1982). Moreover, although not discussed, it is likely that certain types of prosocial experiences provide experiences that enhance children's sociocognitive skills (see Eisenberg, 1986, for a review of children's understanding of, and attributions about, their own and others' kindness).

#### **Intelligence, Cognitive Capacities, and Academic Achievement**

Because cognitive abilities may underlie the ability to discern others' needs or distress, as well as the capacity to devise ways to respond to others' needs, it would be logical to expect a modest relation between measures of intelligence and prosocial responding, particularly prosocial behavior involving sophisticated cognitive skills. Some investigators have obtained modest to moderate positive correlations between measures of intelli-

gence (e.g., IQ, vocabulary or reading skills, language development, developmental level) and self-reported (Carlo, Hausmann, Christiansen, & Randall, 2003; Cassidy, Werner, Rourke, Lubernis, & Balaraman, 2003; Hart et al., 1998; Ma & Leung, 1991; also see Goodman, 1994) or other measures of prosocial behavior (Krebs & Sturup, 1982; Slaughter, Dennis, & Pritchard, 2002; van der Mark et al., 2002; Zahn-Waxler et al., 1982; also see Lourenco, 1993; Zaff et al., 2003). Grade point average also has been linked to prosocial goals and behavior (Caprara, Barbaranelli, Pastorelli, Bandura, & Zimbardo, 2000; Huebner & Mancini, 2003; Johnson et al., 1998; Uggen & Janikula, 1999; Wentzel, 2003; Zeldin & Topitzes, 2002; also see Lichter et al., 2002), as have teachers' ratings of school performance combined with grades (e.g., Welsh, Parke, Widaman, & O'Neil, 2001). In addition, there is some support for a positive relation between scores on achievement tests and children's empathy (Feshbach, 1978) or sympathy (Wise & Cramer, 1988), and between academic self-efficacy and prosocial behavior (Bandura et al., 2001, 2003). Not surprisingly, given the array of measures used, some researchers have found no significant relations between tests of intelligence (or scholastic ability) and children's prosocial behavior (e.g., Jennings, Fitch, & Suwalsky, 1987; Turner & Harris, 1984) or have obtained mixed or inconsistent relations with prosocial behavior (e.g., Strayer & Roberts, 1989) or sympathy (Wise & Cramer, 1988). Intelligence and academic skills likely are associated with certain types of prosocial responding or prosocial behavior in some contexts.

#### **Perspective Taking and Understanding of Emotion**

As noted, it is commonly assumed that perspective-taking skills increase the likelihood of individuals identifying, understanding, and sympathizing with others' distress or need (e.g., Batson et al., 2003; Eisenberg, Shea, et al., 1991; Feshbach, 1978; Hoffman, 1982). Hoffman (1982) proposed that improvement in young children's perspective taking is critical to children's abilities to differentiate between their own and others' distress and to accurately understand others' emotional reactions. These skills are believed to foster empathy and sympathy and, consequently, more and higher quality prosocial behavior.

Information about others' internal states can be obtained by imagining oneself in another's position or through processes such as accessing stored knowledge,

mental associations, and social scripts or deduction (Karniol, 1995). Children also may have “theories” about others’ internal states that they use to infer how others feel (see Eisenberg, Murphy, & Shepard, 1997). For convenience, and because it generally is difficult to identify the processes underlying performance on perspective-taking tasks, the term *perspective taking* is used to refer to the ability to engage in any of these processes when they result in knowledge about others’ internal states.

Researchers have found an association between perspective taking (broadly defined, and including an understanding of theory of mind) and prosocial behavior (including comforting skills) or empathy/sympathy, although findings sometimes have been obtained for only some of the examined associations (e.g., Bengtsson, 2003; Bengtsson & Johnson, 1992; Bosacki, 2003; Carlo et al., 2003; Cassidy et al., 2003; Charbonneau & Nicol, 2002; Denham, Blair, et al., 2003; Denham & Couchoud, 1991; Denham et al., 1994; Dekovic & Gerris, 1994; Eisenberg, Carlo, et al., 1995; Eisenberg, Zhou, & Koller, 2001; Estrada, 1995; Garner & Estep, 2001; Garner, Jones, & Miner, 1994; Ginsburg et al., 2003; Kumru & Edwards, 2003; Litvack-Miller, McDougall, & Romney, 1997; Roberts & Strayer, 1996; Slaughter et al., 2002; Strayer & Roberts, 2004b; also see Eisenberg & Fabes, 1998; Matsuba & Walker, 2005). Although no such association has been found in a minority of studies (e.g., Astington & Jenkins, 1995; Hughes, White, Sharpen, & Dunn, 2000; Lalonde & Chandler, 1995; Peterson, 1983; Zahn-Waxler et al., 1982), to our knowledge, perspective taking seldom has been significantly negatively related to children’s prosocial behavior (e.g., Barrett & Yarrow, 1977; LeMare & Krebs, 1983, for low assertive boys only). Moreover, the match between children’s facial reactions and reported reactions to empathy-inducing stimuli (believed to reflect emotional insight) has been positively related to their empathy (Roberts & Strayer, 1996), whereas young adolescents’ self-understanding has been associated with high levels of prosocial behavior (Bosacki, 2003).

Positive findings were obtained in many studies although most researchers used single measures of perspective-taking abilities or prosocial behavior rather than more reliable indexes created by aggregation across measures. The association does not seem to be due merely to increases in both perspective taking and prosocial behavior with age; often the age range of the study participants was narrow or findings were main-

tained when age was controlled (e.g., Garner, Jones, & Palmer, 1994; see Underwood & Moore, 1982). As might be expected, the relation seems to be stronger when there is a match between the type of perspective-taking skills assessed and the type or level of understanding likely to promote prosocial behavior in the given context (Carlo, Knight, Eisenberg, & Rotenberg, 1991). In some circumstances, perspective-taking skills may be unimportant because prosocial actions are enacted in a relatively automatic fashion due to either their low cost or the compelling, crisis-like nature of the situation. In other contexts, prosocial behavior likely is motivated by any number of factors other than knowledge of another’s internal states.

Some people may take others’ perspectives but lack the motivation, skills, or social assertiveness required to take action. Thus, the relations of measures of perspective taking or emotion understanding with prosocial responding are likely moderated by other variables. Perspective taking has been linked to prosocial behavior for children who are socially assertive (Barrett & Yarrow, 1977; Denham & Couchoud, 1991), but not for children who are less assertive. Similarly, the relation of perspective taking to prosocial behavior sometimes has been mediated or moderated by children’s empathic/sympathetic responding (Barnett & Thompson, 1985; Roberts & Strayer, 1996). In one study, children who donated money to help a child who had been burned were those who not only evidenced relatively sophisticated perspective-taking skills, but also were sympathetic and understood units and value of money (Knight, Johnson, Carlo, & Eisenberg, 1994). In another study, perspective taking was not directly related to reported prosocial behavior; it was indirectly related through its prediction of both sympathy and moral reasoning (Eisenberg, Zhou, & Koller, 2001).

In summary, children with higher perspective-taking skills generally are somewhat more prosocial, particularly if their perspective-taking abilities are relevant to the prosocial task and if they have the social skills (e.g., assertiveness) and emotional motivation (e.g., sympathy) to act on the knowledge obtained by perspective taking. Perspective-taking skills may be involved in discerning others’ needs, providing sensitive help, and evoking the affective motivation for prosocial action (i.e., sympathy, empathy, or guilt). Moreover, it is likely that children with well-developed perspective-taking abilities have more opportunities to be prosocial; for example, older siblings with better perspective-taking

skills are more frequently asked by their mothers to provide caregiving to younger siblings (Stewart & Marvin, 1984).

### Person Attributions and Expressed Motives

Although children sometimes may report socially desirable motives or may have little access to their motives (see Eisenberg, 1986, for a discussion of these issues), there appears to be some relation between children's expressed motives and the quantity (e.g., Bar-Tal, Raviv, et al., 1980) or quality (i.e., maturity; see Bar-Tal, 1982) of their prosocial behavior (see Eisenberg, 1986, for a review). As discussed by Eisenberg (1986), it is unclear whether children's motives influence their prosocial responding or if children formulate motives post hoc to the execution of behavior based on self-observation. In support of the former explanation, Smith et al. (1979) found that individual differences in expressed internality of motives were associated with donating, whereas environmental contingencies (e.g., rewards and punishments) that might influence post hoc evaluations were not. In any case, it is likely that people have greater access to their cognitive processes (including motives) when a task is not so overlearned that it can be performed in a mindless manner. Therefore, it is probable that expressed motives are more accurate for prosocial acts that are not performed automatically; that is, when the potential benefactor must consider whether to assist. At this time, data to test this idea are not available (see, however, Eisenberg & Shell, 1986).

### Moral Reasoning

In general, investigators have hypothesized that there should be some link between children's moral reasoning and their behavior. Krebs and Van Hesteren (1994) asserted: "[A]dvanced stages give rise to higher quantities of altruism than less advanced stages because they give rise to greater social sensitivity, stronger feelings of responsibility, and so on. . . . We propose that advanced stage-structures give rise for forms of altruism that are (1) purer (i.e., more exclusively devoted to enhancing the welfare of others, as opposed to the self) and (2) deeper (i.e., that benefit others in less superficial and less transient ways) than less advanced structures" (p. 136).

Prosocial actions can be motivated by a range of considerations, including altruistic, pragmatic, and even self-oriented concerns; this attenuates the degree to

which one might expect associations between general level of moral reasoning and observed prosocial actions. However, prosocial behavior motivated by a particular type of factor (e.g., sympathy) is likely to be correlated with the types or levels of reasoning reflecting that factor, although not necessarily with an individual's overall level of reasoning.

In published studies involving child participants, prosocial behavior has been inconsistently related to aspects of Piaget's scheme of moral judgment (e.g., intentionality, distributive justice), but generally (albeit not consistently) positively related to Kohlbergian prohibition- and justice-oriented moral reasoning (or modified versions thereof; see Eisenberg, 1986; Eisenberg & Fabes, 1998; Underwood & Moore, 1982). However, there appears to be a stronger correspondence between moral reasoning and prosocial behavior if the moral reasoning dilemma concerns reasoning about prosocial behavior rather than another type of behavior. Levin and Bekerman-Greenberg (1980) found that the strength of the positive relation between reasoning about sharing and actual prosocial behavior was somewhat greater if the dilemma and sharing task were similar in content. Moreover, when researchers have assessed children's moral reasoning about dilemmas involving helping or sharing behavior, generally moral reasoning has been associated in the predicted manner with at least some measures of prosocial behavior (e.g., Carlo & Randall, 2002; Eisenberg, Carlo, et al., 1995; Eisenberg, Miller, et al., 1991; Eisenberg, Zhou, & Koller, 2001; Janssens & Dekovic, 1997; Kumru et al., 2003; Larrieu & Mussen, 1986; Stewart & McBride-Chang, 2000; also see Eisenberg, 1986, and Eisenberg & Fabes, 1998, for reviews). In addition, children who reason at developmentally mature levels are less likely than children who reason at lower levels to say they would discriminate between people close to them and others when deciding whether to help (Eisenberg, 1983; also see Ma, 1992).

Types of reasoning that reflect an other- versus self-orientation or are developmentally mature for the age group are most likely to predict prosocial responding. Hedonistic reasoning and needs-oriented reasoning (i.e., rudimentary other-oriented reasoning) tend to be negatively and positively related, respectively, to prosocial behavior (e.g., Carlo et al., 1996; Carlo et al., 2003; Eisenberg, Boehnke, et al., 1985; Eisenberg, Carlo, et al., 1995; Eisenberg, Miller, et al., 1991; Eisenberg & Shell, 1986). In addition, sometimes a mode of reasoning that is relatively sophisticated for the age group

(Carlo & Randall, 2002; Miller, Eisenberg, Fabes, & Shell, 1996; Schenk & Grusec, 1987) has been significantly associated with prosocial behavior. It is possible that the relation of moral reasoning and prosocial behavior increases with age across adolescence (Pratt et al., 2004) because moral reasoning becomes more mature and internalized with age (Eisenberg, 1986).

The nature of the enacted prosocial behavior also seems to be a critical variable. Higher level self-reported internalized prosocial moral reasoning tends to be positively correlated with adolescents' reports of altruistic prosocial actions and helping in emotional and anonymous situations, whereas lower level reasoning (i.e., approval-oriented or hedonistic) tends to be related positively to reported public helping and negatively to altruism or helping in emotional or dire circumstances (Carlo, Hausmann, et al., 2003). In observational studies, prosocial moral reasoning most often has been significantly positively related to preschoolers' spontaneous sharing behaviors rather than helping behaviors (which, in these studies, generally entailed little cost) or prosocial behaviors performed in compliance with a peer's request (Eisenberg et al., 1984; Eisenberg-Berg & Hand, 1979). Preschoolers' spontaneous prosocial behaviors predict a prosocial, sympathetic orientation across childhood and into early adulthood (Eisenberg, Guthrie, et al., 1999, 2002).

In laboratory studies involving elementary or high school students, prosocial moral reasoning more frequently has been associated with prosocial actions that incur a cost (e.g., donating or volunteering time after school) than with those low in cost (e.g., helping pick up dropped paper clips; Eisenberg, Boehnke, et al., 1985; Eisenberg & Shell, 1986; Eisenberg, Shell, et al., 1987; also see Miller et al., 1996). Eisenberg and Shell (1986) hypothesized that low-cost behaviors are performed rather automatically, without much cognitive reflection, moral or otherwise. In contrast, moral reasoning is likely to be associated with children's prosocial behavior in situations involving a cost because consideration of the cost may evoke cognitive conflict and morally relevant decision making.

It also is likely that other variables moderate the relation between moral judgment and prosocial behavior, particularly for lower level modes of reasoning (at higher levels, moral principles may be sufficient motivation to help). Sympathetic responding is a probable moderator. Consistent with this view, Miller et al. (1996) found that preschoolers who reported sympathy

for hospitalized children *and* who were relatively high in use of needs-oriented reasoning were especially likely to help hospitalized children at a cost to themselves. Affective motivation such as sympathy (and perhaps guilt) often may be necessary to spur the individual to action. Thus, it is important to identify moderators and mediators of the relation between moral reasoning and prosocial responding.

## EMPATHY-RELATED EMOTIONAL RESPONDING

As noted, psychologists (e.g., Eisenberg, 1986; Feshbach, 1978; Hoffman, 1982; Staub, 1979) and philosophers (Blum, 1980; Hume, 1748/1975; Slote, 2004) have proposed that prosocial behavior, particularly altruism, often is motivated by empathy or sympathy. Links between empathy or sympathy and prosocial behavior have been presumed to exist both within specific contexts (e.g., Batson, 1991; Eisenberg & Fabes, 1990) and at the dispositional level (i.e., people with a dispositional tendency toward empathy/sympathy are expected to be altruistic in general; Eisenberg & Miller, 1987).

Although many psychologists have assumed that empathy plays a role in prosocial behavior, in a meta-analytic review, Underwood and Moore (1982) found that empathy was *not* significantly related to prosocial behavior. Many of the studies they reviewed were conducted with children, and most involved a particular type of measure—the picture/story measure of empathy. With this type of measure, children are presented with a series of short vignettes, usually illustrated (rather than videotaped), about children in emotionally evocative contexts (e.g., when a child loses his or her dog). After each vignette, the child is asked, "How do you feel?" or a similar question. If children say they felt an emotion similar to that which the story protagonist would be expected to feel, they typically are viewed as empathizing.

The validity of this sort of measure has been questioned, in part because these measures were not very evocative (see Eisenberg & Lennon, 1983; Lennon, Eisenberg, & Carroll, 1983). In fact, the degree of association between measures of empathy-related responding and prosocial behavior appears to vary as a function of the measure of empathy. In a meta-analytic review of the literature, Eisenberg and Miller (1987) found no significant relation between prosocial behavior and picture/story measures (or children's self-reported reactions to enactments or videotapes of others in dis-

tress or need). In contrast, there were significant positive associations with prosocial behavior for some non-self-report measures of empathy-related responding and self-report measures for older adolescents and adults. At the time of the Eisenberg and Miller review, there were few published studies including facial or physiological measures or the use of questionnaires with children in preschool or early elementary school.

In recent years, it has become clear that it is essential to differentiate among empathy-related emotional reactions. Batson (1991) hypothesized that sympathy (as defined at the beginning of this chapter, although labeled "empathy" by Batson) is intimately linked with other-oriented motivation and, consequently, with other-oriented, altruistic helping behavior. In contrast, personal distress is viewed as involving the egoistic motivation of alleviating one's own distress; therefore, it is expected to motivate prosocial behavior only when the easiest way to reduce one's own distress is to reduce the other's distress (e.g., when one cannot easily escape contact with the empathy-inducing person).

Consistent with his theorizing, Batson and his colleagues, in laboratory studies with adults, have found that sympathy is more likely to be positively associated with helping than is personal distress when it is easy for people to escape contact with the person needing assistance (see Batson, 1991). In a series of studies, Eisenberg, Fabes, and their colleagues obtained similar findings with children. In their studies, children's prosocial behavior was as anonymous as possible and children did not have to interact in any way with the needy other(s) if they did not want to do so. Eisenberg et al. (1994) argued that people tend to experience personal distress when they are physiologically overaroused, whereas they experience sympathy when they experience moderate vicarious arousal. Thus, the researchers hypothesized that high levels of autonomic arousal would be associated with personal distress, whereas the reverse would be true for sympathy (except when low arousal is likely an index of no empathy-related responding, especially to a mild stimulus). In addition, heart rate deceleration tends to occur when individuals are oriented to information in the environment outside the self; this is another reason one might expect an association between experiencing sympathy and heart rate deceleration. Across studies in which children were shown empathy-inducing videotapes, children who exhibited facial or physiological (i.e., heart rate deceleration or lower skin conductance)

markers of sympathy tended to be relatively prosocial when given an opportunity to assist someone in the film or people similar to those in the film (e.g., hospitalized children). In contrast, children who exhibited evidence of personal distress (higher heart rate or skin conductance) tended to be less prosocial (Eisenberg, Fabes, et al., 1993; Eisenberg, Fabes, et al., 1990; Eisenberg, Fabes, Karbon, Murphy, Carlo, et al., 1996; Eisenberg, Fabes, Miller, et al., 1989; Fabes, Eisenberg, Karbon, Bernzweig, et al., 1994; Fabes, Eisenberg, Karbon, Troyer, & Switzer, 1994; Miller et al., 1996). Self-report measures in these studies tended to be less consistently related to children's prosocial behaviors (see Eisenberg & Fabes, 1990). Fabes, Eisenberg, and Eisenbud (1993) also found that skin conductance (a marker of personal distress) predicted girls' (but not boys') low *dispositional* (rather than situational) helpfulness (i.e., parental ratings of helpfulness rather than prosocial behavior in the same context). Moreover, facial reactions of sympathy have been linked to prosocial behavior in another context (Eisenberg, Fabes, et al., 1990; Eisenberg, McCreath, & Ahn, 1988).

As one would expect, not all markers of sympathy or personal distress in Eisenberg, Fabes, and their colleagues' research predicted prosocial behavior (or sometimes for both sexes; e.g., Eisenberg, Fabes, Karbon, Murphy, Carlo, et al., 1996; Miller, et al., 1996). In addition, heart rate markers of reactions to empathy-inducing films predicted prosocial behavior within, but not across, contexts (e.g., Eisenberg, Fabes, et al., 1990). Nonetheless, the overall pattern of findings is consistent. Further, other investigators have obtained similar findings. Zahn-Waxler and her colleagues found that sympathetic concern and prosocial actions seemed to co-occur in the behavior of children aged 14 and 26 months (Zahn-Waxler, Robinson, & Emde, 1992; Zahn-Waxler et al., 2001) and 4 to 5 years (Zahn-Waxler et al., 1995), although self-distress in reaction to another's emotion (Zahn-Waxler, Robinson, & Emde, 1992) and arousal (Zahn-Waxler et al., 1995) were unrelated to prosocial behavior in toddlers (also see Trommsdorff, 1995). Zahn-Waxler et al. (1995) also found (a) children's heart rate deceleration during exposure to sadness (at the peak interval) was associated with 3 of 4 measures of prosocial responding, and (b) behavioral/ facial measures of concerned attention were positively related to prosocial behavior directed toward the target of concern. Similarly, Volling (2001) found that preschoolers who turned

their backs or moved away from a distressed younger sibling were also more likely to display personal distress reactions. Trommsdorff and Friedlmeier (1999) reported that German children's facial sympathy was positively correlated with intensity of observed helping, unless they were distracted by another task.

Preschoolers' personal distress reactions also have been positively related to the children's tendency to engage in compliant, requested prosocial behaviors in other contexts (Eisenberg, Fabes, et al., 1990; Eisenberg et al., 1988). Compliant prosocial behavior, in contrast to spontaneously emitted prosocial behavior, has been correlated with low assertiveness, low levels of positive peer reinforcement, low levels of positive response to peers' prosocial actions, and low levels of social interaction. Children high in compliant prosocial responding, especially boys, seem to be nonassertive and perhaps are viewed as easy targets by their peers (Eisenberg et al., 1981; Eisenberg et al., 1988; Larrieu, 1984). Unlike frequency of spontaneous sharing, young children's compliant prosocial behaviors generally do not predict their sympathy at older ages, although there are a few correlations of compliant sharing with self-reported measures evident in adolescence and early adulthood (Eisenberg, Guthrie, et al., 1999, 2002). It is possible that young children who exhibit high levels of compliant behavior with peers are relatively low in social competence and emotion regulation, and engage in requested prosocial behaviors as a means of curtailing unpleasant social interactions.

Studies since Eisenberg and Miller's (1987) review support the view that questionnaire measures tapping empathy (Albiero & Lo Coco, 2001; Eisenberg, Miller, et al., 1991; Eisenberg, Shell, et al., 1987; Hoffner & Haefner, 1997; cf. Stewart & McBride-Chang, 2000), sympathy (Eisenberg, Carlo, et al., 1995; Eisenberg, Miller, et al., 1991; Estrada, 1995; Knight et al., 1994; Litvack-Miller et al., 1997), sympathy and empathy combined (e.g., Krevans & Gibbs, 1996), or empathic self-efficacy (i.e., perceived ability to experience empathy/sympathy; Bandura et al., 2003) are positively related to some measures of children's prosocial behavior in Asian (e.g., in Japan; Asakawa, Iwawaki, Mondori, & Minami, 1987), mid-Eastern (Kumru & Edwards, 2003), or European samples (Bandura et al., 2003), as well as in North American samples. Relations between dispositional empathy or sympathy and prosocial behavior seem to be most consistent for self-reported or relatively costly prosocial behavior (Eisenberg, Miller, et al., 1991; Eisenberg, Shell, et al., 1987). Findings for

self-reported empathy are not highly consistent (e.g., Larrieu & Mussen, 1986; Strayer & Roberts, 1989; also see Roberts & Strayer, 1996). However, empathy questionnaires often contain items that may reflect personal distress or sympathy in addition to empathy. Children's self-reported personal distress on questionnaires tends not to be related to children's prosocial behavior (e.g., Eisenberg, Carlo, et al., 1995; Eisenberg, Miller, et al., 1991; Litvack-Miller et al., 1997), although a weak negative relation was obtained with adolescents (Estrada, 1995). It may be that questionnaire measures of personal distress, which have been adapted from work with adults, are not optimal for children.

In brief, recent research findings are consistent with the conclusion that sympathy and sometimes empathy (depending on its operationalization) are positively related to prosocial behavior, whereas personal distress, particularly as assessed with nonverbal measures, is negatively related (or unrelated for self-reports) to prosocial behavior. As might be expected, there is more evidence of associations within contexts than across contexts, although children with a sympathetic disposition appear to be somewhat more prosocial in general than are other children. In addition, there is evidence that the relation of sympathy to prosocial behavior is moderated by dispositional perspective taking (Knight et al., 1994) and moral reasoning (Miller et al., 1996). Thus, it is important to identify dispositional and situational factors that influence when and whether empathy-related situational reactions and dispositional characteristics are related to prosocial behavior.

## DISPOSITIONAL AND PERSONALITY CORRELATES OF PROSOCIAL BEHAVIOR

Some, but not all, aspects of personality likely have a substantial genetic basis. Thus, some of the research on personality correlates (particularly those viewed as part of temperament, such as negative emotionality) is relevant to an understanding of the constitutional bases of prosocial behavior and empathy. Moreover, information on the personality correlates of prosocial behavior could provide clues to the environmental origins of prosocial behavior when there is evidence of a link between a given aspect of personality and socialization.

### Consistency of Prosocial Behavior

The assertion that there are personality correlates of prosocial behavior implies a more basic assumption: that

there is some consistency in children's prosocial responding. Consistency of the existence of an altruistic (or moral) personality has been an issue of debate for many years and continues to be discussed in the social psychological literature (see Batson, 1991; Eisenberg, Guthrie, et al., 2002). The empirical findings are reviewed in some detail in other sources (Eisenberg & Fabes, 1998; Graziano & Eisenberg, 1997) and, consequently, are merely summarized briefly here.

Although findings differ considerably across measures of prosocial responding and age, there is evidence of modest consistency across situations and time. Evidence of consistency is weakest in studies of infants and preschoolers (e.g., Dunn & Munn, 1986; Eisenberg et al., 1984; Strayer & Roberts, 1989), but sometimes modest or even compelling evidence of consistency has been obtained (e.g., Denham et al., 1994; Gill & Calkins, 2003; Kienbaum et al., 2001; Robinson et al., 2001; van der Mark et al., 2002). Although nonsignificant correlations have been obtained in some studies (e.g., Koenig et al., 2004), positive relations among measures of prosocial or empathy-related responding, across situations, raters, or time, often have been obtained in studies of elementary school children (e.g., Dekovic & Janssens, 1992; Hastings et al., 2000; Rushton & Teachman, 1978; Strayer & Roberts, 1997b; Tremblay, Vitaro, Gagnon, Piche, & Royer, 1992; Vitaro, Gagnon, & Tremblay, 1990, 1991; Warden, Cheyne, Christie, Fitzpatrick, & Reid, 2003; Welsh et al., 2001) and particularly adolescents (Davis & Franzoi, 1991; Eberly & Montemayor, 1999; Eisenberg, Carlo, et al., 1995; Goodman, 2001; Savin-Williams, Small, & Zeldin, 1981; Wentzel, 2003). Given the diversity of motives likely to be associated with prosocial- and empathy-related responses, it is impressive that investigators frequently have found significant relations across situations or time, even if many are modest in size.

### Sociability and Shyness

Sociability, which likely has a temperamental basis (see Kagan & Fox or Rothbart & Bates, Chapter 3, this *Handbook*, this volume), appears to influence if and when children assist others. In preschool and beyond, children who are prone to participate in activities at school (Jennings et al., 1987), who tend to approach novel people and things (Stanhope et al., 1987), and who are sociable and low in shyness, social anxiety, or social withdrawal are somewhat more likely to help than are other children (Diener & Kim, 2004; Eisenberg, Fabes,

Karbon, Murphy, Carlo, et al., 1996; Hart et al., 2003; Howes & Farver, 1987; Inglés, Hidalgo, Mendéz, & Inderbitzen, 2003; Russell et al., 2003; Silva, 1992; cf. Farver & Branstetter, 1994). Moreover, behavioral inhibition at age 2 years has been associated with lower empathy and prosocial behavior, especially with strangers (Young, Fox, & Zahn-Waxler, 1999). In one study, however (Volling et al., 2004), preschoolers who were high in social fear were relatively likely to provide caregiving to a young sibling during a separation from mother, perhaps because they were especially likely to experience their sibling's distress and were not inhibited in interactions with the sibling.

There is some reason to believe that early adolescents high in evaluative concerns are more prosocial and less aggressive toward others (if one controls for depression; Rudolph & Conley, 2005). Perhaps children and youth prone to social anxiety are particularly likely to engage in prosocial behavior with those they know; they also may be more easily socialized to comply with adults' expectations for prosocial behavior. In one of the few other studies of adolescents, social anxiety was positively correlated with dispositional personal distress but not sympathy (Davis & Franzoi, 1991).

Sociability is particularly likely to be associated with the performance of prosocial behaviors that are spontaneously emitted (rather than in response to a request for assistance; Eisenberg et al., 1981; Eisenberg et al., 1984; Eisenberg-Berg & Hand, 1979) or directed toward an unfamiliar person in an unfamiliar setting (rather than a familiar person at home; Stanhope et al., 1987; Young et al., 1999). Further, extroversion (which includes an element of sociability) was related to elementary school children's helping in an emergency when another peer was present (but not when the child was alone) and to helping that involved approaching the other person; introverts tended to help in ways that did not involve approaching the injured individual (Suda & Fouts, 1980). Thus, sociable children seem to be more prosocial than their less social peers when assisting another involves social initiation or results in social interaction.

### Social Competence and Socially Appropriate Behavior

Because prosocial behavior is socially appropriate in many contexts, it is not surprising that children's prosocial behavior often is correlated with indexes of socially appropriate behavior. Although not all researchers have obtained significant results (e.g., Sawyer et al., 2002),

prosocial children tend to be viewed by adults as socially skilled and constructive copers (Cassidy et al., 2003; Eisenberg, Fabes, Karbon, Murphy, Wosinski, et al., 1996; Eisenberg, Fabes, Murphy, et al., 1996; Eisenberg, Guthrie, et al., 1997; Inglés et al., 2003; Peterson, Ridley-Johnson, & Carter, 1984) and are high in social problem-solving skills (Marsh, Serafica, & Barenboim, 1981; also see Warden & Mackinnon, 2003), positive social interaction with peers (Farver & Branstetter, 1994; Howes & Farver, 1987; also see Warden & Mackinnon, 2003), developmentally advanced play (Howes & Matheson, 1992), and cooperation (e.g., Dunn & Munn, 1986; Jennings et al., 1987). In addition, sympathy and empathy have been correlated (sometimes over years) with enacted or adult-reported socially competent behavior (Eisenberg & Fabes, 1995; Eisenberg, Fabes, Murphy, Karbon, et al., 1996; Murphy, Shepard, Eisenberg, Fabes, & Guthrie, 1999; see Eisenberg & Miller, 1987) or with self-reports of number of friends (Coleman & Byrd, 2003).

Consistent with the link between socially appropriate behavior and prosocial behavior, preschoolers' prosocial and sympathetic responding have been linked to having a close friend or more friends (Clark & Ladd, 2000; Coleman & Byrd, 2003; Farver & Branstetter, 1994; McGuire & Weisz, 1982; Sebanc, 2003; cf. Huebner & Mancini, 2003), supportive peer relationships (de Guzman & Carlos, 2004; Laible et al., 2000; Lerner et al., 2005; Sebanc, 2003), the receipt of prosocial actions from peers (Persson, 2005), less conflict with friends (Dunn, Cutting, & Fisher, 2002), low levels of peer victimization (Johnson et al., 2002; cf. Coleman & Byrd, 2003), and being popular (rather than rejected) with peers (Caprara et al., 2000; Clark & Ladd, 2000; Coleman & Byrd, 2003; Dekovic & Gerris, 1994; Dekovic & Janssens, 1992; Denham, Blair, et al., 2003; Eisenberg, Fabes, Murphy, et al., 1996; Hampson, 1984; Keane & Calkins, 2004; Pakaslahti & Keltikangas-Jarvinen, 2001; Ramsey, 1988; Slaughter et al., 2002; Tremblay et al., 1992; Warden et al., 2003; Welsh et al., 2001; Wentzel, 2003; Wilson, 2003; also see Haselager, Cillessen, Van Lieshout, Riksen-Walraven, & Hartup, 2002; LaFontana & Cillessen, 2002; Pakaslahti et al., 2002; cf. McGuire & Weisz, 1982). Stability of rejection by peers in early elementary school is predicted by low levels of children's prosocial behavior (Vitaro et al., 1990); children's skill at comforting predicts whether children are rejected, neglected, or accepted by peers (Burleson et al., 1986); and nonsupportive goals or strategies in hypothetical help-giving situations are

linked to having few and lower quality friends (Rose & Asher, 2004). Clark and Ladd (2000) obtained concurrent relations consistent with the hypothesis that children's prosocial tendencies mediate the relation between a positive, warm parent-child relationship and children's peer acceptance and number of mutual friends. In addition, mature prosocial moral reasoning has been positively correlated with sociometric status, as well as with teachers' reports of social competence and low levels of acting-out behavior (Bear & Rys, 1994). Thus, children who are prosocial tend to have positive relationships and interactions with peers.

Degree of social competence or popularity also may affect the types of prosocial behavior children prefer to perform. Hampson (1984) found that popular prosocial adolescents tended to engage in peer-related prosocial behavior, whereas less popular helpers preferred non-peer-related tasks. Peer acceptance may affect children's comfort level when helping peers; alternatively, people who prefer to help in ways that do not involve social contact with peers may be less popular due to their avoidant behavior.

### Aggression and Externalizing Problems

Prosocial children are relatively likely to evaluate aggression negatively (Nelson & Crick, 1999) and are low in aggression and externalizing problems (e.g., Caprara, Barbaranelli, & Pastorelli, 2001; Caprara et al., 2000; Crick, Casas, & Mosher, 1997; Denham, Blair, et al., 2003; Diener & Kim, 2004; Goodman, 1994; Hughes et al., 2000; Inglés et al., 2003; Keane & Calkins, 2004; Ma & Leung, 1991; Muris, Meesters, & van den Berg, 2003; Nagin & Tremblay, 2001; Uggen & Janikula, 1999; Warden et al., 2003; Welsh et al., 2001; Wilson, 2003; also see Haselager et al., 2002; Silva, 1992; Slaughter et al., 2002; Youniss, McLellan, Su, & Yates, 1999). Relations are found across time: Hay and Pawlby (2003) found that externalizing problems at age 4 predicted low levels of prosocial behavior at age 11. Furthermore, sympathy (Eisenberg, Fabes, Murphy, et al., 1996; Laible, Carlos, & Raffaelli, 2000; Murphy et al., 1999; Zahn-Waxler et al., 1995) and empathy (Albiero & Lo Coco, 2001; Braaten & Rosen, 2000; Cohen & Strayer, 1996; Endresen & Olweus, 2001; Strayer & Roberts, 2004a; Warden & Mackinnon, 2003; see Miller & Eisenberg, 1988, for a review) have been linked to low levels of externalizing problem behaviors (including aggression or ADHD). Children's and adolescents' self-reported delinquency and externalizing problem behaviors also have

been negatively related to their self-reported empathic efficacy (Bandura et al., 2001, 2003).

The relation of prosocial responding to aggression likely varies depending on the actor's motive for engaging in prosocial behavior. Although prosocial actions that involve a positive affective response to an individual and those not motivated by personal gain tend to be negatively related to adolescents' reports of aggression (and their belief that aggression is acceptable), reports of prosocial actions performed for personal gain have been positively related to reported aggressive actions and the acceptance of aggression (Boxer et al., 2004).

The relation between aggressiveness and prosocial behavior may be more complex in the early years than at older ages. Gil and Calkins (2003) found that aggressive toddlers displayed *more* evidence of empathy or concern than less aggressive toddlers. Moreover, Yarrow et al. (1976) found a positive correlation between prosocial and aggressive behavior for preschool boys (but not girls) below the mean in exhibited aggression, whereas there was a negative relation between prosocial behavior and aggression for boys above the mean in aggression. For those young children who are relatively nonaggressive overall, aggression often may be indicative of assertiveness rather than hostility or the intent to harm another (Eisenberg & Mussen, 1989). Moreover, the lack of regulation reflected in aggression may allow young children to approach and exhibit concern toward an unfamiliar adult (the measure of concern used by Gil and Calkins, 2003).

Thus, a negative relation between aggression and prosocial tendencies may develop with age. Although Hastings and colleagues (2000) did not find a relation between concern for others and the behavior problems of 4- to 5-year-olds, children with clinical behavior problems decreased in their concern and were reported by both mothers and themselves to be relatively low in concern by age 6 to 7 years. Moreover, greater concern at 4 to 5 years predicted a decline in the severity of externalizing problems over the 2 years. Thus, the inverse relation between sympathy and externalizing problems seems to begin consolidation during the preschool to early school years.

### Assertiveness and Dominance

Assertiveness and dominance also have been associated with frequency and type of children's prosocial behaviors. Assertive children (e.g., those who issue commands or defend their possessions) are relatively high in sym-

pathy versus personal distress reactions (Eisenberg, Fabes, et al., 1990) and prosocial behavior (Barrett & Yarrow, 1977; Denham & Couchoud, 1991; Inglés et al., 2003; Larrieu & Mussen, 1986), particularly spontaneously emitted (unrequested) instances of helping and sharing (Eisenberg et al., 1984; cf. Eisenberg et al., 1981). A certain level of assertiveness may be necessary for many children to spontaneously approach others needing assistance. In contrast, nonassertive, nondominant children tend to be prosocial in response to a request (Eisenberg et al., 1981; Eisenberg et al., 1984; Larrieu, 1984), apparently because they frequently are asked for help or sharing (probably due to their compliance; Eisenberg et al., 1981; Eisenberg, McCreath, & Ahn, 1988). Children who are not simply assertive but seek to dominate others may be low in prosocial behavior (Krebs & Sturup, 1984).

### Self-Esteem and Related Constructs

It appears that there is a positive relation between children's self-esteem and their prosocial tendencies, but more so for older than for younger children. In studies of preschoolers and elementary school children, investigators typically have found no evidence of a relation between self-reports of self-esteem or self-concept and measures of prosocial behavior (Cauley & Tyler, 1989; Rehberg & Richman, 1989). In studies of children in fourth grade to high school, investigators generally have found that prosocial children have a positive self-concept (Laible & Carlo, 2004; Larrieu & Mussen, 1986; Rigby & Slee, 1993; also see Jacobs et al., 2004; cf. Huebner & Mancini, 2003; Karafantis & Levy, 2004), are high in self-efficacy (Bandura et al., 2001, 2003; Lichter et al., 2002; Sugiyama, Matsui, Satoh, Yoshimi, & Takeuchi, 1992), and tend to have prosocial self-schemas (that affect donating when children are self-aware; Froming, Nasby, & McManus, 1998). Johnson et al. (1998) found that girls, but not boys, with higher academic and positive self-esteem in ninth grade were more likely to volunteer in grades 10 to 12. Perhaps young children's self-reports do not adequately tap relevant dimensions of their self-concepts. However, it is also possible that young children's self-concept often is not based on enduring characteristics that are relevant to prosocial responding (see Harter, Chapter 9, this *Handbook*, this volume).

It also is probable that the relation between self-concept or self-esteem and prosocial behavior varies as a function of the psychological significance or quality of

the prosocial act. Children who are anxious or emotionally unstable may enact prosocial behaviors to ingratiate, avoid disapproval, or prevent overreactivity to social distress. In fact, there is some evidence that boys who are particularly high in prosocial behavior performed or promised in a public context are anxious, inhibited, and emotionally unstable (Bond & Phillips, 1971; O'Connor, Dollinger, Kennedy, & Pelletier-Smetko, 1979). Similarly, Jacobs et al. (2004) found that although socially confident adolescents were relatively high in self-reported prosocial activities, so were anxious adolescents. Youth who had a low social self-concept but were not worried about their standing with peers were lower in prosocial activities than the socially confident or anxious adolescents.

The association between older children's self-conceptions and prosocial behavior probably is bidirectional in causality. Children who feel good about themselves may be able to focus on others' needs because their own needs are being met; further, they may feel that they have the competencies needed to assist others. In addition, it has been argued that involvement in activities that help others may foster the development of self-efficacy (Yates & Youniss, 1996b). It is reasonable to assume that the performance of socially competent behavior, including prosocial behavior, and children's self-concept are complexly related during development.

### Values and Goals

An important component of the self is one's values. Colby and Damon (1992) noted two morally relevant characteristics that were dramatically evident in adult moral exemplars: (1) exemplars' certainty or exceptional clarity about what they believed was right and about their own personal responsibility to act in ways consistent with those beliefs; and (2) the unity of self and moral goals, that is, the central role of exemplars' moral goals in their conceptions of their own identity and the integration of moral and personal goals.

Consistent with Colby and Damon's findings, Hart and Fegley (1995) found that adolescents who demonstrated exceptional commitments to care for others were particularly likely to describe themselves in terms of moral personality traits and goals and to articulate theories of self in which personal beliefs and philosophies were important. Moreover, Pratt et al. (2003) found that adolescents who were more actively involved in community helping activities reported closer agreement with

parents about the importance of moral values for the self 2 years later than did their less involved peers.

More generally, there is evidence that prosocial behavior is positively associated with measures of moral functioning, including other-oriented values and beliefs (Dlugokinski & Firestone, 1974; Janoski, Musick, & Wison, 1998; Larrieu & Mussen, 1986); social responsibility, responsibility goals, or low levels of irresponsibility (Savin-Williams et al., 1981; Wentzel, 2003); integrative goals (i.e., concern with the maintenance and promotion of other individuals or social groups; Estrada, 1995); guilt or need for reparation (Caprara et al., 2001; Chapman, Zahn-Waxler, Cooperman, & Iannotti, 1987); and low levels of moral disengagement (Bandura et al., 2001). Further, adolescents sometimes cite moral values and responsibility for others as reasons for enacting prosocial behaviors (e.g., Carlo, Eisenberg, & Knight, 1992; Eisenberg, Carlo, et al., 1995). Thus, it appears that older children and adolescents who have internalized moral (including altruistic) values and who view morality as central to their self-concept are particularly likely to be altruistic. In addition, prosocial tendencies appear to be linked to relational rather than instrumental goals (Nelson & Crick, 1999) and to collaborative goals in the school environment (Cheung, Ma, & Shek, 1998).

In addition, empathic or sympathetic youth not only exhibit values and a social conscience (Lerner et al., 2005), but also may be more likely than less responsive youth to extend their prosocial behaviors to members outside their own group. Empathic youth are more likely than their less empathic peers to say that they are comfortable being near children who are different from them and who might be viewed negatively (e.g., a child who is depressed, immature, aggressive, overweight, or doing poorly academically; Bryant, 1982; cf. Strayer & Roberts, 1997a). Similarly, sympathetic youth value diversity (Lerner et al., 2005), and school children feel less interpersonal distance from those with whom they empathize/sympathize (Strayer & Roberts, 1997a; see, however, Batson, Chang, Orr, & Rowland, 2002). Inclusive reactions such as these would be expected to enhance prosocial behavior directed toward out-group members (Oliner & Oliner, 1988).

### Religiosity

Religiosity (as measured by attending religious services) has been positively related to participation in volunteer

activities during adolescence (Huebner & Mancini, 2003; Lichter et al., 2002) and predicts subsequent volunteering behavior in early adulthood (Zaff et al., 2003). Similarly, going to a Catholic or church-based school (but not being Catholic; Youniss, McLellan, Su, & Yates, 1999) predicted adolescents' community service (Youniss, McLellan, & Yates, 1999). Because involvement in church and other community-based youth groups is related to doing volunteer service (McLellan & Youniss, 2003), it is likely that religious institutions provide opportunities for organized prosocial activities. In addition, Youniss, McLellan, and Yates (1999) argued that involvement in church-sponsored services makes it more likely that youth will internalize or adopt the religious rationales provided for engaging in service. More generally, a religious identity, if it involves moral overtones, has been linked with a prosocial personality (Furrow, King, & White, 2004). At this time, it is unclear whether prosocial behavior is differentially linked to identification with, or acceptance of, various religions.

### Regulation

In studies involving adult-reported or behavioral measures of self-regulation (generally defined in terms of processes involved in modulating emotional states and behaviors; Eisenberg, Spinrad, & Sadovsky, 2005), prosocial children tend to be relatively well regulated, as well as low in impulsivity (e.g., Eisenberg, Fabes, Karbon, Murphy, Wosinski, et al., 1996; Eisenberg, Fabes, Karlo, Murphy, Wosinski, et al., 1996; Eisenberg, Guthrie, et al., 1997; Moore, Barresi, & Thompson, 1998; Rothbart, Ahadi, & Hershey, 1994; Silva, 1992; Thompson, Barresi, Moore, 1997; Wilson, 2003; also see Deater-Deckard, Dunn, et al., 2001). The association between regulation and prosociality is not surprising because engaging in prosocial actions often requires regulated behavior and emotion (e.g., controlling one's own negative emotion) or involves actions that help regulate others' emotions (Bergin, Talley, & Hamer, 2003). In fact, degree of regulation is a stronger positive predictor of prosocial behavior for children prone to negative emotions such as anger (Diener & Kim, 2004; also see Eisenberg, Guthrie, et al., 1997).

Similarly, sympathy has been associated with high levels of children's regulation (Eisenberg & Fabes, 1995; Eisenberg, Fabes, Murphy, Karbon, et al., 1994; Eisenberg, Fabes, Murphy, et al., 1996; Eisenberg, Liew, & Pidada, 2001; Murphy et al., 1999), whereas

personal distress sometimes has been associated with low regulation (Eisenberg, Fabes, Murphy, Karbon, et al., 1994; Ungerer et al., 1990; Valiente et al., 2004; cf. Eisenberg & Fabes, 1995). The few findings for empathy are mixed, some positive (Sneed, 2002), some not (Saklofske & Eysenck, 1983). In addition, resilient children, who may be viewed as optimally regulated, tend to be prosocial and empathic (Atkins, Hart, & Donnelly, 2005; Eisenberg, Guthrie, et al., 1997; Strayer & Roberts, 1989; also see Hart et al., 1998). In contrast, boys with ADHD were found to be lower on empathy than boys without a diagnosis of ADHD. Because children diagnosed with ADHD have low attentional control, these children may be at a disadvantage for the development of empathy and prosocial behavior (Braaten & Rosen, 2000).

It appears that well-regulated children can modulate their vicarious arousal and, consequently, focus their attention on others' emotions and needs rather than on their own aversive vicarious emotion (Trommsdorff & Friedlmeier, 1999). Consistent with this idea, Bengtsson (2003) found that Swedish elementary school students who were high in self-reported empathy and teacher-reported prosocial behavior tended to experience moderate (rather than high) levels of threat and to modulate the emotional significance of empathy-eliciting stimuli through cognitive restructuring (which can be viewed as a mode of emotion regulation). Moreover, well-regulated children would be expected to be relatively likely to sustain their attentional focus on others and to suppress any tendencies to try to avoid contact with distressed or needy individuals.

Findings for measures of physiological emotional regulation are somewhat inconsistent and may vary as a function of age of the child or evocativeness of the empathy-inducing situation. In the relevant studies, physiological emotion-related regulation often is assessed with higher heart rate variance, high vagal tone, or vagal suppression. These intercorrelated measures, especially the latter two, are viewed as reflecting emotion-related physiological regulation based on the control of parasympathetic functioning by the vagal nerve (Porges, Doussard-Roosevelt, & Maiti, 1994; see Rothbart & Bates, Chapter 3, this *Handbook*, this volume). Such measures have been positively related with elementary school students' observed comforting (Eisenberg, Fabes, Karbon, Murphy, Carlo, & Wosinski, 1996) and dispositional sympathy (Fabes et al., 1993), although findings for girls have been positive for maternal report of girls' sympathy

(Fabes et al., 1993), but negative for girls' self-reported sympathy (and positive for boys' sympathy; Eisenberg, Fabes, Murphy, Karbon, Smith, et al., 1996).

Moreover, contrary to expectations, toddlers' vagal suppression in response to a crying infant was *negatively* related to observed concern in response to an adult feigning distress to an injury (Gill & Calkins, 2003). Similarly, Zahn-Waxler et al. (1995) found that preschool children's concerned reactions during the same type of feigned injury task were negatively related to their vagal tone. The same children's vagal tone was weakly negatively related to teacher- (but not parent- or child-reported) prosocial behavior 2 years later (Hastings et al., 2000). Gill and Calkins suggested that a positive relation between concern and physiological regulation might develop with age. Alternatively, it may be difficult to differentiate between personal distress and sympathy with some of the measures (e.g., reactions to feigned distress) typically used with younger children. It is not clear whether the complex pattern of findings is due to age-related factors, to differences in the measures of prosocial behavior used with younger and older children, or to other moderating factors.

### Emotionality

Children who are emotionally positive—a characteristic that may be viewed as partly an outcome of emotional regulation—also tend to be prosocial (Denham, 1986; Denham & Burger, 1991; Eisenberg et al., 1981; Garner & Estep, 2001; also see Bandura et al., 2003; cf. Braaten & Rosen, 2000; Denham, Blair, et al., 2003; Farver & Branstetter, 1994) and empathic/sympathetic (Eisenberg, Fabes, Murphy, Karbon, et al., 1996; Robinson et al., 1994; also see Eisenberg et al., 1994; cf. Volling, Herrera, & Poris, 2004). In contrast, the data pertaining to the relation between negative emotionality and prosocial responding are more complex. Prosocial behavior generally (albeit sometimes for one sex or the other) has been negatively related to negative emotionality, including anger, fear, anxiety, or sadness (Bandura et al., 2001; Denham, 1986; Denham & Burger, 1991; Diener & Kim, 2004; Eisenberg, Fabes, Karbon, Murphy, Wosinski, et al., 1996; Hoffner & Haefner, 1997; Ma & Leung, 1991; Tremblay et al., 1992; Volling et al., 2004; Wentzel & McNamara, 1999; also see Caprara, Barbaranelli, Pastorelli, et al., 2001; Strayer & Roberts, 2004a, 2004b; cf. Denham & Burger, 1991; Farver &

Branstetter, 1994; Hart et al., 2003), albeit not for some measures of depression or internalizing problems (Bandura et al., 2003; Goodman, 1994; Hay & Pawlby, 2003; Muris et al., 2003). In addition, intensity of emotional responding in general may be negatively related to prosocial tendencies (Garner & Estep, 2001). However, relations of negative emotionality (intensity and/or frequency) to empathy/sympathy have been negative (Eisenberg, Fabes, Murphy, Karbon, et al., 1996; Eisenberg, Fabes, Shepard, et al., 1998; Murphy et al., 1999; Roberts & Strayer, 1996, for anger; Strayer & Roberts, 2004a; van der Mark et al., 2002), nonsignificant (Braaten & Rosen, 2000; Denham, Blair, et al., 2003), and positive (Saklofske & Eysenck, 1983), although positive findings have been obtained primarily when negative emotionality was measured during the early years and related to empathy (or mixed empathy and sympathy) rather than sympathy (Howes & Farver, 1987; Robinson et al., 1994; Rothbart et al., 1994). There also is some evidence that children who are extremely worried about the well-being of family members are relatively prosocial (Hay & Pawlby, 2003).

Thus, in general, prosocial behavior and sympathy or empathy have been linked to dispositional positive emotionality. Further, low negative emotionality has been consistently associated with children's prosocial behavior, but not young children's empathy/sympathy. The inconsistencies in findings may be partly due to both type and intensity of the negative emotion experienced and type of measure. Relations between negative emotionality and empathy/sympathy or prosocial behavior seem to be negative especially for externalizing types of emotions (e.g., anger) rather than depression, anxiety, or dysphoric emotions (e.g., Laible et al., 2000; Strayer & Roberts, 2004a). Children's anger and frustration seem to be salient to adults and, like aggression, covary inversely with prosocial behaviors and empathy-related emotions.

In addition, intensity of negative emotion may be related to whether people experience sympathy or personal distress, which, in turn, predicts prosocial behavior. Eisenberg et al. (1994) proposed that situational emotional overarousal due to empathy is associated with personal distress, whereas moderate empathic responding is associated with sympathy (also see Hoffman, 1982). If people can maintain their vicarious emotional reactions at a tolerable range, they are likely to vicariously experience the emotion of needy or dis-

tressed others, but are relatively unlikely to become overwhelmed by the emotion and, consequently, self-focused. In contrast, people who are overaroused by vicarious negative emotion are expected to experience that emotion as aversive and as a distressed, self-focused reaction (personal distress). Consistent with this view, general negative emotional arousal has been found to result in a self-focus (Wood, Saltzberg, & Goldsamt, 1990), and empathically induced distress reactions are associated with higher skin conductance reactivity than is sympathy (Eisenberg, Fabes, Schaller, Carlo, & Miller, 1991; Eisenberg, Fabes, Schaller, Miller, et al., 1991).

Based on this line of reasoning, Eisenberg and colleagues argued that individual differences in the dispositional tendency to experience sympathy versus personal distress vary as a function of dispositional differences in both typical level of emotional intensity and individuals' abilities to regulate their emotional reactions. People high in effortful regulation (e.g., who have control over their ability to focus and shift attention) are hypothesized to be relatively high in sympathy regardless of their emotional intensity. Well-regulated people would be expected to modulate their negative vicarious emotion and to maintain an optimal level of emotional arousal that has emotional force and enhances attention, but is not so aversive and physiologically arousing that it engenders a self-focus. In contrast, people low in the ability to regulate their emotion, especially if they are emotionally intense, are hypothesized to be low in dispositional sympathy. Further, measures of tendencies to display anger and frustration probably partly reflect low regulation and high emotional reactivity and, consequently, would be expected to relate to personal distress and low prosocial behavior.

Modest support has been obtained for these ideas. As noted, regulation has been linked to high sympathy and low personal distress. Further, low and moderate levels of negative emotional intensity, but not high levels, have been associated with situational concern (Eisenberg & Fabes, 1995) and children who experience more negative emotion than that of the stimulus person eliciting empathy (i.e., become overaroused) are relatively low in empathy/sympathy (Strayer, 1993). In addition, there is limited evidence that unregulated children are low in sympathy regardless of their level of emotional intensity whereas, for moderately and highly regulated children, level of sympathy increases with level of emotional in-

tensity (Eisenberg, Fabes, Murphy, Karbon, et al., 1996; also see Eisenberg et al., 1998).

Thus, there is initial support for the notion that emotional intensity (including intensity of both positive and negative emotions) interacts with regulation in predicting children's sympathy, although the pattern of relations is complex and depends on the type of regulation. For children in mid-elementary school, behavioral regulation was positively related to dispositional sympathy for boys who were average or high, but not low, in the tendency to experience emotions intensely. In contrast, attentional regulation predicted high dispositional sympathy (for both sexes) only for children low in general emotional intensity. For children low in emotional intensity, attentional control may be important in helping children focus on and process others' emotions and needs (Eisenberg et al., 1998).

Positive relations between some measures of negative emotionality and empathy/sympathy in the literature also may be due to empathic or sympathetic people being relatively likely to express or report their emotions (see Roberts & Strayer, 1996), in empathy-inducing contexts (Roberts & Strayer, 1996; also see Eisenberg, Losoya, et al., 2001). In future work on empathy-related reactions, it will be useful to differentiate among types of negative emotion (e.g., externalizing and internalizing emotions), between expressed (i.e., observable) and experienced emotion, and between individuals' general emotional intensity and the intensity of solely negative emotions.

## THE ROLE OF RELATIONSHIP HISTORY IN PROSOCIAL BEHAVIOR

The degree to which children are prosocial frequently depends on the identity and characteristics of the potential recipient. Children prefer to help people who are relatively important in their lives, such as family members (e.g., Killen & Turiel, 1998; Rheingold et al., 1976; van der Mark et al., 2002; Young et al., 1999). In adolescence, help is as likely or more likely to be directed toward known peers as toward known, nonfamilial adults (e.g., Zeldin, Savin-Williams, & Small, 1984). Moreover, children often share or help friends or liked peers more than less liked peers (Buhrmester, Goldfarb, & Cantrell, 1992) or acquaintances (Buhrmester et al.,

1992; Farver & Branstetter, 1994; Pilgram & Rueda-Riedle, 2002; Rao & Stewart, 1999). In fact, children as young as age 4 or 5 years or in elementary school report more sympathy toward the plight of a friend or liked peer than toward an acquaintance (Costin & Jones, 1992). Prosocial behavior among friends appears to be motivated by not only liking and concern (Costin & Jones, 1992), but also loyalty, consideration of reciprocity obligations, and the fact that friends more often ask for sharing or help (Birch & Billman, 1986).

Sometimes children are equally prosocial to friends and other peers or even help or share less with friends (Berndt, Hawkins, & Hoyle, 1986). In studies in which children have had to choose between friends and strangers, children apparently sometimes assisted people they did not know well to eliminate inequities between a stranger and a friend because they believed that their friend would understand, they wanted to gain the unknown person's approval or friendship, or they were competing with the friend (Berndt, 1982; Staub & Norenberg, 1981).

### SEX DIFFERENCES IN CHILDREN'S PROSOCIAL BEHAVIOR

Based on stereotypic gender roles, females generally are expected and believed to be more responsive, empathic, and prosocial than males, whereas males are expected to be relatively independent and achievement oriented (e.g., Spence, Helmreich, & Stapp, 1974). Further, cross-cultural work has verified that gender differences in prosocial responding are not limited to only a few cultures and may develop with age. Whiting and Edwards (1973) found that helpfulness and support giving generally were greater for girls than boys across six different cultures, although these differences were significant for older but not younger children. More recent work confirms the cross-cultural tendency of girls to be more prosocial than boys (e.g., Carlo, Reoesch, Knight, & Koller, 2001; Russell et al., 2003).

Despite the prevailing view that females are more prosocial than males, findings vary depending on the age of the actor and the type of prosocial behavior. Eagly and Crowley (1986) conducted a meta-analysis of sex differences in older adolescents' and adults' helping behavior and found that *men* helped more than women, particularly in situations involving instrumental and

chivalrous assistance. Sex differences in helping were inconsistent across studies and were successfully predicted by various attributes of the studies. Carlo et al. (2003) also found sex differences varied with type of reported prosocial behavior: Adolescent girls were more likely to report altruistic and emotional prosocial behaviors than were boys; boys were more likely to report prosocial tendencies in public situations; and no sex differences were found in situations involving anonymous or compliant prosocial behavior or helping in dire circumstances. Becker and Eagly (2004) examined extreme forms of prosocial behavior—heroism—and found that men were overrepresented in some forms of heroism (e.g., Carnegie Hero Fund medalists who engaged in life-risking rescue actions), but in other heroic actions (organ donors, peace corps volunteers, holocaust rescuers), the percentage of women was at least equal to and, in several cases, higher than that found for men. Such findings suggest that the qualities associated with different types of prosocial behavior (e.g., the role of risk taking in extremely dangerous heroic acts) more likely explain differences in males' and females' tendencies to engage in prosocial actions than a general sex difference model of prosociality *per se*.

Eisenberg and Fabes (1998) reported a meta-analysis of sex differences in children's prosocial behavior involving 259 studies yielding a total of 450 effect sizes ( $M$  age = 7.93 years). Only one effect size was used per sample (i.e., when different variables were used for a single sample, one was selected randomly). For both the full and partial sample of effect sizes, the mean unweighted effect size was modest (.18) and favored girls. Although effect sizes were significant for all types of prosocial behavior and for various design, method, or recipient characteristics, they varied in strength by the type of prosocial behavior studied. Sex differences were significantly greater when prosocial responding was measured with self-reports or reports from others than with observational methods. The effect size also was significantly greater for aggregated indices or indices reflecting kindness/consideration than for indices reflecting instrumental help, comforting, or sharing, and in correlational/naturalistic studies than in structured/experimental studies. However, the latter two differences disappeared when study characteristics were controlled in regression analyses, probably because self-report measures have been used disproportionately in assessment of kindness/consideration and aggregated in-

dices, and in observational/correlational studies. In addition, sex differences in prosocial behavior were significantly greater when the target was an adult or was unspecified than when the target was another child.

When controlling for other study or participant variables, the sex difference in prosocial behavior was greater for larger samples and when the age span of study participants was relatively small. Instrumental help also was significantly less predictive of sex differences in prosocial behavior than were other types of prosocial indices.

These findings support Eagly and Crowley's (1986) conclusion that sex differences in adults' prosocial behavior vary as a function of the qualities of the studies. In contrast to Eagly and Crowley's findings for adults and older adolescents (combined), Eisenberg and Fabes (1998) found that girls tended to be more prosocial than boys. The finding that the sex difference was weakest for instrumental helping is particularly interesting because many of the studies in the adult literature in which men helped more were assessments of instrumental helping (Eagly & Crowley, 1986).

With increasing age, sex differences in prosocial behavior tended to get larger (see Eisenberg & Fabes, 1998; Fabes, Carlo, Kupanoff, & Laible, 1999). However, the effect for age in the meta-analysis was eliminated once other study qualities were controlled, probably because type of study was associated with age, with older children involved in more naturalistic/correlational studies.

Since the Eisenberg and Fabes' meta-analysis, investigators have continued to find sex differences in reports of children's prosocial behaviors (e.g., Bosacki, 2003; Caprara, Barbaranelli, & Pastorelli, 2001). Peers, especially girls, are more likely to nominate girls as being prosocial and to nominate boys as being bullies (Warden et al., 2003; Warden & Mackinnon, 2003). Fewer differences have been found in some observational studies (Fabes, Martin, & Hanish, 2002; contrast with Zahn-Waxler et al., 2001). To some degree, sex differences in self- and other-reported prosocial behavior may reflect people's conceptions of what boys and girls are *supposed* to be like rather than how they actually behave. Parents emphasize prosocial behaviors and politeness more with their daughters than with their sons (Power & Parke, 1986). Moreover, peers, parents, and teachers tend to perceive girls as more prosocial than either behavioral or self-reported data indicate (Bond & Phillips,

1971; Shigetomi, Hartmann, & Gelfand, 1981). Furthermore, parents have been found to attribute girls' actions to inborn factors significantly more often than boys' actions, whereas boys' prosocial actions are more likely to be viewed as due to environmental factors (Gretarsson & Gelfand, 1988). These findings are consistent with the view that girls' reputations for prosocial behavior are greater than the actual sex difference. In addition, children may self-socialize their prosocial tendencies by means of having their thoughts, emotions, and behavioral scripts conform to parents', teachers', and peers' expectations (Maccoby, 1998). Nonetheless, there is a small sex difference favoring girls even in observational studies (Eisenberg & Fabes, 1998), so there likely is some truth to the stereotype.

Sex differences in the literature may also be due, in part, to biases in measures of prosocial behavior. Zarbatany, Hartmann, Gelfand, and Vinciguerra (1985) argued that measures used to evaluate children's prosocial tendencies include a disproportionate number of sex-biased items favoring girls (items pertaining to feminine activities). They found that masculine items (e.g., helping get a cat out of a tree) elicited endorsements for boys, and feminine-related and neutral items elicited endorsements for girls. Masculine items likely included acts of instrumental helping, the category for which there was the smallest sex difference favoring girls (when study characteristics were controlled) in the meta-analysis.

Findings about sex differences in empathy and sympathy, like those for prosocial behavior, vary with the method used to assess empathy-related responding. As mentioned, Eisenberg and Lennon (1983; also see Lennon & Eisenberg, 1987), in a meta-analytic review, found large differences favoring girls for self-report measures of empathy/sympathy, especially questionnaire indices. No gender differences were found when the measure of empathy was either physiological or unobtrusive observations of nonverbal behavior. In work in which sympathy and personal distress have been differentiated, investigators have obtained similar findings, although they occasionally have found weak (but significant) sex differences in facial reactions (generally favoring females; see Eisenberg, Fabes, Schaller, & Miller, 1989) and in observational assessments of young children using developmentally appropriate stimuli such as puppets to elicit distress (Kienbaum et al., 2001) or feigned distress (Zahn-Waxler et al., 2001). Eisenberg

and Lennon (1983) suggested that the general pattern of results was due to differences among measures in the degree to which both the intent of the measure was obvious and people could control their responses. Sex differences were greatest when demand characteristics were high (it was clear what was being assessed) and individuals had conscious control over their responses (i.e., self-report indices were used); gender differences were virtually nonexistent when demand characteristics were subtle and study participants were unlikely to exercise much conscious control over their responding (i.e., physiological indices). Thus, when gender-related stereotypes are activated and people can easily control their responses, they may try to project a socially desirable image to others or to themselves.

Eisenberg and Fabes (1998; Fabes & Eisenberg, 1996) also conducted a follow-up meta-analysis of empathy/sympathy data published since Eisenberg and Lennon's (1983) first review and found an overall unweighted effect size (favoring girls) of .34. Relatively large effect sizes were found in self-report studies (significantly larger than in the studies involving other methods) and in studies in which the targets of the empathic response were unspecified or unknown individuals. Moreover, sex differences were larger for older children. When sex differences were examined by method, significant sex differences favoring girls were obtained for self-report indices (weighted effect size of .60) and observational measures (in which a combination of behavioral and facial reactions usually were used, .29). The gender difference in observed reactions, especially for young children, suggests that there is a real, albeit modest, difference in children's empathy. No sex differences were obtained for nonverbal facial and physiological measures. Further, the sex difference in self-reported empathy/sympathy increased with mean age of the sample ( $\beta = .24$ ). Sex differences in reported empathy may increase as children become more aware of, and perhaps are more likely to internalize, sex-role stereotypes and expectations into their self-image (Karniol et al., 1998).

Although there are no sex differences in prosocial moral reasoning in young children, in later elementary school and beyond, girls use more of some relatively sophisticated types of prosocial moral reasoning, whereas boys sometimes verbalize more of less mature types of reasoning (Eisenberg, Carlo, et al., 1995; Eisenberg, Miller, et al., 1991; also see Jaffee & Hyde, 2000). Moreover, in adolescence, femininity is positively re-

lated to internalized prosocial moral reasoning (but also related to hedonistic reasoning for males; Carlo et al., 1996). It is unclear the degree to which these sex differences, which generally are relatively weak, are due to real differences in moral reasoning or to differences in the ways that adolescent males and females view themselves and desire to be viewed by others.

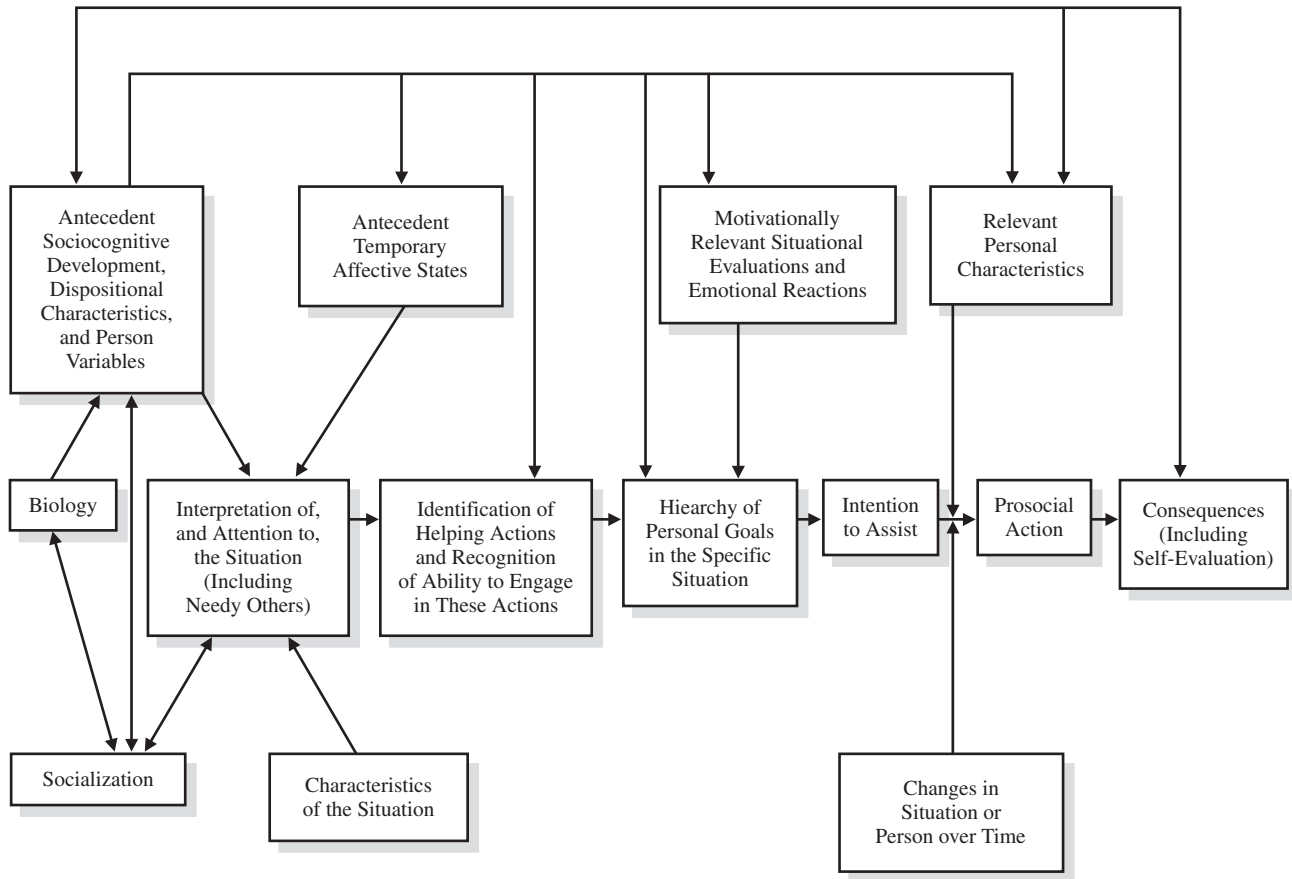

In summary, although girls appear to be more prosocial than boys, the issue of sex differences in prosocial responding and their origins is far from resolved. It is difficult to determine the degree to which the sex difference reflects a difference in moral or other-orientation versus other factors (e.g., self-presentation). It also is unclear whether the sex difference changes with age. Although age was related to the prosocial effect size in the univariate analysis in our meta-analysis, there was no effect of age when study characteristics were controlled. There is a need to better assess the developmental trajectory of the sex differences and to investigate the origins of sex differences in prosocial behavior.

## AN INTEGRATIVE MODEL OF PROSOCIAL ACTION

Based on the available evidence, prosocial action appears to be the outcome of multiple individual (including biological) and situational factors. A simplified model of the major variables believed to contribute to the performance of prosocial behavior (and steps in the process itself) is depicted in Figure 11.1 (see Eisenberg, 1986, for extended discussion of this model). This heuristic model can be used to integrate many of the topics discussed in this chapter.

In our model, biological factors are viewed as having an effect on both the child's individual characteristics (e.g., sociocognitive development, empathy, sociability) and parental interactions with the child (i.e., socialization experiences). The child's individual characteristics and socialization experiences affect one another and, together with objective characteristics of the situation (see Eisenberg & Fabes, 1998, for a review of situational influences), influence how the child interprets events involving another's need or distress in a specific context. For example, individual differences in perspective taking and in decoding skills, which likely are influenced by socialization experiences as well as heritability (e.g., genetic effects on intelligence), may affect whether a child notices another's distress, as might the clarity of the dis-

**Figure 11.1** Heuristic model of prosocial behavior. Adapted from *Altruistic Emotion, Cognition, and Behavior*, by N. Eisenberg, 1986, Hillsdale, NJ: Erlbaum.

tressed other's nonverbal and verbal cues of emotion (a situational factor). Moreover, socialization influences and person variables likely interact; as discussed, Valiente et al. (2004) found that parental expressivity related differently to children's sympathy and personal distress depending on the children's regulation. It also is likely that antecedent characteristics interact when predicting children's prosocial tendencies; examples were discussed in our review (e.g., between regulation and emotional intensity, or between perspective taking and sympathy; Diener & Kim, 2004; Eisenberg, Fabes, Karbon, Murphy, Wosinski, et al., 1996; Knight et al., 1994).

How the child interprets the situation logically leads to and affects the child's identification of prosocial actions and the child's recognition of his or her ability to engage in these actions. A temporary state such as the child's mood may determine his or her attention to, or interpretation of, a situation (see Eisenberg & Fabes, 1998). Level of arousal seems to alter the ways in which

people interpret others' verbal statements and facial expressions (Clark, Milberg, & Erber, 1983).

In addition, a child who feels capable of assisting must then decide whether he or she intends to assist. The child's emotional reactions (e.g., sympathy or personal distress), relationship with the other person (which affects the child's emotional reactions and perceived costs and benefits of assisting), and attributions about the cause of the other's need or distress (e.g., whether the needy person is responsible for his or her situation) are examples of motivationally relevant situational evaluations and emotional reactions that can play a role in this decision. The decision of whether to engage in prosocial action also is affected by antecedent person variables such as individual differences in concern about social approval, values, personal goals, and self-identity in regard to the trait of altruism (see Figure 11.1).

In the given context, the various relevant moral and nonmoral factors—be they perceived costs and benefits,

values, sympathetic emotion, or other factors—influence the individual's relative hierarchy of goals in the particular situation. Often goals, needs, or values conflict in a situation and must be prioritized. This ordering of personal goals undoubtedly varies across individuals and across situations for a given person (see Figure 11.1). In a situation in which important people are present, social approval needs may be salient (particularly for people who value such approval). In another situation in which there are material costs for assisting, valuing of the object to be shared or donated will be particularly relevant for some people (but not others who do not value the commodity). Moreover, if the situation evokes an emotional reaction such as sympathy or personal distress, then other- or self-related goals linked to those emotional reactions will be salient and perhaps activated.

The values, goals, and needs that underlie personal goals and their relative importance (in general and in specific contexts) change with age (e.g., Bar-Tal, Raviv, et al., 1980). An individual's values, goals, and needs, as expressed in his or her prosocial moral reasoning, provide some insight into the child's typical hierarchy of goals, needs, and values (i.e., one's general hierarchy rather than one's hierarchy in a specific context), although, as noted, different factors will be particularly salient in different situations (see Eisenberg, 1986). Because other-oriented values based in part on perspective taking, sympathetic reactions, or the capacity for abstract principles increase with age (Eisenberg, 1986), one would expect prosocial moral goals to rank higher in the hierarchies of older children than in those of young children.

Thus, the hierarchy of an individual's goals or priorities in the particular situation is viewed as determining whether the child wants to assist, as well as the intention to assist. However, even if the child intends to perform a prosocial behavior, he or she may not be able to do so due to the lack of relevant personal competencies (physical, psychological, or material) needed to intervene or provide appropriate helping skills. In addition, the situation may change, as might the potential benefactor's situation, prior to the actual helping opportunity. For example, the potential benefactor may receive help from someone else before the child can assist.

Finally, there are consequences of engaging in prosocial behavior or choosing not to do so. Children who help may develop new helping competencies or sociocognitive skills that can be applied in future situations. Assist-

ing another also may affect socializers' efforts to promote the child's prosocial behavior and the degree to which an individual develops a prosocial self-concept (e.g., Eisenberg, Cialdini, et al., 1987). These consequences are reflected in the future in terms of the child's ongoing dispositional or person variables (see Figure 11.1), as well as in the range of the child's prosocial-relevant personal competencies. Thus, there is a cycle by which children's prosocial behavior (or the lack thereof) has consequences for future prosocial responding.

## CHALLENGES AND FUTURE DIRECTIONS

As is evident in this review, there is considerable research on antecedents and correlates of children's prosocial responding. This work has provided a rudimentary understanding of the factors that may foster prosocial action, although in many cases, it is premature to confidently assume causation. Many of the deficiencies in the research on prosocial development noted in 1998 still exist. Although there is more research on some topics (e.g., volunteering, personality/person correlates), the field would benefit from new emphases in methods, conceptual frameworks, and empirical foci.

### Methodological Issues

In this chapter, we have discussed a few of the mediators and moderators of the bivariate relations associated with the development of prosocial behavior. There is initial evidence that regulation mediates the relation between parental expression of negative emotion and children's sympathy (Eisenberg, Liew, & Pidada, 2001) and that sympathy and prosocial moral reasoning mediate the relation of perspective taking to prosocial behavior (Eisenberg, Zhou, & Koller, 2001). A greater focus on mediation would enhance our understanding of the processes related to prosocial development and behavior. Little is known about factors that mediate the relations of parental inductions or assignment of responsibilities to children and their prosocial behavior or empathy-related responding. Consistent with Hoffman's (2000) thinking, inductions may affect perspective taking and empathy, which then foster prosocial action. Additionally, certain types of interactions with peers or teachers may promote children's understanding of others' emotions and mental states in a manner that in turn fosters

sympathy. Sympathy may act as a mediator of the relation of many environmental influences or genetic predispositions (e.g., regulation) to children's prosocial behavior. Examination of such mediational processes requires that investigators refine their conceptual explanations and go beyond looking at global associations to focus on process-oriented explanations.

In contrast, a focus on moderation forces investigators to think about the ways in which predictors of prosocial responding interact in their potential influence. The strength of many predictors of prosocial responding (e.g., perspective taking or parental use of inductions) likely varies based on factors such as sex, age, general parenting style, cultural experiences, personality predispositions, or children's susceptibility to experience empathy or sympathy. We live in a multivariate world, and prosocial behavior in specific situations, is determined by numerous additive and interacting factors. For example, as mentioned, Knight et al. (1994) found that children who donated to needy children were not only high in perspective taking, but also high in sympathy and understood the commodity to be donated (money; also see Eisenberg, Zhou, & Koller, 2001, who found that sympathy and perspective taking jointly predicted prosocial moral reasoning). As noted, parental expression of emotion and children's regulation also interact when predicting children's empathy-related responding (Valiente et al., 2004). Based on the work of Kochanska (1995), who found that children's temperament moderated the relations between maternal gentle discipline and measures of conscience, it is likely that temperament affects the relations of parental practices to children's prosocial tendencies. In addition, it is important to go beyond moderational models to examine the ways in which configurations of numerous variables (e.g., child-rearing practices) predict prosocial outcomes.

Most of the research on prosocial development continues to be correlational. To better examine issues of causality, longitudinal designs and structural equation modeling can be used to test causal hypotheses (although structural modeling can only assess if a causal sequence is consistent with the data and does not prove causality). Longitudinal data are especially important for testing mediated relations; concurrent data provide a weak test of causal, mediated relations. Further, experimental research designs could be used more frequently to test causal assumptions. Although experimental designs usually (but need not) require relatively artificial

laboratory situations, researchers have tended to shy away from experiments in the past decade or two. Yet experiments, especially those performed in more natural settings (e.g., at school), can be valuable in testing ideas about causality. Interventions and prevention programs provide a rigorous test of causal relations.

A multimethod approach in the design of studies also is necessary because different methods address somewhat different questions, including questions about causality. Moreover, all methods of measurement have limitations, but these differ for different measures. Thus, the convergence of findings across methods increases one's confidence in the veracity of the findings. In addition, as illustrated by the results of the Eisenberg and Fabes (1998) meta-analyses, certain types of methods tend to be used with certain ages of children, and such confounds may undermine our ability to understand the development of prosocial behavior.

### Conceptual and Content-Related Directions

The study of prosocial behavior would benefit from greater integration with conceptual work on related issues. Prosocial behavior can be considered in a manner similar to most interpersonal behaviors—in terms of its social appropriateness and social and personal outcomes both in specific situations and in the long term. In many, but not all, settings, prosocial behavior is a socially appropriate behavior; indeed, prosocial behaviors frequently are used in measures of social competence. Thus, conceptual work on social competence and the development of interpersonal competence in attachment and peer relationships is relevant to the understanding of prosocial development. Moreover, research on moral emotions such as guilt, moral cognitions, and the development of an egoistic or antisocial orientation could be used to a greater degree than in the past to inform our understanding of prosocial behavior, particularly altruism.

As an example, we have seen that individual differences in children's emotionality and their ability to regulate emotional arousal appear to be related to whether children experience sympathy or egoistic, personal distress in helping contexts. Moreover, enactment of prosocial behaviors often involves not only emotional regulation, but also behavioral regulation, particularly if prosocial action requires self-denial. Thus, developmental change and individual differences in children's abilities to inhibit their behavior, delay gratification, and

activate behavior when desirable are of considerable importance to understanding prosocial development. Environmental factors associated with optimal regulation and moderate levels of emotional reactivity likely foster prosocial responding, including sympathy. Thus, the growing bodies of literature on the socialization of emotion and coping, as well as cultural influences on emotion and its regulation, are highly relevant to a comprehensive perspective on prosocial development. A better understanding of these issues may be especially useful in delineating the emergence of sympathy and prosocial tendencies in the first years of life when children's regulatory skills are changing rapidly.

Work on prosocial behavior too often has been isolated from work on related topics, and greater integration across content domains would have broad benefits. This situation has improved somewhat in the past decade, especially in the literature on peer relationships and social competence. We have tried to make further inroads in that direction in this chapter, although our attempts were limited by the need to cover much material in a restricted space. Moreover, prosocial behaviors can be characterized as *attractors* ("absorbing" states that pull the behavior of the system from other potential states) that affect the organization of individual and group behaviors (Martin, Fabes, Hanish, & Hollenstien, in press). As such, integration of concepts from dynamic systems may lead to new insights in research and theorizing about prosocial behavior and development.

Advances in some fields of the behavioral sciences are just beginning to provide methods and data that can inform our understanding of prosocial development. Developments in brain-scanning procedures are providing new venues for studying emotion, attention, and decision making and, hence, processes related to sympathy and prosocial behavior. This technology may provide new insights on the role of emotion and attentional processes in prosocial decision making, although it is unlikely to provide in-depth information relevant to the role of antecedent biological and environmental influences on prosocial development.

Finally, not only has the field of prosocial behavior been relatively intellectually isolated from relevant literature on other topics, but investigators studying other issues (e.g., psychopathology, information processing, peer relationships, academic success) also have not attended sufficiently to findings in the domain of prosocial development. The broader field of developmental sci-

ences would benefit if the boundaries among content areas, as well as across disciplines, were more permeable.

homicide arrest rates and assault victimization reports reveal little secular change since 1965, juvenile violent crime rates have risen markedly: Since 1965, the homicide rate by juveniles aged 18 or under has increased by close to 400% (Blumstein, 2000).

---

The authors wish to thank Lynda Harrison for her careful scrutiny of the text, Amber Runion for assembling over 1,000 references, Terrie Moffitt for her insightful review, and

Nancy Eisenberg for her valuable editing. The first author is grateful for the support of Senior Research Scientist Award 5 K05 DA-015226.

Secular swings in juvenile violence have been especially dramatic. Between 1988 and 1997, the number of juvenile arrests increased by 35% and arrests of juveniles under age 13 for violent crimes increased by 45% (Snyder, 2003). Since then, however, juvenile arrests and violent crime receded back to the level of the 1980s (Blumstein & Wallman, 2000). The decrease in adolescent violence, however, is attributable primarily to decreases in crime among older juveniles. While the aggravated assault arrest rate among older juveniles in 2001 dropped 38% from its peak in 1994, the rate for juveniles under age 13 dropped only 3% (Snyder, 2003). Thus, the violent crime rate among younger children remains dramatically higher than it was 40 years ago. Similarly, the prevalence of psychiatrically diagnosed conduct disorder is several times greater than it was 70, or even 40, years ago, in both the United States (Robins, 1999), and the United Kingdom, even controlling for reporter effects (Collishaw, Maughan, Goodman, & Pickles, 2004).

The annual aggregate burden of crime in the United States now exceeds \$1 trillion (D. Anderson, 1999). In the eyes of the U.S. public, crime and violence perennially rank among the most important problems facing this country (Berke, 1994). Both the magnitude of the current problem and the urgency of a solution are represented in the U.S. Surgeon General's national objectives for 2010 to reduce the prevalence of physical fighting among adolescents to less than 32% and to reduce the prevalence of weapon-carrying on high school property to less than 4.9% (U.S. Department of Health and Human Services, 2000).

The rapid swings in U.S. crime rates have been paralleled by growth in research on the development of aggressive and other antisocial behavior. Research in the past 2 decades has increasingly focused on the development of chronically antisocial individuals, in contrast to research on species-wide patterns in aggressive behavior. This shift in emphasis has grown from recognition that a small group of chronically violent youth are responsible for over half of all crimes (Howell, Krisberg, & Jones, 1995), that criminal careers can be charted across the life span beginning in childhood (Blumstein & Cohen, 1987), that career criminals cost society up to \$2 million *each* (M. Cohen, 1998), and that citizens may be willing to pay a great deal in extra taxes for interventions that could confidently reduce crime (Cohen, Rust, Steen, & Tidd, 2004).

Four questions guide the organization of this chapter:

1. What is the human species-wide developmental course of aggression and antisocial behavior?
2. What stability and change occur in the life course of individual differences in antisocial behavior?
3. Why do some individuals become more antisocial than others?
4. What promising avenues exist in the prevention and treatment of aggressive behavior in children?

## DEFINING THE DOMAIN OF AGGRESSION AND ANTISOCIAL BEHAVIOR

Previous editions of the *Handbook* have restricted the discussion of antisocial behavior to aggression, perhaps because that form of antisocial behavior has been studied most often. Over the past 10 years, research has increasingly emphasized individual differences in aggressive behavior, and this shift has led to the recognition that aggressive behaviors often occur in a context of other antisocial behaviors, such as noncompliance with adults, lying, stealing, destruction of property in the childhood years, and more serious antisocial behaviors such as illegal drug selling, sexual assault, burglary, and other violent crimes. Even the psychiatric diagnosis of conduct disorder has evolved over the past half-century to address the co-occurrence of physical aggression with other forms of aggressive behavior (e.g., verbal aggression) and other antisocial behaviors (e.g., illicit substance use; Robins, 1999). This comorbidity of aggression with other antisocial behaviors suggests that an understanding of the etiology and developmental course of aggression might be enhanced by including it in the broader class of antisocial behaviors (Menard & Elliott, 1994). Substance use and abuse, as well as participation in drug sales activities, have particular significance in any discussion of contemporary antisocial behavior because the increased rate of violence in the United States, especially for teenage males, parallels the rise in certain kinds of illegal substance use in our society. Nonetheless, an explicit treatment of developmental issues relating to substance use and trafficking is not included in this chapter because of space limitations.

Although definitions of aggression and antisocial behavior usually have considerable overlap, there are important differences between them. The definition of aggression embraced by Parke and Slaby (1983), "behavior that is aimed at harming or injuring another person or persons" (p. 50), is similar to the broader definition that Loeber (1985) offered for antisocial behaviors, namely those "that inflict physical or mental harm or property loss or damage on others, and which

may or may not constitute the breaking of criminal laws" (p. 6). This latter definition includes aggression but is not restricted to it. Sometimes aggression is defined broadly enough to include property loss or damage, as in the case of instrumental aggression; however, the feature of instrumental aggression that makes it aggressive, in our view, is the use or threat of force to obtain possession. An important difference in the two definitions is the inclusion of intent in the Parke and Slaby (1983) definition, a distinction that we endorse.

Part of the ambiguity in definition arises from the fact that governmental and professional institutions have their own contextually based definitions for antisocial behavioral problems. Loeber's (1985) definition of antisocial behavior makes reference to violations of criminal code. For children and adolescents, legal violations constitute delinquency, although some delinquent acts such as truancy and running away from home do not conform to usual definitions of antisocial behavior. Conversely, fighting and threats of harm occur frequently among school-aged children, and yet these behaviors are rarely considered as a possible cause for arrest even though the same acts by adults would be construed as assault. In education, the terms *Serious Emotional Disturbance* (SED) and *Behavior Disorders* (BD) have been applied to children whose classroom behavior is too disruptive to allow for the education of other children. These children are typically removed to special education classrooms with other similar children. *Conduct disorder* is a psychiatric term that refers to a disorder that is diagnosed by the frequency of problem behaviors exhibited by a child or adolescent across a given period (three or more across a 6-month period). The term is applied to individuals rather than to acts and is considered to reflect a diagnostic syndrome. *Oppositional defiant disorder*, which includes disobedience or disrespect for adults often accompanied by irritability, is a psychiatric syndrome that is distinct from conduct disorder and is most often applied to elementary-school children but is thought to predict conduct disorder. *Antisocial personality disorder* is a chronic psychiatric condition that requires a life-persistent pattern of antisocial behavior (Hinshaw & Anderson, 1996).

In earlier *Handbook* chapters on aggression, including our own, the merits and flaws in various approaches to defining aggression have been discussed at length. As noted earlier, the study of aggression prior to the 1980s focused more on the behavioral analysis of aggression than on individual differences in aggressive behavior and the need for precision in defining aggression was

quite obvious. For those who study individual differences, the need for precision in defining aggressive acts is not as important as precision in identifying aggressive persons. Because the identification of aggressive persons often depends on consensus in social judgments by third parties, the need to be clear about what constitutes aggression might not seem important. Nonetheless, the need to be clear about the nature of this judgment invariably brings us back to the definitional issue. The topographical approach to defining aggression, taken from ethology, focuses on the form of the act itself and has been successful with lower-order species but is less reliable with humans because of the greater range of diversity in human aggressive behavior (Hartup & deWit, 1974). Antecedent approaches focus on the conditions eliciting aggression and emphasize the importance of determining the intent involved. This approach has its origins in the concept of the goal response introduced by Dollard, Doob, Miller, Mowrer, and Sears (1939). Defining aggression by the outcome (Buss, 1961) avoids the pitfalls of inferring intention but suffers from other problems. First, injury can result unintentionally from the behavior of others. Second, this definition excludes behaviors that have obvious aggressive intent but fail, somehow, to lead to injury. Third, such an approach emphasizes the instrumental aspect of aggression while ignoring the emotional component. Finally, Walters and Parke (1964) have suggested that aggression is determined by the social judgment of observers operating in a specific cultural context that must be understood as influencing the definition of aggression. Such an approach clearly fits legal approaches to defining guilt (Dodge, 1991) and may be necessary to any culturally sensitive research strategy for studying aggression, but it also suggests the challenge of defining aggression in the abstract. Viewed in the context of various cultures or social contexts, the same act might be classified as aggressive or not depending on how it contrasts with base rates for similar behavior in each of these contexts. Also, identification might depend on the perspectives of those whose resources are being controlled (Hawley, Little, & Pasupathi, 2002). One way to understand this point in the context of contemporary American culture is to note that some acts might be considered as acts of aggression when exhibited by a girl but not when exhibited by a boy.

These problems in defining aggression have led Tremblay, Hartup, and Archer (2005) to suggest that a weakness in the study of aggression is the ambiguity in its definition. We conclude that there is less ambiguity

to the definition of aggression than in observers' ability to determine when it has actually occurred. This ambiguity plays itself out in everyday life, leading, perhaps, to much of the conflict and violence that surrounds us. We suggest that most people would readily agree with the very simple definition offered by Parke and Slaby (1983): Aggression is behavior aimed at harming or injuring another person or persons. The problem, as Tremblay and most other reviewers have pointed out, is that it is not always easy to decide whether harm was intended. This ambiguity, in our view, is not a definitional issue but a measurement issue. To confound the conceptual definition with the criterion for measurement is to fall prey to the limits of operationism—a philosophical approach to science that guided much of early experimental psychology. Human aggression may best be viewed as a heterogeneous category of human behavior, defined simply as acts intended to harm others, which requires a multifactor framework (Brain, 1994) to address the measurement problem. In other words, no single statement can adequately bound the acts that we would want to describe as aggressive behaviors. Instead, a judgment is made that relies on cues to intent, outcome potential, biological arousal, and social context. As with many other behavioral constructs, aggression is a “fuzzy set,” and unreliability in assessment is part of the price that one pays for investigating an important aspect of human behavior.

### **DIMENSIONS OF AGGRESSION AND OTHER ANTISOCIAL BEHAVIOR**

Because antisocial or disruptive behavior is a heterogeneous set, numerous attempts have been made to establish dimensions of antisocial behavior by factor-analytic or multidimensional scaling techniques. Frick et al. (1993) conducted a meta-analysis of factor-analytic studies of oppositional defiant disorder and conduct disorder behaviors in over 23,000 youth and extracted two dimensions of antisocial behavior. One dimension runs from overt to covert behaviors, a distinction that Loeber and Schmaleng (1985) found to be quite robust, and the second dimension ranges in level of destructiveness. The resulting quadrants constitute categories of aggression (overt, high destructive), oppositional behavior (overt, low destructive), property violations (covert, high destructive), and status violations (covert, low destructive).

The category of aggressive behaviors can be further subcategorized into dimensions that reflect both the

forms and functions of aggression. Little, Brauner, Jones, Nock, and Hawley (2003a) have demonstrated the validity of a dimensional system from self-reports by 1,723 German adolescents from grades 5 to 10. The form of aggression varies as direct, involving verbal or physical attack, or relational, involving damage to the target's friendships or inclusion in the peer group (Crick & Grotpeter, 1995). The function of aggression is either instrumental, occurring in the anticipation of self-serving outcomes, or reactive, occurring as an angry defensive response to goal blocking or provocation (Little, Jones, Henrich, & Hawley, 2003b). This latter distinction follows from Hartup's (1974) distinction between instrumental and hostile aggression and Dodge, Lochman, Harnish, Bates, and Pettit's (1997) empirical distinction between reactive and proactive aggressive behavior in chronically assaultive youth. Dodge and Coie (1987) demonstrated that reactive and proactive aggressive boys differ in social information-processing patterns. Little et al. (2003b) found that the reactive group showed consistent maladaptive behavior patterns not found in the instrumental group. Finally, adaptive functions of aggressive behavior, such as providing an opportunity for social-cognitive growth in very young children attracting peers' interest (Rodkin, Farmer, Pearl, & Van Acker, 2000), and maintenance of high-influence status in adolescent peer groups (Prinstein & Cillessen, 2003) suggest that the complexity of this behavior pattern may be tied to its robustness to evolutionary threats across the ages (Hawley, 2003).

The perspective of this chapter is that human aggressive behavior, because of its many adaptive features, has evolved to be part of a broader social communication system (Tedeschi & Felson, 1994). Aggression must be interpreted as a social event. It has meaningful subtypes and multiple topographies, antecedents, and functions. To understand processes in specific aggressive events may require subclassification and behavioral analysis. To understand the broader adaptive (and maladaptive) functions of aggression may require integration with other antisocial patterns.

### **HISTORICAL PERSPECTIVES ON THEORY AND EMPIRICAL INQUIRY**

Through the 1980s, scholarly inquiry in aggressive behavior was dominated by broad debates among theorists. These debates addressed the very nature of the human species. The frustration-aggression hypothesis

of Dollard et al. (1939) posited a drive theory that aggressive behavior is an inevitable, species-wide response to perceived goal-blocking. They suggested that frustration necessarily results in aggression and that all aggressive behavior is instigated by frustration. This hypothesis led to the first major empirical studies of aggression, and the findings disputed that premise. Berkowitz (1962) noted that frustration does not always lead to aggression but maintained the hypothesis that frustration creates a driveline readiness to aggress, namely the arousal of anger.

The ethological approach of Lorenz (1966) similarly suggested the inevitability of aggressive behavior but emphasized the instinctual system that relies on internal energy that is generated even in the absence of external stimuli and must be released periodically. Even though empirical studies fail to support this hypothesis, Lorenz contributed the general perspective that the adaptive species-preserving functions of intraspecific aggression are to balance the distribution of the species across a limited ecology, to allow for the natural selection of the fittest of the species through combat, and to promote the selection of the most able family defenders against extraspecific threat. Thus, aggressive behavior has evolved as a necessary, species-preserving, component of human adaptation.

Bandura (1973) hypothesized that aggressive behavior develops through social learning processes, including imitation of aggressive models, direct operant reinforcement for aggressive acts, and vicarious reinforcement through observational learning. Most empirical research on human aggression during the 1970s and 1980s was inspired by this perspective. Bandura acknowledged the biological constraints on human learning but argued that these constraints are much less restrictive than in other species. Biological and genetic theories, other than those relating to instinct, have been posed primarily to account for age and individual differences in aggression and have proliferated in the past decade.

Two other developments have reshaped the nature of theory and empirical enquiry over the past 2 decades. First, the emerging field of developmental psychopathology (D. Shaw, 2003) has come to dominate the study of aggressive development. Microbehavioral analyses of aggressive events have been supplemented by epidemiological studies of individual differences in the life course of aggressive behavior. Models of reciprocal influence, transactional development, and biological-psychosocial interaction have been formulated (Dodge & Pettit, 2003). What has emerged is a theory of the devel-

opment of early starting aggressive behavior that has received growing consensus (Conduct Problems Prevention Research Group, 1992; Moffitt, 1990; Patterson, Reid, & Dishion, 1992). Much less studied and more poorly understood are later-onset patterns of aggressive behavior in adolescence and factors in desistance. The early starter theory incorporates an understanding of how biological factors, sociocultural contexts, and early life experiences with parents, peers, and schooling contribute to the development of enduring patterns of aggressive behavior. Rather than understand these factors as orthogonal influences, the emergent theory highlights the power of the interaction effect between genes and the environment (Caspi et al., 2002) and describes the social-cognitive processes by which children actively relate their experiences to future behavior. Second, methods have been developed to test these theories by identifying trajectories of growth and change over time (Nagin, 1999) and to parse influences that are nested across levels of the individual child who lives in a family nested with neighborhoods and schools (Bryk & Raudenbush, 1992).

## CULTURAL DIFFERENCES AND AGGRESSION

How various cultures define aggression is beyond the scope of this chapter, but the impact of culture on the development of aggression and whether developmental models of aggression hold across cultures are important questions addressed here. Emerging literature suggests that many of the developmental processes first studied in the United States operate similarly across cultures, including China (Chang, Schwartz, Dodge, & McBride-Chang, 2003; Chen, Wang, Chen, & Liu, 2002) and Indonesia (Eisenberg, Pidada, & Liew, 2001), but future work may clarify the circumstances in which patterns diverge.

## AGGRESSIVE AND ANTISOCIAL DEVELOPMENT IN THE HUMAN SPECIES

Charting species-wide patterns of growth and change in aggressive behavior across the life span is complicated by the qualitatively different measures of aggression across contexts. Even though infancy and toddlerhood represent the periods of highest frequency in aggression, the most dangerously aggressive periods are clearly late

adolescence and early adulthood. Different measures of aggressive behavior provide discrepant pictures of aggressive development. Some of these discrepancies imply that the construct of antisocial behavior itself changes across development. Grabbing objects, tattling on others, and homicide are all valid measures, but developmental norms and base rates alter their validity at different ages. Tremblay et al. (2005) and Farrington (1993) suggest that different measures at different ages (e.g., fighting at age 8, vandalism at age 12, and homicide at age 18) may be indicators of the same underlying antisocial construct. Cairns (1979) described the concept of continuity across development as including intraindividual continuity (absolute stability), interindividual continuity (relative stability in rank), organizational continuity (the fact that the organism is fundamentally the same from birth to death), factor structure continuity (whether covariance matrices in variables are identical across ages), process continuity (whether rates of change or factors in change vary across age), and societal or generational continuity (whether the construct is conceptualized similarly across time by societies). Aggressive behavior is such a complex developmental construct partly because even though its intraindividual, factor-structure, and process continuities are weak, its interindividual continuity is strong.

### **The Emergence of Anger and Physical Aggression in Infancy**

The fundamental human emotion of anger is crucial to survival because of its self-regulatory and social communication functions (Lemerise & Dodge, 2000). It prepares the body physiologically and psychologically to initiate self-protective and instrumental activity (Frijda, 1986) and may be an important reason for the adaptation and survival of the species (Lorenz, 1966). When not controlled properly, anger is a source of much human misery.

If anger is functional and innate, when does it emerge, and what are its earliest elicitors? Stenberg and Campos (1990) used a forearm restraint procedure to elicit responses in 1-, 4-, and 7-month-old infants. They grasped the infant's forearms, pulled them together, and held them approximately 6 inches in front of the infant's torso for up to 3 minutes. Even though 1-month-olds did display undifferentiated negative facial expressions, not one of the 16 1-month-olds displayed a discrete anger template that differentiated the anger expression from

all other negative expressions. In contrast, 5 of the 16 infants at 4 months and 6 of the 16 infants at 7 months displayed the discrete anger template. Thus, even though the capacity for negative emotional expression is present by 1 month of age, only over the course of the first 4 months of life does a distinct anger response become coordinated.

At what age does anger expression come to have a social communication function? Stenberg and Campos (1990) found that, following restraint, 1-month-olds turned their heads randomly, but 4-month-olds turned their heads toward the frustrator or the frustrator's hands. Immediately following the onset of the first display of anger, 7-month-olds, but not 4-month-olds, turned their heads not toward the frustrator but toward their mothers. Stenberg and Campos (1990) concluded, "By at least 4 months anger facial displays may function as discrete social signals. These signals are at first directed proximally to the immediate source of frustration, but by 7 months they become expressed directly to social objects such as the mother" (pp. 270–271). The failure to observe a discrete anger expression in 1-month-olds does not rule out its existence at this age, because other stimuli might have elicited the anger response or other observational codes might be necessary to detect a different form of anger at an early age. Likewise, if intent-to-harm is a necessary component of aggression as it is defined here, labeling these behaviors as aggressive requires the scientist to make a high level of inference.

### **Aggression and Conflict in the Second Year of Life**

Trivers (1974) suggested that conflict, anger, and aggression increase in frequency and intensity across the 2nd year of life in all mammalian species that undergo a prolonged period of symbiosis between mother and infant. Following a period of total dependence by the infant, the mother is motivated to help the infant achieve independence for survival, but the infant is ambivalent and may be motivated to sustain the mother's attention. The infant's growing size and weight or the birth of a younger sibling may accelerate the mother's interest in pushing the infant/toddler toward independence and the toddler's interest in keeping the mother's attention (Dunn, 1988). Mother-infant conflict is thus inevitable in the 2nd year of life as the individuation process intensifies (Mahler, 1968).

Although individual differences in intensity and ease of recovery from attack can be measured from responses

to blood drawn as early as 2 days of life (Keenan, Gunthorpe, & Young, 2002), the stability of individual differences over the first several months of life is modest (Gunnar, Brodersen, & Krueger, 1996). Stable individual differences in anger expression emerge later during the 1st year and into the 2nd year of life (Stifter, Spinrad, & Braungart-Rieker, 1999). The earliest documented observations of peer-directed aggression have been found at the end of the 1st year of life. This period coincides with emerging interest in one's own possessions, in control over one's own activities, and in peer communication. Six-month-olds appear not to be bothered by peers who grab their objects or invade their space (Hay, Nash, & Pedersen, 1983). By 12 months of age, however, infants respond to peer provocations with protest and aggressive retaliation (Caplan, Vespo, Pedersen, & Hay, 1991). Up to half of all peer exchanges among children 12 to 18 months old involve conflict (Holmberg, 1977). Hay and Ross (1982) found that 87% of 21-month-old children participated in at least one conflict during four 15-minute laboratory peer group observation sessions.

### **Aggression during the Preschool Years**

Although physical aggression decreases, verbal aggression increases normatively between 2 and 4 years of age (Cairns, 1979), coinciding with growth in expressive vocabulary. A twin study revealed that the negative correlation between physical aggression and expressive vocabulary in toddlers cannot be dismissed as due to a common genetic origin; rather, the most likely causal path goes from the development of expressive vocabulary to decreases in physical aggression (Dionne, Boivin, Tremblay, Laplante, & Perusse, 2003). But language onset also provides children with a new means of aggressing (e.g., through insults, threats, and name-calling), and the general parental perspective is that problem behavior by toddlers increases during this era. Jenkins, Bax, and Hart (1980) found that parental concerns about behavior problems and management peak at age 3. Other epidemiological studies have revealed high rates (up to 13%) of tantrum, peer fighting, and frustration tolerance problems in 3-year-olds, with declines thereafter (Crowther, Bond, & Rolf, 1981).

Whereas the most frequent elicitors of aggression in infancy are physical discomfort and the need for attention, elicitors become "habit training" in the 3rd year and peer conflicts and conflicts over material possessions (Fabes & Eisenberg, 1992) in the 4th and 5th

years. Caregivers' demands for compliance increase during these years, and the probability of noncompliant responses increases. Klimes-Dougan and Kopp (1999) found that, in response to a clean-up task, rates of noncompliance were 68% among 18-month-olds but as high as 97% among 30-month-olds. Abramovitch, Corter, and Lando (1979) found that siblings become a predominant source of agonistic behavior for preschoolers, with 45% of all interactions between younger and older siblings involving conflict.

Although relatively few sex differences have been found in infancy and toddlerhood in the rate and form of aggressive behaviors, by the time that children interact in naturally occurring preschool groups, the differences become striking (Underwood, 2003), especially in physical aggression.

### **Aggression during the Elementary School Years**

It is not surprising that the start of elementary school is often experienced with a sense of relief by parents, both because behavior management is now shared with a teacher and because the overall level of aggressive behaviors decline. Analyses of mothers' Child Behavior Checklist Reports of the 1,195 children studied by the National Institute of Child Health and Human Development Early Child Care Research Network (2004) indicate "The most frequent form of early aggression, hits others, occurred in about 70% of the sample at ages 2 and 3, but declined to 20% by ages 4 and 5 (kindergarten), and to 12% by third grade" (p. 42). Keenan and Shaw (2003) have suggested that growth in self-control over emotion, known as the development of emotion regulation, is responsible for the decline in aggression during these years. Lingering problems with aggression during this period have been called adaptive disability (AD) and deficient self-regulation by Barkley et al. (2002).

Numerous factors may account for the joint growth in emotion regulation and decline in aggression across the period from 4 to 8 years of age, all of which are subsumed in the development of executive functions. Rapid neural development in the anterior cingulate gyrus during these years has been hypothesized by Posner and Rothbart (1998) to be responsible for the development of effortful control and, indirectly, decreases in aggressive behavior. Mischel (1974) suggested that the emerging ability to delay gratification is a crucial factor in declines in aggression during this era. Through interpersonal exchanges, children acquire cognitive strategies for delaying gratification (e.g., distraction, mentally

representing delayed rewards) and effortful control (Eisenberg et al., 2004) that may help them avoid impulsive grabbing of others' possessions and hitting. The ability to delay gratification, in turn, may be aided by the corresponding development of broader representational abilities (Gelman & Baillargeon, 1983), perspective taking (Selman, 1980), empathy (Zahn-Waxler, Radke-Yarrow, & King, 1979), emotion processing (Schultz, Izard, & Bear, 2004), and memory strategies (Brown, Bransford, Ferrara, & Campione, 1983). Replicating the work of Eisenberg et al. (1999), Gilliom, Shaw, Beck, Schonberg, and Lukon (2002) found that the ability to deploy attention-shifting strategies such as seeking information about situational constraints and ignoring frustrating stimuli is associated with anger control at age 42 months and is predictive of teacher-reported externalizing problems at age 6. Eisenberg and Fabes (1999) have articulated a broader theory of emergent emotional self-regulation during this period, with children progressing from externally controlled regulation to internally mediated cognitive controls that lead to reduced aggressive behavior. Quite a different explanation for declines in aggression during this period is that peers begin to provide feedback to aggressors that extinguishes aggression.

With the gradual decline in the rate of aggression comes a shift in its form and function. An increasing proportion of aggressive behaviors becomes directed toward specific dyadic relationships (Coie et al., 1999), and its form becomes increasingly hostile, in contrast with the relatively nonsocial, instrumental nature of aggression in the preschool period. Aggressive behaviors also become more person-directed and relational (Crick & Bigbee, 1998). Finally, covert forms of antisocial behavior such as lying, cheating, and stealing emerge with greater frequency (Loeber, Farrington, Stouthamer-Loeber, & van Kammen, 1998).

Major elicitors of aggression come to include perceived threats and insults to one's ego (Schwartz, McFadden-Ketchum, Dodge, Pettit, & Bates, 1998). Although the emerging recognition that provocations may be accidental contributes to declines in aggression, the emergent recognition that another may be acting with intentional and hostile motives instigates increased retaliatory, angry responding (Gifford-Smith & Rabiner, 2004). During the early elementary school years, children learn that some actions are unintended but others are under the volitional control of the actor; the result is that the attribution that a peer has acted with

hostile intent has an inflammatory effect (Hubbard, Dodge, Cillessen, Coie, & Schwartz, 2001).

An important distinction made during this age period is between reactive and proactive aggression. Animal behaviorists have long distinguished between hostile-affective (reactive) aggression, characterized by intensive patterned autonomic arousal, anger, and defensive postures that lead to frenzied attacks in response to perceived threat, and instrumental (proactive) aggression, characterized by little autonomic activation but highly patterned appetitive behavior oriented toward a reward (Lorenz, 1966). These behaviors have been distinguished reliably in direct observations of children aged 5 to 9 (Coie et al., 1999), teacher ratings, and ratings of violent behaviors in clinical records (Dodge et al., 1997). Vitaro, Brendgen, and Tremblay (2002) found distinct correlates of these two types of aggression in inattentiveness and anxiety (reactives higher) and in overt delinquency (proactives higher). Smithmyer, Hubbard, and Simons (2000) found that proactive aggression is a function of outcome expectancies, whereas reactive aggression grows out of maltreatment and emotion dysregulation (Shields & Cicchetti, 1998).

Although most children aggress less frequently during the elementary school years, a select few become highly troublesome to peers, parents, and teachers (Loeber et al., 1998). It is during the elementary school years that many children, boys especially, are referred to mental health clinics for conduct problems. Lahey and Loeber (1994) have outlined a developmental path for aggressive conduct problems, beginning with oppositional defiant disorder (ODD), which is characterized by temper tantrums and defiant, irritable, blameful, argumentative, and annoying behavior. These behaviors are not uncommon at 4 to 5 years of age (Achenbach & Edelbrock, 1983) but become less common and clinically problematic by age 8 (Loeber, Lahey, & Thomas, 1991). Clinically referred elementary school children typically do not present with these problems as new symptoms; rather, these children have been unable to outgrow problems that have carried over from earlier times (Loeber, Tremblay, Gagnon, & Charlebois, 1989). Some ODD children begin to diversify their deviant repertoire in the elementary school years (usually about age 8 to 11) to include setting fires, lying, fighting, weapon use, and vandalism (Loeber et al., 1998). This pattern is called conduct disorder (CD), and its prevalence in the United States is about 9% of males and 2% of females (American Psychological Association, 1994). Canadian surveys

of 3,300 children indicate a prevalence of 7% of males and 3% of females (Offord, Boyle, & Racine, 1989).

Between age 11 and 13, a subset of children who could be diagnosed as CD begin to diversify their deviant behaviors even further to include violent criminal behavior such as mugging, breaking and entering, and forced sex. The group of children whose early aggressive behavior does not dissipate over time has been called early starters (Moffitt, 1993). Broidy et al. (2003) used Nagin and Tremblay's (1999) semiparametric methods to identify trajectories of aggressive development with six independent longitudinal samples from across the world. In all samples, a group of early starting aggressive boys was found to persist in physically aggressive behavior across the ages 7 to 13.

### **Aggression during the Adolescent Years**

Loeber et al. (1998) concluded that most longitudinal studies show decrements in ratings of aggressive behavior as children enter adolescence. However, adolescence is a time when serious acts of violence increase, as age-crime curves regularly demonstrate (e.g., U.S. Department of Justice, 2003), when a second group of youth joins the early starting group in antisocial behavior, and when aggressive behavior broadens to new contexts, including romantic relationships.

### ***Growth of Serious Violence***

Data from the National Youth Survey (NYS) of 1,725 youths first surveyed in 1976 (D. Elliott & Huizinga, 1983) indicate that violent offending almost always begins in the adolescent years. Self-reports of serious violent offenses (SVOs, defined as aggravated assault, robbery, or rape, necessarily involving some injury or a weapon) rise sharply from age 12 to 20. The onset hazard rate (first-time offending) for SVOs is almost zero (< 0.5%) through age 11 but doubles between ages 13 and 14 and rises sharply to 5.1% at age 16. The onset rate then halves between ages 16 and 18 and declines to less than 1% after age 20. Thus, over half of the persons who become involved in serious violent offending, prior to age 27, commit their first violent offense between the ages of 14 and 17, and almost all offenders commit their first offense before age 21. Not only is the rise in first-time offending dramatic, but the overall prevalence rates for offending in adolescence are also startlingly high. At the peak age of 17, 19% of males and 12% of females reported committing at least one SVO.

Official arrest records reported by the Federal Bureau of Investigation (FBI; U.S. Department of Justice, 2003) indicate 3 to 4 times lower prevalence rates of SVOs and a similar but lagged (delayed) curvilinear developmental function. At age 17, about 15% of all boys in the United States are arrested (Blumstein, 2000). Of those adolescents who commit offenses, only 15% to 33% are in fact arrested (Farrington, 1989). Of those arrested, about 64% are referred to juvenile or adult court, and of those referred to court, only about 2% to 10% are incarcerated. Thus, very few offenders are ever incarcerated. Because those arrested probably are a very biased group of all offenders, due to gender, socioeconomic, and racial discrimination, arrest records and self-reports provide different pictures of violence (Huizinga & Dunford, 1985). Based solely on arrest records, Weiner (1989) concluded that most first-time SVOs occur between ages 18 and 24. However, as noted by D. Elliott (1994), "If we assume the accuracy of both (self-report and official record) measures, it appears that most first arrests for a violent offense in a serious violent career take place several years after the initiation into this type of behavior and extend into ages where the hazard rate for initiation is close to 0" (p. 10).

Ethnic differences in aggression in the social context of the United States are almost negligible in the elementary school years (Achenbach, 1991) but are more pronounced in adolescence. Arrest record data indicate that even though African American youth make up 15% of the juvenile population, they account for 52% of those arrested for juvenile violent crimes (Dryfoos, 1990). The lifetime chances that an urban African American male will be arrested for an FBI "index" offense (murder, forcible rape, aggravated assault, robbery, burglary, larceny, and auto theft) is 50%, in contrast with 14% for urban White males (Blumstein & Cohen, 1987). The problem is so great that more African American male adolescents are incarcerated or on probation for a crime than are gainfully employed (Edelman, 1992). Self-reports indicate a much narrower race difference in actual behavior, however. The Black-to-White ratio in prevalence of SVOs is about 5 to 4, a statistically significant but substantially small effect (D. Elliott, 1994). When socioeconomic class confounds are controlled, this ratio is reduced to about 7 to 6. D. Elliott (1994) has reported that the higher prevalence rate of self-reported SVOs among African Americans can be almost entirely accounted for by the particularly high risk of onset between the ages of 13 and 16 for African American male

adolescents. This age period obviously is a risky one for this group in terms of self-reported SVOs, but an even more tragic time in terms of arrest rates and rates of victimization.

These data suggest common developmental patterns in serious violence that begin with minor aggressive acts and delinquent behaviors in middle childhood and progress to frequent and serious offending by age 17. The initiation of substance use and sexual activity adds incrementally to the risk for increased aggressive behavior during this period (Jessor, Donovan, & Costa, 1991). D. Elliott (1994) concluded that minor forms of delinquent behavior and alcohol use typically precede more serious forms of violence. Thus, the developmental path for a small portion of the population involves progressively serious and violent behaviors, although most offenders usually desist from crime in early adulthood.

### *Adolescent Culture*

In American peer culture, physical aggression and delinquent deviance become more socially acceptable during adolescence (Coie, Terry, Zakriski, & Lochman, 1995). Moffitt (1993) hypothesized that early starting children contribute to the growth of a deviant peer culture by acting as role models and by offering opportunities for deviant behavior. Indeed, some deviant youth begin to hold positive status among peers (Miller-Johnson & Costanzo, 2004). The positive correlation between physical aggression and being disliked by peers dissolves during middle school (Cillessen & Mayeux, 2004), and the base rates of self-reported antisocial behavior rise. In turn, as the contextual normativeness of antisocial behavior increases, the effects of this context are to increase the display of aggressive behavior by individual youth (Espelage, Holt, & Henkel, 2003). The new group of aggressors has been called adolescence-limited by Moffitt (1993), who asserted that this group engages in delinquent behavior only during adolescence.

### *Violence in Romantic Relationships*

Studying a representative birth cohort in New Zealand, Magdol, Moffitt, Caspi, and Silva (1998) found that 32% of late-adolescent males and females reported perpetrating physical aggression in an intimate relationship during the past year. This domain is one of the few in which violence by females equals that by males, although male violence is more likely to result in partner injury (Archer, 2000). Although many individuals who are violent toward intimate partners are also violent in

other situations, quite a few display violence only in this context (Holtzworth-Munroe & Stuart, 1994). Indeed, existing theory and research concerning intimate partner violence generally is based on the premise that intimate partner violence is distinct from other forms of violence (Moffitt, Krueger, Caspi, & Fagan, 2000).

### *Aggression during Adulthood*

Most self-report studies indicate that between ages 18 and 25 the overall rate of aggressive behavior declines, and virtually no new cases of antisocial behavior begin in adulthood (Robins, 1966). Sampson and Laub (2003) examined trajectories of adult development in the Glueck sample of delinquents and found that further declines in crime are found after age 35 in all groups of early offenders. In the Cambridge study, Farrington (1993) found that self-reported prevalence of all criminal behaviors, including violence, decreased markedly in early adulthood, for example, self-reports of burglary decreased from 11% at age 18 to 5% at age 21 and 2% at both ages 25 and 32. In the NYS, D. Elliott, Huizinga, and Menard (1989) found that self-reported offending peaked at age 17 and declined linearly in subsequent years. Official arrest record data indicate a similar decline in violent offending in adulthood, although the decline as measured by arrests begins later and is less sharp than that by self-reports (Blumstein, 2000).

An important caveat to these findings is that almost all of these studies fail to include child abuse and spousal battery as instances of violence. Thus, it might be misleading to conclude that adulthood brings about less violence. Straus and Gelles (1990) reported that 16% of American couples report physically assaulting each other, and 11% report physically abusing their children, in the past 12 months; however, systematic epidemiological research that would adequately describe the life course and origins of child and spouse abuse does not yet exist. Huesmann, Eron, Lefkowitz, and Walder (1984) have reported some continuity between peer-directed aggression at age 8 and spousal and child abuse at age 30, suggesting that this behavior may have similar antecedents to other forms of violence.

There is a significant exception to the general pattern of decline in serious violence in early adulthood, for both early-starting and late-starting youth (Coie, 2004). Among African American males, there is no decline in violence from age 22 to 30. Nearly twice as many African Americans continue their violent careers as do Whites; thus, the violent careers of African Americans

last longer than they do for Whites (D. Elliott, 1994), in sharp contrast with the finding of few race differences in the propensity for initial violence. It seems that the underclass, especially poor African American males, are unable to escape the system of incarceration, labeling, unemployment, and negative identity once the course of violence begins. As D. Elliott (1994), concluded:

Once involved in a lifestyle that includes serious forms of violence, theft, and substance use, persons from disadvantaged families and neighborhoods find it very difficult to escape. They have fewer opportunities for conventional adult roles, and they are more deeply embedded in and dependent upon the gangs and the illicit economy that flourish in their neighborhoods. . . . Poverty is related less to the onset of violence than to the continuity of violence, once initiated. (p. 19)

It is important to note that there is no race disparity in continuing violence among persons who are employed at ages 18 to 20 or married or living with a partner. The evidence suggests that those persons who are able to establish stable work and family life and careers, regardless of ethnicity, tend to give up their involvement in criminal violence (Rutter, 1989). As D. Elliott (1994) pointed out, these findings have enormous implications for the focus of intervention, which might be directed toward job training and economic opportunity.

### *Continuity of Individual Differences in Adulthood*

The early starter model of antisocial individuals posits that early starters are more likely to continue breaking the law in their adult years than are the late starters. The distinction between early and late starters, however, cannot be sharply drawn because curves for the onset of offending do not show clear demarcation and some so-called late starters do continue offending in the adult years. Continuity of offending into adult years has been shown by Farrington (1995). Nearly 75% of those convicted of juvenile offenses (at age 10 to 16) were reconvicted between age 17 and 24, and half of the juvenile offenders were reconvicted between age 25 and 32. Thus, although the peak of offending in this study was age 17, a substantial number of juvenile offenders continue in criminal careers well into adulthood.

The continuity of antisocial activity in adulthood takes on other forms besides criminal offending. This heterotypic continuity includes spouse abuse, drunk driving, moving traffic violations, and severe punishment of children (Huesmann, Eron, et al., 1984), what

Pulkkinen (1990) described as a relapsed lifestyle, and less stable marriages that more frequently end in divorce (Caspi, Elder, & Bem, 1987). Longitudinal studies also reflect substantial discontinuity. Not all early-starting antisocial youth become adult offenders or follow the pathway of poor occupational or marital adjustment.

The idea that a stable marriage and regular employment provide support for desistance from crime is consistent with social control theories of crime. Sampson and Laub's (2003) analyses of the Glueck and Glueck (1968) longitudinal study indicated that strong ties to adult institutions, such as work and family, protect one from subsequent criminal behavior among those with a previous history of delinquency. Job stability had a consistently inverse influence on crime and deviance in young adulthood (age 17 to 25) and in later adulthood (age 25 to 32), whereas income did not have effects when other factors were controlled. Following up that part of the sample that had been married at some time, Sampson and Laub found that marital cohesiveness had a significant effect on crime and deviance, independent of other factors. Sampson and Laub (1990) concluded that "job stability is central in explaining adult desistance from crime; however, this effect is reduced among those who were never married, for whom attachment to wife assumes greater relative importance" (p. 621).

## **GENDER AND AGGRESSION**

Long-standing interest in the issue of gender differences in antisocial behavior has typically taken two forms. One is interest in the size of the difference between men and women as a function of developmental phase and the type of antisocial behavior examined. The other focus is on differences in the processes and outcomes of antisocial behavior for males and females. The evidence is stronger in the first case than in the second.

### **Physical Aggression**

Gender differences begin to emerge as early as 3 years of age, particularly for more serious and stable aggression. Crick, Casas, and Mosher (1997) found that teachers rated preschool boys aged 3 to 5 as more aggressive than girls. Kingston and Prior (1995) used annual maternal assessments taken between ages 3 and 8 in the 1,721 participants in the Australian Temperament Project to find that 41 out of the 53 members of a stable aggressive group were boys.

These differences in physical aggression remain stable through childhood and adolescence. Broidy et al. (2003) examined developmental trajectories of physical aggression in six large, well-known, longitudinal samples from three different countries: the Pittsburgh Youth Study and Child Development Project from the United States, the Dunedin and Christchurch studies from New Zealand, and the Montreal and Quebec samples from Canada. These authors found that “girls exhibit lower mean levels of physical aggression than do boys across all four sites with comparable data for boys and girls. Even among girls who exhibit chronic physical aggression across assessment periods, their mean levels of physical aggression are notably lower than those of chronic physically aggressive boys in the same sample” (p. 232). Stanger, Achenbach, and Verhulst (1997) found that boys were more aggressive than girls at every age from 4 to 18, using the aggression subscale of the Child Behavior Checklist (CBC) in a sample of over 2,000 Dutch children.

### Antisocial Behavior

Similar sex differences have been observed for antisocial behavior more broadly defined. Stanger et al. (1997) reported that scores on the delinquency subscale of the CBC were higher for boys than girls at every age from 4 to 18. Gender differences on the externalizing subscale, a combination of aggression and delinquency, have been found across 12 different cultures (Crijnen, Achenbach, & Verhulst, 1997). In their intensive examination of gender differences in antisocial behavior using data from the Dunedin Study, Moffitt, Caspi, Rutter, and Silva (2001) reported that males score higher on antisocial behavior from age 5 to age 21 on parent, teacher, informant, and self-reports. The difference between boys and girls, averaged across method, ranged from .15 standard deviations at age 15 to almost a half standard deviation at age 21. Finally, Fergusson and Horwood (2002) examined the offending trajectories from ages 8 until 20 for boys and girls enrolled in the Christchurch study and found that the female offending rate was about half the male offending rate at all ages.

### Conduct Disorder

Not surprisingly, similar gender differences are found when CD is examined. In the Virginia Twin Study of Adolescent Development, Simonoff et al. (1997) found a

rate for CD of 5.9% for boys compared to 2.8% for girls. This sex ratio is consistent with the ratios obtained from other epidemiological studies. For example, Costello et al. (1996) reported a sex ratio of 4.8:1 in the Great Smoky Mountains study. The sex ratio in the New York State study was 2.3:1 (P. Cohen et al., 1993) and in the Ontario study it was 2.4:1 (Offord et al., 1989).

The gender differences are especially pronounced for more severe conduct problems that begin early. Moffitt and Caspi (2001), using data from the Dunedin Study, identified two groups of antisocial individuals using data from age 5 through age 18: life-course persistent (LCP) offenders and adolescent limited (AL) offenders. Twenty-six percent of males were placed into the AL group compared to 18% of females. In contrast, 10% of males were placed in the LCP group compared to only 1% of females. Thus, the male-to-female ratio for the LCP path was 10:1, whereas the sex ratio for the AL path was 1.5:1.

### Female Aggression

One type of antisocial behavior for which there is either very little difference between boys and girls (Underwood, 2003) or for which girls actually score higher than boys (Crick & Zahn-Waxler, 2003) has been studied under several terms, each of which is meant to refer to a type of aggression that is more subtle than physical aggression and which may be used preferentially by girls. Indirect aggression has been defined as “a noxious behavior in which the target person is attacked not physically or directly through verbal intimidation but in a circuitous way, through social manipulation” (Kaukiainen et al., 1999). Galen and Underwood (1997) defined social aggression as aggression “directed toward damaging and another’s self-esteem, social status, or both” (p. 589). Relational aggression has been defined as “harming others through purposeful manipulation and damage of their peer relationships” (Crick & Grotpeter, 1995, p. 711). Although there may be subtle differences between these conceptions (see Underwood, 2003), they are highly overlapping constructs and we treat them as assessing a single type of aggression that we label, following Underwood, *social aggression*.

Social aggression can be reliably identified using multiple methods in children as young as 3 years old (Crick et al., 1997). An explosion in interest on the topic has resulted in dozens of studies that examine the construct from early childhood until late adolescence. In terms of gender differences, there is agreement that this

construct references a form of aggression that is more normative in girls than is physical aggression. There is disagreement, however, as to whether girls are more socially aggressive than boys.

Results are mixed in preschool studies. McNeilly-Choque, Hart, Robinson, Nelson, and Olsen (1996) found that 4- and 5-year-old girls, relative to boys, displayed more relationally aggressive behaviors on the playground and were rated as more relationally aggressive by classmates and teachers. Crick et al. (1997) found that girls were more relationally aggressive than boys according to teacher ratings but not according to peer nominations. A study by Hart, Nelson, Robinson, Olsen, and McNeilly-Choque (1998) of Russian nursery school children failed to find gender differences for relational aggression as did a study of Head Start and community preschool participants (Kupersmidt, Bryant, & Willoughby, 2000).

The issue of gender differences is no clearer in middle childhood. Archer, Pearson, and Westeman (1998), using observational data from a sample of 7- to 11-year-olds in Great Britain, found that girls engaged in more verbal aggression than did boys. However, a cross-cultural study using peer ratings found that boys were rated as more verbally aggressive than girls (Osterman et al., 1994). Tiet, Wasserman, Loeber, McReynolds, and Miller (2001) used parent reports of relational aggression for boys and girls aged 4 to 18 and found no gender differences. However, Crick (1996) used teacher reports to find that girls were more relationally aggressive than boys. Studies using peer nominations are also discordant. Crick and colleagues often report that girls receive more nominations for relational aggression than do boys (e.g., Crick & Grotpeter, 1995). Other studies, using the same methodology, have either failed to find gender differences in relational aggression (e.g., Rys & Bear, 1997) or have found that boys received more nominations for relational aggression than girls (e.g., David & Kistner, 2000).

In adolescence, the picture is the same. Several studies report that girls are more socially aggressive than boys, whereas others find no differences or that boys are more socially aggressive than girls. For example, for verbal aggression, Salmivalli, Kaukiainen, and Lagerspetz (2000) found that 15- and 16-year-old boys were rated by peers as higher in verbal aggression than girls, but Kashani and Shepperd (1990) failed to find gender differences in verbal aggression. For indirect aggression, one study found that girls were more aggressive than boys (Salmivalli et al., 2000) and two other studies failed to find such dif-

ferences (Pakaslahti & Keltigangas-Jarvinen, 2000). Results are also mixed for studies of social aggression (Paquette & Underwood, 1999).

### Gender Differences in Process

It is clear that for most forms of antisocial behavior boys are more antisocial than girls. What is not clear, however, is whether the processes that lead to antisocial behavior are the same or different for girls and boys. Moffitt et al. (2001) examined correlations separately for males and females between antisocial behavior and five classes of important risk factors: maternal factors, family factors, cognitive and neurological factors, child behavior factors, and peer factors. Of the 35 correlations examined, 14 differed significantly for males and females. These differences, however, were differences in magnitude rather than direction: All correlations were in the same direction and, in almost every case, the correlation was significant for both males and females.

## DETERMINANTS OF INDIVIDUAL DIFFERENCES IN ANTISOCIAL BEHAVIOR

Causes of individual differences in antisocial behavior range from genetic to socialization, and contemporary models integrate these factors through interactions, transactions, moderation, and mediation.

### Genetics

It is homiletic to say that antisocial behavior is the result of both nature and nurture. To move beyond homily, we must disentangle these effects and examine their interplay. This is the realm of behavior genetics, which relies on genetically sensitive designs (e.g., twin and adoption studies) to accomplish these goals. Genetically sensitive designs utilize the differing degrees of genetic similarity in relatives (e.g., monozygotic and dizygotic twins, parents and children, stepsiblings) to determine how much of the variance in a trait is due to variation in genetic similarity and environmental similarity.

Contemporary behavior-genetics researchers provide estimates of four types of influences. The first two, additive and nonadditive genetic effects, constitute heritability. The third component, shared environment, indexes the degree to which environmental factors are responsible for the resemblance of family members. The fourth component, nonshared environment, indexes the

degree to which environmental factors contribute to differences between family members.

Before examining the estimates themselves, two cautions are important to note. First, it is understood that genetic effects may be mediated environmentally through gene-environment transactions in which genes influence surrounding environments, which, in turn, influence phenotypic expression (cf., Scarr & McCartney, 1983). In behavior genetics studies, the effects of such transactions are included in the heritability estimates and not counted as environmental effects. Second, all estimates are context specific. The influence of genes on behavior varies across social contexts, and a change in the social context may change the relative importance of genes and environment (cf., Dunne et al., 1997).

Even with these cautions, the conclusions from this research regarding the relative influences of genes and environment on antisocial behavior are impossible to escape. Over 100 quantitative genetic studies on antisocial behavior have been published from more than 60 different samples, with over one-third of these published in the past 10 years. As Moffitt (2005) has written, there is a "new look" about the current generation of behavior genetics studies. The samples have grown larger, more representative, and more global. Reports have appeared from large, representative samples in Australia, the Netherlands, Scandinavia, the United Kingdom, and the United States. Statistical techniques have grown more sophisticated. Multiple sources (i.e., self-reports, reports from others, and observational reports) have been utilized to measure antisocial behavior. Finally, research has spanned the entire range of development from early childhood to late adulthood. Two examples of the new behavior genetics approach appear below.

Arseneault et al. (2003) reported on the results of a behavior-genetic analysis among 5-year-old children from the Environmental Risk Longitudinal Twin Study (E-risk), which drew an initial 1,210 families from a national registry of twins born in England and Wales with an over-representation of high-risk families defined as young age of the mother at first birth. Antisocial behavior was assessed using mother, teacher, examiner, and self-reports. In univariate analyses, considering one antisocial behavior variable at a time, heritability estimates ranged from .42 for self-reports to .76 for teacher reports, nonshared environmental estimates ranged from .24 for teacher reports to .58 for child reports, and shared environmental estimates were zero. Multivariate analyses, which included a common latent ASB factor

that combined across raters and contexts as well as four specific factors corresponding to each informant, revealed that 82% of the variance in the common latent factor was influenced by genetic influences with the remaining 18% influenced by nonshared environment. Similarly, moderate proportions of the variance unique to each reporter were accounted for by genetic influences. Thus, measures that combine across social contexts yield estimates that minimize environmental estimates and maximize genetic estimates.

O'Connor, McGuire, Reiss, Hetherington, and Plomin (1998) reported results from the Nonshared Environment and Adolescent Development (NEAD) project. The goals of this project were to identify sources of nonshared environment, estimate its impact on adolescent development, and integrate genetic and environmental models of adolescent development. The sample consisted of 720 same-sex adolescent siblings between 10 and 18 years of age, including monozygotic and dizygotic twins, full siblings, half siblings, and unrelated siblings. Antisocial behavior was assessed using multiple instruments collected from multiple sources. Results from model-fitting analyses yielded estimates of .56 for the genetic component, .25 for shared environment, and .19 for nonshared environment.

Rhee and Waldman (2002) recently meta-analyzed the genetic influences on antisocial behavior from 42 independent twin samples and 10 adoption samples. These studies varied in their operationalizations of antisocial behavior, sources of information, and ages of the participants. The best-fitting model for the data included additive genetic influences (.32), nonadditive genetic influences (.09), shared environmental influences (.16), and nonshared environmental influences (.43). Following this overall analysis, the authors examined potential moderators of the estimates. They found no differences as a function of gender. Differences, however, were identified as functions of operationalization and age. For diagnosis (e.g., CD or antisocial personality disorder), aggression, and antisocial behavior (an omnibus operationalization) a model that included additive genetic, shared, and nonshared environmental influences best fit the data. Heritability estimates were .44, .44, and .47 for diagnosis, aggression, and antisocial behavior, respectively. Estimates for shared and nonshared environment were .11 and .45, .06 and .50, and .22 and .31 for diagnosis, aggression, and antisocial behavior, respectively. For antisocial behavior assessed via criminality, however, the best-fitting model included an

additive genetic component (.33), a nonadditive genetic component (.42), and a nonshared environment component (.25). Age also significantly moderated the magnitude of genetic and environmental influences with the magnitude of familial influences decreasing with age and the magnitude of nonfamilial influences increasing. For children, additive genetic effects accounted for 46% of the variance, shared environment accounted for 20%, and nonshared accounted for the remaining 34%. The corresponding figures for adolescents were .43, .16, and .41; for adults, these figures were .41, .09, and .50. In general, these results suggest that there are moderate genetic (.41) and nonshared environmental effects (.43), and small shared environmental effects (.16) on antisocial behavior.

A recent review by Moffitt (2005) came to similar conclusions as Rhee and Waldman. One moderator not examined by Rhee and Waldman (2002), but discussed in detail by Moffitt, is the type of offender in question. Moffitt argues that LCP antisocial behavior may be more heritable than AL antisocial behavior. First, she points to the results from studies of large representative samples of very young twins that yield higher heritability coefficients than those reported by Rhee and Waldman (2002), ranging from 50% for externalizing behaviors among 2- to 3-year-old boys to 76% for teacher reports of antisocial behavior among 5-year-olds. Second, Moffitt points to several studies that have shown higher heritability for the Aggression (around 60%) than the Delinquency (around 30 to 40%) subscales of the CBCL (Achenbach, 1991). She argues that because the Aggression scale measures antisocial personality and physical violence and its scores are relatively stable across development, it is a better measure of LCP antisocial behavior than the delinquency scale, which measures rule-breaking and shows a rise in its mean scores across adolescence. Third, Moffitt points to two studies that have contrasted preadolescent onset antisocial behavior against antisocial behavior that begins during adolescence, showing that preadolescent onset is substantially more heritable. Finally, she points to two studies demonstrating that the heritability of antisocial behavior that persists from adolescence into adulthood is more heritable than antisocial behavior confined to adolescence.

### ***Gene-by-Environment Interactions***

Studies of antisocial behavior were among the first to document interactions between genetic and environmen-

tal risk factors. Mednick and Christiansen (1977) provided the first evidence that genetic and environmental risk factors interact to produce offending. Among the 6,000 families in the Danish Adoption Study, 14% of adoptees were convicted when neither their biological nor adoptive parents had been convicted of a crime; 15% were convicted if only their adoptive parent had been convicted; 20% were convicted if only their biological parent had been; finally, 25% were convicted if both their adoptive and biological parents had been convicted.

The dynamic interaction effect was found to be even stronger in several later studies. Cloninger, Sigvardsson, Bohman, and van Knorring (1982), in a sample of 2000 Swedish adoptees, found that 3% were convicted if both biological and rearing environments were normal; 7% offended if only rearing were abnormal; 12% offended in the face of offending in the biological parent; however, 40% offended if both the biological parent offended and the rearing environment was abnormal. Cadoret, Cain, and Crowe (1983), in a sample of 500 adoptees, found that the most antisocial adoptees were those that had birth mothers with antisocial personality disorder or alcoholism *and* came from adoptive homes marked by adverse circumstances. These findings were replicated in a separate sample by Cadoret, Yates, Troughton, Woodworth, and Stewart (1995) who showed that adversity in adoptive homes (e.g., marital or problems, substance use, psychopathology) interacted with antisocial personality disorder in the biological parents to predict childhood and adolescent antisocial behavior. Similar findings have been reported in twin studies as well. Jaffe et al. (in press), in the E-risk twin study, showed that environmental risk interacted with genetic risk to predict CD; physical maltreatment was associated with a 24% increase in the probability of CD among twins at high genetic risk (i.e., having a co-twin with conduct disorder), but only a 2% increase among twins at low risk. Thus, there is a *stronger* environmental impact among subgroups at higher genetic risk.

Caspi et al. (2002) provided evidence for the interaction between a specific gene and environmental risk in predicting antisocial behavior. These authors examined the interaction between childhood maltreatment and a functional polymorphism in the MAO-A gene in 442 males from the Dunedin Multidisciplinary Health and Development Study. The MAO-A gene was chosen because it encodes the MAO-A enzyme, which is responsible for metabolizing neurotransmitters, such as norepinephrine, dopamine, and serotonin, several of

which have been linked with antisocial behavior. Caspi et al. reported a significant interaction between childhood maltreatment and MAO-A genotype, such that 85% of the males with the low-activity allele and a history of childhood maltreatment developed some form of antisocial outcome. Importantly, this finding was recently replicated in the 514 male twins from the Virginia Twin Study for Adolescent Behavioral Development (Foley et al., 2004). These authors found an interaction between the MAO-A genotype and childhood adversity (i.e., parental neglect, interparental violence, and inconsistent discipline) in predicting CD. As in the Caspi et al. study, individuals with low MAO-A activity and an adverse childhood environment were the most likely to develop CD. Again, there is a *stronger* environmental impact among subpopulations at higher genetic risk.

Thus, antisocial behavior is quite heritable, especially for LCP antisocial behavior and individuals growing up in risky environments. Genes, and therefore biological factors, play an important role in the causation of antisocial behavior. However, there are several caveats to this conclusion. First, these results do not imply that antisocial behavior is the result of a single gene; as noted by Carey and Goldman (1997) “it defies credulity to imagine that millions of years of primate and the hominid evolution produced a sequence of DNA whose *raison d’être* is to forge checks or cheat on income taxes” (p. 249). They do not imply anything about the cause of antisocial behavior in a given individual; heritability is a population statistic. They do not imply immutability; phenylketonuria is a simple single-gene recessive disorder whose ill effects (i.e., mental retardation) can be eliminated by an environmental intervention (i.e., avoiding phenylalanine in the diet). Next, there are caveats about the estimates themselves. As noted earlier, the estimates of genetic effects include gene-environment transactions in which genes influence surrounding environments, which, in turn, influence phenotypic expression. The ratings of aggressive and antisocial behavior typically used (i.e., ratings by teachers, parents, peers, or the self) represent generalized perceptions about someone’s aggressive behavior. They necessarily ignore the context-specificity of antisocial behavior. The latent modeling techniques used to composite data from multiple sources (e.g., multiple raters) typically lead to a loss of rater-specific information. Although some information that is lost may be error, at least some substantial portion may reflect the different

contexts in which different raters have observed the individual, which represent real environmental effects. This conclusion is consistent with Arseneault et al.’s (2003) finding that source-specific factors (separate parent, teacher, child, and examiner ratings) were less heritable than the combined factor. Thus, these studies are most relevant to understanding antisocial personalities rather than antisocial behaviors.

There are also conclusions to be drawn about environmental influence. The contribution of shared or common environment to antisocial behavior, although small, is larger than for other psychiatric disorders (Kendler, Prescott, Myers, & Neale, 2003). Consistent with research in other areas, the contribution of nonshared environment is moderate. Taken together, these findings indicate an important role for the environment. However, they do suggest that it is the “person-specific” experiences of individuals in families that are the more important environmental causes.

### Dispositional Factors

Personality (i.e., characteristic ways of thinking, feeling, and acting) and its earliest manifestations in temperament have been studied in relation to antisocial behavior for a number of years. The evidence for the influence of both personality and temperament is mounting. Large, prospective studies have shown that early temperament is predictive of antisocial behavior in the preschool period (Keenan, Shaw, Delliquadri, Giovannelli, & Walsh, 1998), childhood (Raine, Reynolds, Venables, Mednick, & Farrington, 1998), and even into adolescence (Caspi et al., 1994). Personality is robustly related to antisocial behavior in childhood (e.g., Krueger, Caspi, Moffitt, White, & Stouthamer-Loeber, 1996) and adulthood (Ball, Tennen, Poling, Kranzler, & Rounsaville, 1997). Thus, the question is no longer is there a relation, but which dimensions of temperament and personality are most strongly related to antisocial behavior?

### Temperament

Buss and Plomin (1984, p. 84) define temperament as “inherited personality traits present in early childhood”; thus, we restrict our review to those studies that have measured temperament in early life. Original work on temperament by Thomas, Chess, and Birch (1968) identified nine separable dimensions: (1) activity level, (2) threshold, (3) mood, (4) rhythmicity, (5) ap-

proach/withdrawal, (6) intensity, (7) adaptability, (8) distractibility, and (9) attention span/persistence. The authors identified three constellations of these dimensions that they believed were clinically significant: (1) difficult temperament, (2) easy temperament, and (3) slow-to-warm-up temperament. The first of these, difficult temperament, has been frequently examined in the context of antisocial behavior and conduct problems; it refers to children who are irregular in their behavior, tend to withdraw from novel situations, are slow to adapt to environmental change, react intensely, and experience predominantly irritable and negative mood. Several studies have found that early measured difficult temperament is predictive of later antisocial behavior. Bates found that mothers' ratings of infant temperament as early as age 6 months significantly predict mothers' ratings of child conduct problems at age 3 years (Bates, Maslin, & Frankel, 1985) and, to a lesser degree, mothers' CBCL Externalizing Scores at age 7 to 8 years (Bates, Bayles, Bennett, Ridge, & Brown, 1991). Similar results have been obtained from the Australian Temperament Project, a prospective, longitudinal study of temperament and development in a large and representative sample of a whole state population. Kingston and Prior (1995) found that early "difficult" temperament significantly discriminated children whose aggression started early and maintained over time from other aggressive and nonaggressive children.

As noted above, the construct of difficult temperament is a concretion of multiple elements of temperament and is therefore of limited use in understanding which specific elements of temperament are important predictors of outcomes. Studies that have utilized more specific measurements of temperament indicate that the strongest predictors of later antisocial behavior are, borrowing terminology from Rothbart, Ahadi, and Evans (2000), dimensions dealing with fearlessness, irritability/anger/frustration, and effortful control. Many cross-sectional studies and short-term longitudinal studies have found these dimensions to be moderately related to aggression and conduct problems in early, middle, and late childhood (e.g., Lengua, West, & Sandler, 1998). For example, in a study of 214 children aged 4.5 to 8 years, Eisenberg, Cumberland, et al. (2001) found that measures of fear, anger, and control distinguished children with externalizing problems from other children defined when using parent and teacher reports. In one of the strongest demonstrations, Valiente et al. (2003) found that effortful control rated

by parents and teachers was related to externalizing problems at age 11 even after controlling for effortful control and externalizing problems 4 years earlier. These results typically hold for mother-reported temperament and observationally assessed temperament (Eisenberg, Cumberland, et al., 2001).

Even more impressive, however, are the results from longer-term longitudinal studies from several countries. Shaw, Gilliom, Ingoldsby, and Nagin (2003) identified developmental trajectories of conduct problems from ages 2 to 8 in a sample of 284 low-income boys from an American city. They found that observed fearlessness at age 2 distinguished the chronically high trajectory group from all other trajectory groups. Raine et al. (1998) found that measures of fearlessness and stimulation seeking at age 3 predicted aggression at age 11 in a sample of 1130 male and female children from the island of Mauritius. Tremblay, Pihl, Vitaro, and Dobkin (1994), using data from the Montreal Longitudinal Study on over 1,000 boys, showed that teacher-rated impulsivity in kindergarten predicted self-reported delinquency at age 13. Finally, the relation between early temperament and later antisocial behavior has also been documented in several papers from the Dunedin Multidisciplinary Study of Health and Development. Caspi, Henry, Moffitt, and Silva (1995) used temperament ratings derived from examiners' behavioral ratings at ages 3 and 5 to find that early lack of control was consistently related to antisocial behavior at 9 and 11 and CD at 13 and 15. Henry, Caspi, Moffitt, and Silva (1996) found this same dimension to predict violent convictions at age 18. Moffitt and Caspi (2001) found that lack of control distinguished LCP offenders from AL offenders.

These findings cohere with theoretical and empirical work on conscience development. Kochanska (1997) posited the existence of two regulatory processes necessary for the adequate development of conscience: (1) affective discomfort and (2) behavioral control. She found that temperamental variations are important to these processes, with fear being important for the first process and inhibitory/effortful control important for the second.

There is also evidence for the interaction between temperament and the socialization context, particularly features of parenting. Coon, Carey, Corley, and Fulker (1992) found that among "difficult-temperament" young children, only those with conjoint maladaptive parenting were at risk for later conduct-disordered behavior. Kochanska (1997) has also reported an interaction between temperament and parenting style in producing

compliance (see also Brennan, Hall, Bor, Najman, & Williams, 2003).

### *Personality*

Scientific inquiry in personality development has grown rapidly, as documented by Caspi and Shiner (Chapter 6, this *Handbook*, this volume). J. Miller and Lynam (2001) meta-analyzed 59 studies that examined the relation between antisocial behavior, broadly defined, and one or more structural models of personality. Structural models are derived from basic research in personality and utilize multiple dimensions to organize the vast array of personality traits according to their interrelations. They share the fundamental assumption that a finite number of traits are the basic building blocks of personality, providing comprehensive coverage of human personality. Importantly, there is a great deal of overlap between various structural models (e.g., Five Factor Model; Tellegen's three-factor model, Eysenck's Psychoticism, Extraversion, Neuroticism [PEN] model), making it easier to compare results from different studies. Approximately one-third of the studies examined by J. Miller and Lynam were conducted in samples consisting of children and adolescents. Across the 18 dimensions in the 4 different structural models examined, 8 dimensions showed correlations greater than .25 with antisocial behavior: (1) Five Factor Model (FFM) Agreeableness (negative) and Conscientiousness (negative); (2) Eysenck's Psychoticism (positive); (3) Tellegen's Negative Emotionality (positive) and Constraint (negative); and (4) Cloninger's Novelty Seeking (positive), Self-Directedness (negative), and Cooperativeness (negative). All of these scales can be understood as assessing either Agreeableness or Conscientiousness/Constraint. The strength of these relations did not vary across age, type of sample (institutionalized versus not), or assessment source (e.g., self versus other, official versus self). Other dimensions, theorized to be important to antisocial behavior, such as Neuroticism and Extraversion bore no significant overall relations to antisocial behavior.

These effects are not due to predictor-criterion overlap. The personality inventories contain very little reference to explicitly antisocial behavior; in cases where this is not true, results hold even when overlapping elements are removed (e.g., Krueger et al., 1996). These relations hold prospectively: in a particularly stringent test, Krueger (1999), in the Dunedin Study, found that low levels of constraint and agreeableness at age 18 pre-

dicted symptoms of antisocial personality disorder at age 21 above and beyond the effect of antisocial personality disorder at age 18.

Although studied infrequently, there is evidence for personality by context interactions. Lynam et al. (in press) found that impulsivity and neighborhood-socioeconomic status interacted to produce violent and nonviolent offending among 430 boys from the Middle Sample of the Pittsburgh Youth Study, such that impulsivity was more strongly related to self-reported offending in poorer neighborhoods.

### *Psychopathy*

The construct of psychopathy has been studied intensively at the adult level. Interpersonally, the psychopath is grandiose, egocentric, manipulative, forceful, and cold-hearted; affectively, he or she displays shallow emotions, is unable to maintain close-relationships, and lacks empathy, anxiety, and remorse. Behaviorally, the psychopath commits more types of crime, more crimes of any type, and more violent crimes, in or out of prison, than nonpsychopathic counterparts (see Hare, 2003). Lynam and colleagues (i.e., Lynam, 2002; Lynam et al., in press; Miller, Lynam, Widiger, & Leukefeld, 2001) have argued that psychopathy can be understood as a specific constellation of personality traits; in particular, they argue that psychopathy consists of extremely low Agreeableness, low Conscientiousness, a mixture of high and low Neuroticism (i.e., high in angry hostility and impulsiveness and low in anxiety, self-consciousness, and vulnerability), and a mixture of high and low Extraversion (i.e., high in assertiveness and excitement seeking and low in warmth). As a constellation of traits, it warrants mention in the present discussion of dispositional factors, particularly given that several investigators have imported the concept of psychopathy to juveniles (Frick, O'Brien, Wootton, & McBurnett, 1994; Lynam, 1997).

Over 20 studies have examined the relation between juvenile psychopathy and offending. Almost without exception, these studies have found similar relations between psychopathy and antisocial behavior in juveniles as those found in adults. Juvenile psychopathy is moderately strongly related to age at onset (e.g., Corrado, Vincent, Hart, & Cohen, 2004), number and variety of offenses (e.g., Kosson, Cyterski, Steuerwald, Neumann, & Walker-Matthews, 2002), stability of offending across time (e.g., Lynam, 1997), and quantity and quality of aggression (e.g., Frick et al., 1994; Murrie, Cor-

nell, Kaplan, McConville, & Levy-Elkon, 2004). For example, using his Childhood Psychopathy Scale, in a sample of 430 12- to 13-year-old boys from a high-risk study, Lynam (1997) reported that juvenile psychopathy was moderately correlated ( $r$ s range from .19 to .39) with past and current delinquency and related to serious delinquency that is stable across time. Kosson et al. (2002) examined correlations between offending history and scores on the Personality Checklist Youth Version (PCL-YV) in a sample of 115 adolescent males on probation. They report that psychopathy scores correlated with the number of nonviolent charges ( $r = .35$ ), number of violent charges ( $r = .27$ ), total number of charges ( $r = .42$ ), and the number of different charges ( $r = .45$ ). These results held across different measurement instruments, reporting sources, samples, and ages.

Moreover, several of these studies have examined the *predictive* relations between juvenile psychopathy and antisocial behavior, including the relation between juvenile psychopathy and institutional infractions (e.g., Edens, Poythress, & Lilienfeld, 1999; Murrie et al., 2004; Stafford & Cornell, 2003). Spain, Douglas, Poythress, and Epstein (2004) administered three psychopathy instruments to 85 male adolescent offenders aged 11 to 18 in a residential treatment facility and found significant relations between the total number of infractions (physical, verbal, and administrative) and each of the psychopathy indices, with  $r$ s of .27, .38, and .43 for the PCL-YV, Antisocial Process Screening Device (APSD) and Child Psychopathy Scale (CPS), respectively. Additional studies have examined the predictive relations between juvenile psychopathy measures and recidivism (e.g., Gretton, Hare, & Catchpole, 2004). Corrado et al. (2004) followed 182 male adolescent offenders for, on average, 14.5 months. They found that high scorers on the PCL-YV reoffended earlier than low scorers; this was true for both nonviolent (6.87 months versus 12.33 months) and violent offenses (13.55 months versus 18.17 months). Again, these results mirror those found among adults.

Two studies examined the relation between juvenile psychopathy and treatment outcomes (O'Neil, Lidz, & Heilbrun, 2003; Spain et al., 2004). Using the PCL-YV in a sample of 64 adjudicated youth in a substance treatment program, O'Neil et al. (2003) found that high scorers on the PCL-YV attended the program for fewer days, participated more poorly when they did attend, and showed less clinical improvement across the course of treatment.

Finally, and importantly, several studies have attempted to demonstrate the incremental validity provided by the construct of juvenile psychopathy in predicting antisocial behavior (Lynam, 1997; Murrie et al., 2004; Stafford & Cornell, 2003). Lynam (1997) demonstrated that scores on the CPS were related to concurrent serious delinquency above and beyond social class, IQ, impulsivity, and delinquency. In the strongest demonstrations, studies showed that psychopathy predicted future antisocial behavior above and beyond current antisocial behavior. Murrie et al. (2004), in a sample of 113 incarcerated adolescents, reported that scores on the PCL-YV predicted institutional violence above and beyond previous violence.

### Neuropsychological Factors

The idea of a link between the physical health of an individual's brain and his or her level of antisocial behavior has been in the literature for centuries. Benjamin Rush (1812; cited in F. Elliott, 1978, p. 147) referred to the "total perversion of the moral faculties" in people who displayed "innate preternatural moral depravity." Rush further suggested that "there is probably an original defective organization in those parts of the body that are occupied by the moral faculties of the mind." Since Rush's day, there have been numerous advances in our understanding of the human brain and in our ability to measure its functioning. There is strong evidence that antisocial children, adolescents, and adults are impaired, relative to nonantisocial controls, in verbal ability and executive functioning (see Lynam & Henry, 2001, for a review). There is also some indication that antisocial individuals may be impaired in spatial functions, particularly at young ages.

### Verbal Ability

One of the most robust correlates of severe conduct problems is impaired verbal ability. Verbal deficits have been found in aggressive toddlers, conduct-disordered children, serious adolescent delinquents, and adult criminals. There have been at least six comprehensive reviews since the first by Prentice and Kelly in 1963; each review includes additional confirming studies (see Lynam & Henry, 2001). The finding of impaired verbal ability in antisocial persons continues to be replicated (e.g., Dery, Toupin, Pauze, Mercier, & Fortin, 1999; Dionne et al., 2003; Fergusson, Lynskey, & Horwood, 1996; Lahey et al., 1995; Lynam, Moffitt, &

Stouthamer-Loeber, 1993; Moffitt, Lynam, & Silva, 1994). Deficient verbal functioning has been found in studies using Verbal IQ tests as well as in those using standard neuropsychological tests.

The Dunedin Multidisciplinary Health and Development Study, a longitudinal study of a birth cohort of over 1,000 subjects who have been studied extensively from birth to age 27 through comprehensive, biannual assessments, has provided some of the strongest evidence. In addition to several biennial IQ assessments, the sample was administered a comprehensive neuropsychological assessment battery when participants were 13 years old. When Moffitt (1990) examined the developmental trajectories of boys with both conduct problems (CP) and hyperactive-impulsive-attention problems (HIA) and boys with only conduct problems or only HIA from age 3 to 15, the comorbid cases were found to have histories of extreme antisocial behavior that remained stable across this period. Their neuropsychological problems were as long-standing as their antisocial behavior. At ages 3 and 5, these boys had scored more than a standard deviation below the age-norm for boys on the Bayley and McCarthy tests of motor coordination; at each age (5, 7, 9, 11, and 13), these boys scored a more than .75 of a standard deviation below the age-norm for boys on verbal IQ (VIQ). Moffitt et al. (1994) demonstrated the ability of deficits in neuropsychological functioning at 13 to predict antisocial behavior in later adolescence. Whether antisocial behavior was measured with self-reports, police reports, or court reports, the poorer a boy's neuropsychological functioning at age 13, the more likely he was to have committed crimes at age 18. The strongest relations were obtained on the verbal and verbal memory factors of the test battery. Not only did scores on verbal and verbal memory factors relate to the early onset of offending, they also related to the persistence of offending across time. In an even more recent report, these same measures of verbal functioning distinguished LCP offenders from AL offenders, defined on the basis of antisocial behavior from ages 5 to 18 (Moffitt & Caspi, 2001).

The relation between poor verbal ability and the persistence of antisocial behavior has also been found among clinic-referred children. Lahey et al. (1995) examined factors related to the persistence of CD across 4 years in a relatively large, prospective study of clinic-referred boys. As expected, low VIQ was related to CD at Time 1. More important, low VIQ was related to the persistence of CD over time, particularly when VIQ was

considered in conjunction with a parental history of antisocial personality disorder (APD); only boys with above average VIQ and without a parental history of APD improved across time. Similarly, Farrington and Hawkins (1991) found that low VIQ at age 8 to 10 predicted persistence in crime after the 21st birthday ( $\phi = .23$ ), even after controlling for other predictors. It is important to note that the differences between antisocial and nonantisocial youth remain even after controlling for potential confounds, such as ethnicity (e.g., Lynam et al., 1993), socioeconomic status (e.g., Dery et al., 1999; Lynam et al., 1993, Moffitt, Gabrielli, Mednick, & Schulsinger, 1981), academic attainment (e.g., Denno, 1989; Lynam et al., 1993), test motivation (e.g., Lynam et al., 1993), and the differential detection of low-IQ delinquents (Moffitt & Silva, 1988a).

### *Executive Functions*

Antisocial behavior has been associated with deficiencies in the brain's self-control or executive functions, which include operations such as sustaining attention and concentration, abstract reasoning and concept formation, formulating goals, anticipating and planning, programming and initiating purposive sequences of behavior, and inhibiting unsuccessful, inappropriate, or impulsive behaviors. Evidence of the relation between executive deficits and antisocial behavior has been found among incarcerated subjects, among nonconduct-disordered subjects in laboratory situations, and among general-population samples.

Several studies that have applied batteries of formal tests of executive functions to delinquent subjects have shown that test scores discriminate between antisocial and nonantisocial children and adolescents (see Moffitt, 1990; Lynam & Henry, 2001, for reviews). Multivariate analyses of frontal lobe batteries, for example, the Wisconsin Card Sorting Task, Verbal Fluency, Trails B, Mazes, and the Rey Osterreith Complex Figure Test, with a general population sample in New Zealand (Moffitt & Henry, 1989) have demonstrated that a linear combination of these scores significantly discriminated self-reported early delinquents from nondelinquents. This effect was most robust among the delinquents with co-occurring HIA; differences between this comorbid group and nondisordered controls ranged from two-thirds to over one standard deviation and remained even after controlling for IQ.

Other studies, although not focusing specifically upon executive functions, have reported findings from

individual measures typically included in frontal lobe batteries. Berman and Siegal (1976) found that delinquents scored poorly on the Category Test and Trails B. Wolff, Waber, Bauermeister, Cohen, and Ferber (1982) reported delinquency-related impairments on tests of selective attention and on the Stroop Color-Word Test. A number of studies have shown delinquents to score poorly on various tests requiring sequencing of motor behavior (e.g., Brickman, McManus, Grapentine, & Alessi, 1984; Lueger & Gill, 1990).

Recently, several investigators have employed more sophisticated measures, such as the Self-Ordered Pointing (SOP; Petrides & Milner, 1982) task and the Conditional Association Task (CAT; Petrides, 1985), to investigate the relation between aggression and frontal lobe functions, particularly working memory. Positron emission topography studies have found that the SOP is specifically associated with the mid-dorsolateral frontal region, whereas the CAT is specifically associated with the posterior dorsolateral frontal region (Petrides, Alivisatos, Evans, & Meyer, 1993). Lau, Pihl, and Peterson (1995) found that poor performance on these two measures was associated with aggression in a laboratory setting. Giancola and Zeichner (1994) reported that performance on the CAT was associated with intensity of shocks administered to a fictitious opponent in a laboratory setting.

As was the case for verbal deficits, the evidence suggests that poor executive functioning may be especially characteristic of the most antisocial group: boys with symptoms of conduct problems and HIA. In the New Zealand study, adolescent boys who exhibited symptoms of both CD and HIA scored more poorly on neuropsychological tests of executive functions than their peers who had either CD or HIA alone (Moffitt & Henry, 1989; Moffitt & Silva, 1988b). In a companion study of executive functions and conduct problems in the Pittsburgh Youth Study (White et al., 1994), data were gathered on "self-control and impulsivity" using multiple tests and measures for 430 12-year-old boys. The impulsivity measures were strongly related to delinquency at two ages even after controlling for IQ and socioeconomic status; additionally, these measures were related to the 3-year longevity of antisocial behavior, even after controlling for initial levels of delinquency. In a separate study, Aronowitz et al. (1994) reported that adolescents with both CD and HIA performed more poorly on measures of executive function than did CD-only adolescents.

Longitudinal studies have demonstrated that executive function deficits are associated with the stability and continuity of conduct problems. Seguin, Pihl, Harden, Tremblay, and Boulerice (1995) found that boys who exhibited a stable pattern of aggression between the ages of 6 and 12 performed significantly more poorly on measures of executive functions than did unstable aggressive or nonaggressive boys. Seguin, Nagin, Assaad, and Tremblay (in press) have shown that deficits in working memory, an aspect of executive functioning, are most pronounced in adolescents who are consistently high in physical aggression and motoric hyperactivity.

Taken together, these studies suggest that neuropsychological dysfunctions that manifest themselves as poor scores on tests of self-control are linked with early onset and persistence of antisocial behavior. Additionally, the findings in regard to the group comorbid for HIA and CP are of considerable interest in light of evidence that the co-occurrence of CP and HIA may represent a distinct subtype of CD that is particularly severe and persistent and places the child at risk for serious antisocial behavior in adolescence and adulthood.

### *Spatial Deficits*

A few studies suggest that spatial deficits may also characterize severely antisocial children and adolescents, particularly at younger ages (Raine, Yaralian, Reynolds, & Venables, 2002). Dietz, Lavigne, Arend, and Rosenbaum (1997) found that both performance and VIQ were related to externalizing problems in a sample of 2- to 5-year-old children. In perhaps the most compelling report, Raine et al. (2002) examined the relation between verbal and spatial abilities at 3 years of age and antisocial behavior at ages 8 and 17. These authors found that early spatial, not verbal, deficits predicted later antisocial behavior, even after controlling for potential covariates including test behavior and social adversity.

### *Neuroimaging*

Researchers have employed methods that assess both the structural (e.g., computerized tomography, magnetic resonance imaging) and functional (e.g., positron emission tomography, single photon emission computed tomography) characteristics of the brains of antisocial individuals (for reviews, see Bassarath, 2001; Lynam & Henry, 2001). Almost all of these studies have been conducted with adults, using violent, aggressive, criminal, sexual, and/or psychopathic individuals. Results have

varied, but where significant findings do emerge, they generally involve dysfunction in the temporal and frontal regions among offenders, a pattern supportive of results found in studies using performance tests. For example, Raine, Lencz, Bihle, LaCasse, and Colletti (2000) employed structural magnetic resonance imaging in 21 community volunteers with APD and 2 control groups, one consisting of 27 men with substance dependence but without APD and one of 34 men with neither substance dependence nor APD. They found that the APD group had lower prefrontal volumes than both control groups. The few studies that have been conducted in children and adolescents are consistent with the findings among adults. For example, Lyoo, Lee, Jung, Noam, and Renshaw (2002) administered magnetic resonance imaging (MRI) assessments to over 400 children and adolescents with psychiatric disorders and found that the group with attention deficit disorder and CD had more severe levels of white matter signal hyperintensities in the frontal lobes than did controls.
