# *Preface to Handbook of Child Psychology, Sixth Edition*

WILLIAM DAMON

Scholarly handbooks play several key roles in their disciplines. First and foremost, they reflect recent changes in the field as well as classic works that have survived those changes. In this sense, all handbooks present their editors' and authors' best judgments about what is most important to know in the field at the time of publication. But many handbooks also influence the fields that they report on. Scholars—especially younger ones—look to them for sources of information and inspiration to guide their own work. While taking stock of the shape of its field, a handbook also shapes the stock of ideas that will define the field's future. It serves both as an indicator and as a generator, a pool of received knowledge and a pool for spawning new insight.

## THE HANDBOOK'S LIVING TRADITION

Within the field of human development, the *Handbook of Child Psychology* has served these key roles to a degree that has been exceptional even among the impressive panoply of the world's many distinguished scholarly handbooks. The *Handbook of Child Psychology* has had a widely heralded tradition as a beacon, organizer, and encyclopedia of developmental study for almost 75 years—a period that covers the vast majority of scientific work in this field.

It is impossible to imagine what the field would look like if it had not occurred to Carl Murchison in 1931 to assemble an eclectic assortment of contributions into the first *Handbook of Child Psychology*. Whether or not Murchison realized this potential (an interesting speculation in itself, given his visionary and ambitious nature), he gave birth to a seminal publishing project that

not only has endured over time but has evolved into a thriving tradition across a number of related academic disciplines.

All through its history, the *Handbook* has drawn on, and played a formative role in, the worldwide study of human development. What does the *Handbook's* history tell us about where we, as developmentalists, have been, what we have learned, and where we are going? What does it tell us about what has changed and what has remained the same in the questions that we ask, in the methods that we use, and in the theoretical ideas that we draw on in our quest to understand human development? By asking these questions, we follow the spirit of the science itself, for developmental questions may be asked about any endeavor, including the enterprise of studying human development. To best understand what this field has to tell us about human development, we must ask how the field itself has developed. In a field that examines continuities and changes, we must ask, for the field itself, what are the continuities and what are the changes?

The history of the *Handbook* is by no means the whole story of why the field is where it is today, but it is a fundamental part of the story. It has defined the choices that have determined the field's direction and has influenced the making of those choices. In this regard, the *Handbook's* history reveals much about the judgments and other human factors that shape a science.

## THE CAST OF CHARACTERS

Carl Murchison was a scholar/impresario who edited *The Psychological Register*; founded and edited key psychological journals; wrote books on social psychology,

politics, and the criminal mind; and compiled an assortment of handbooks, psychology texts, autobiographies of renowned psychologists, and even a book on psychic beliefs (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure research in the field of experimental psychology than is being spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion, of course, is from another era; it could furnish some good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time Murchison wrote the preface to his *Handbook*, developmental psychology was known only in Europe and in a few forward-looking American labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For his original 1931 *Handbook*, Murchison looked to Europe and to a handful of American centers (or "field stations") for child research (Iowa, Minnesota, the University of California at Berkeley, Columbia, Stanford, Yale, Clark). Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," quoted extensively from interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide American readers with an introduction to his seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on children's social behavior. In this chapter,

which still is fresh today, Bühler described intricate play and communication patterns among toddlers, patterns that developmental psychology would not rediscover until the late 1970s. Bühler also anticipated the critiques of Piaget that would appear during the sociolinguistics heyday of the 1970s:

Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social . . . that children from 3 to 7 years accompany all their manipulations with talk which actually is not so much intercourse as monologue . . . [but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Bühler, 1931, p. 138)

Other Europeans included Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development."

The Americans whom Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies, an enterprise that remains familiar to us today, and Stanford's Louis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character*, a notion that was to become lost to the field during the cognitive-developmental revolution, but that reemerged in the 1990s as the primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the views that Piaget, Levy-Bruhl, and other nascent "structuralists" had put forth concerning "animism" in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow animism.) Mead reported some data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or

inanimate objects” (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology’s ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead also offered a research guide for developmental fieldworkers in strange cultures, complete with methodological and practical advice, such as the following: Translate questions into native linguistic categories; don’t do controlled experiments; don’t do studies that require knowing ages of subjects, which are usually unknowable; and live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison assembled for the 1931 *Handbook of Child Psychology*, his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: “Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology*. This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor” (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already evolving.

Murchison saw fit to provide the following warning in his second edition: “There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience” (Murchison, 1933, p. vii). It is likely that sales of Murchison’s first volume did not approach textbook levels; perhaps he received negative comments regarding its accessibility.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison’s continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children’s drawings, and Gesell wrote a general statement of his maturational theory that went well beyond the twin studies.

But Murchison also made some abrupt changes. He dropped Anna Freud entirely, auguring the marginalization of psychoanalysis within academic psychology. Leonard Carmichael, who was later to play a pivotal role

in the *Handbook* tradition, made an appearance as author of a major chapter (by far the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual-manual functions during the first 2 years of life, and one on physiological “appetites” such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* more of a biological thrust, in keeping with Murchison’s long-standing desire to display the hard science backbone of the emerging field.

Leonard Carmichael was president of Tufts University when he organized Wiley’s first edition of the *Handbook*. The switch from a university press to the long-established commercial firm of John Wiley & Sons was commensurate with Carmichael’s well-known ambition; indeed, Carmichael’s effort was to become influential beyond anything that Murchison might have anticipated. The book (one volume at that time) was called the *Manual of Child Psychology*, in keeping with Carmichael’s intention of producing an “advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature” (Carmichael, 1946, p. viii).

The publication date was 1946, and Carmichael complained that “this book has been a difficult and expensive one to produce, especially under wartime conditions” (Carmichael, 1946, p. viii). Nevertheless, the project was worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to the 1954 second edition, “The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child” (Carmichael, 1954, p. vii).

Carmichael’s second edition had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of the third edition; it was called, improbably, *Carmichael’s Manual of Child Psychology*, even though it had a new editor and an entirely different cast of authors and advisors. Paul Mussen took over as the editor, and once again the project flourished. Now a two-volume set,

the third edition swept across the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The set became an essential source for graduate students and advanced scholars alike. Publishers referred to *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

The fourth edition, published in 1983, was now redesignated by John Wiley & Sons to become once again the *Handbook of Child Psychology*. By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as “the Mussen handbook.”

## WHAT CARMICHAEL CHOSE FOR THE NOW EMERGENT FIELD

Leonard Carmichael, who became Wiley's editor for the project in its now commercially funded and expanded versions (the 1946 and 1954 *Manuals*), made the following comments about where he looked for his all-important choices of content:

Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition*. (1946, p. viii)

Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition*, were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (1954, p. viii)

The first quote comes from Carmichael's preface to the 1946 edition, the second from his preface to the 1954 edition. We shall never know why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael's notice. Or perhaps 8 years of further adult development increased Carmichael's generosity of spirit. (It also may be possible that Murchison or his family com-

plained.) In any case, Carmichael acknowledged the roots of his *Manuals*, if not always their original editor. His choice to start with those roots is a revealing part of the *Handbook's* history, and it established a strong intellectual legacy for our present-day descendants of the early pioneers who wrote for the Murchison and Carmichael editions.

Although Leonard Carmichael took the 1946 *Manual* in much the same direction established by Murchison back in 1931 and 1933, he did bring it several steps further in that direction, added a few twists of his own, and dropped a couple of Murchison's bolder selections. Carmichael first appropriated five Murchison chapters on biological or experimental topics, such as physiological growth, scientific methods, and mental testing. He added three new biologically oriented chapters on animal infancy, physical growth, and motor and behavioral maturation (a tour de force by Myrtal McGraw that instantly made Gesell's chapter in the same volume obsolete). Then he commissioned Wayne Dennis to write an adolescence chapter that focused exclusively on physiological changes associated with puberty.

On the subject of social and cultural influences in development, Carmichael retained five of the Murchison chapters: two chapters on environmental forces on the child by Kurt Lewin and by Harold Jones, Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled “Character Development—An Objective Approach”), and Margaret Mead's chapter on “primitive” children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stayed with three other Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them. But Carmichael dropped Piaget and Bühler.

Carmichael's 1954 revision, his second and final edition, was very close in structure and content to the 1946 *Manual*. Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook*. Not surprisingly, the chapters that were closest to Carmichael's own interests got the most significant updating. Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet he still kept the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and

Vernon Jones, and he even went so far as to add one new chapter on social development by Harold and Gladys Anderson and one new chapter on emotional development by Arthur Jersild.

The Murchison and Carmichael volumes make for fascinating reading, even today. The perennial themes of the field were there from the start: the nature-nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow inextricably joined in the dynamic mix of human development.

These things have not changed. Yet, much in the early editions is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were written prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience*, *neuronal networks*, *behavior genetics*, *social cognition*, *dynamic systems*, and *positive youth development* were of course unknown. Even Mead's rendition of the "primitive child" stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's *cultural psychology*.

Most telling, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That, of course, is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

By 1970, the importance of theory for understanding human development had become apparent. Looking back

on Carmichael's last *Manual*, Paul Mussen wrote, "The 1954 edition of this *Manual* had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The Mussen 1970 edition—or *Carmichael's Manual*, as it was still called—had a new look and an almost entirely new set of contents. The two-volume edition carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset . . . that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn) and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in an ethological chapter by Eckhard Hess and a behavior genetics chapter by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next 3 decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He reappeared in the *Manual*, this time authoring a comprehensive (and, some say, definitive) statement of his entire theory, which now bore little resemblance to his 1931/1933 sortings of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek all gave major treatments to one or another aspect of Piaget's

body of work. Other approaches were represented as well. Herbert and Ann Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was soon to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the book's previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshback), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us in the new millennium.

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, a bit unruly but glorious in its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume *Mussen Handbook*, with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented by his 1970 piece, but his influence was on the wane throughout the other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. No return to dust bowl empiricism could be found anywhere in the set. Instead, a variety of classical and innovative ideas were coexisting: Ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none

quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

This brings us to the efforts under the present editorial team: the *Handbook's* fifth and sixth editions (but really the seventh and eighth editions, if the germinal two pre-Wiley Murchison editions are counted). I must leave it to future commentators to provide a critical summation of what we have done. The volume editors have offered introductory and/or concluding renditions of their own volumes. I will add to their efforts here only by stating the overall intent of our design and by commenting on some directions that our field has taken in the years from 1931 to 2006.

We approached our editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: "to provide," as Mussen wrote, "a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development" (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed "specifically for the scholar," as Murchison declared, and that it should have the character of an "advanced text," as Carmichael defined it. We expected, though, that our audiences may be more interdisciplinary than the readerships of previous editions, given the greater tendency of today's scholars to cross back and forth among fields such as psychology, cognitive science, neurobiology, history, linguistics, sociology, anthropology, education, and psychiatry. We also believed that research-oriented practitioners should be included under the rubric of the "scholars" for whom this *Handbook* was intended. To that end, for the first time in 1998 and again in the present edition, we devoted an entire volume to child psychology in practice.

Beyond these very general intentions, we have let chapters in the *Handbook's* fifth and sixth editions take their own shape. We solicited the chapters from authors who were widely acknowledged to be among the leading experts in their areas of the field, although we know that, given an entirely open-ended selection process and

no limits of budget, we would have invited a large number of other leading researchers whom we did not have the space—and thus the privilege—to include. With very few exceptions, every author whom we invited agreed to accept the challenge. Our only real, and great, sadness was to hear of the passing of several authors from the 1998 edition prior to our assembly of the present edition. Where possible, we arranged to have their collaborators revise and update their chapters.

Our directive to authors was simple: Convey your area of the field as you see it. From then on, the authors took center stage—with, of course, much constructive feedback from reviewers and volume editors. No one tried to impose a perspective, a preferred method of inquiry, or domain boundaries on any of the chapters. The authors expressed their views on what researchers in their areas attempt to accomplish, why they do so, how they go about it, what intellectual sources they draw on, what progress they have made, and what conclusions they have reached.

The result, in my opinion, is still more glorious profusion of the English garden genre, but perhaps contained a bit by some broad patterns that have emerged over the past decade. Powerful theoretical models and approaches—not quite unified theories, such as the three grand systems—have begun once again to organize much of the field's research and practice. There is great variety in these models and approaches, and each is drawing together significant clusters of work. Some have been only recently formulated, and some are combinations or modifications of classic theories that still have staying power.

Among the formidable models and approaches that the reader will find in this *Handbook* are the dynamic system theories, the life span and life course approaches, cognitive science and neuronal models, the behavior genetics approach, person-context interaction theories, action theories, cultural psychology, and a wide assortment of neo-Piagetian and neo-Vygotskian models. Although some of these models and approaches have been in the making for some time, they have now come into their own. Researchers are drawing on them directly, taking their implied assumptions and hypotheses seriously, using them with specificity and control, and exploiting their implications for practice.

Another pattern that emerges is a rediscovery and exploration of core processes in human development that had been underexamined by the generation of researchers just prior to the present one. Scientific interest

has a way of moving in alternating cycles (or spirals, for those who wish to capture the progressive nature of scientific development). In our time, developmental study has cycled away from classic topics such as motivation and learning—not in the sense that they were entirely forgotten, or that good work ceased to be done in such areas, but in the sense that they no longer were the most prominent subjects of theoretical reflection and debate. Some of the relative neglect was intentional, as scholars got caught up in controversies about whether psychological motivation was a “real” phenomenon worthy of study or whether learning could or should be distinguished from development in the first place. All this has changed. As the contents of our current edition attest, developmental science always returns, sooner or later, to concepts that are necessary for explaining the heart of its concerns, progressive change in individuals and social groups over time, and concepts such as learning and motivation are indispensable for this task. Among the exciting features of this *Handbook* edition are the advances it presents in theoretical and empirical work on these classic concepts.

The other concept that has met some resistance in recent years is the notion of development itself. For some social critics, the idea of progress, implicit in the notion of development, has seemed out of step with principles such as equality and cultural diversity. Some genuine benefits have accrued from that critique; for example, the field has worked to better appreciate diverse developmental pathways. But, like many critique positions, it led to excesses. For some, it became questionable to explore issues that lie at the heart of human development. Growth, advancement, positive change, achievement, and standards for improved performance and conduct, all were questioned as legitimate subjects of investigation.

Just as in the cases of learning and motivation, no doubt it was inevitable that the field's center of gravity sooner or later would return to broad concerns of development. The story of growth from infancy to adulthood is a developmental story of multifaceted learning, acquisitions of skills and knowledge, waxing powers of attention and memory, growing neuronal and other biological capacities, formations and transformations of character and personality, increases and reorganizations in the understanding of self and others, advances in emotional and behavioral regulation, progress in communicating and collaborating with others, and a host of other achievements documented in this edition. Parents, teachers, and

other adults in all parts of the world recognize and value such developmental achievements in children, although they do not always know how to understand them, let alone how to foster them.

The sorts of scientific findings that the *Handbook's* authors explicate in their chapters are needed to provide such understanding. The importance of sound scientific understanding has become especially clear in recent years, when news media broadcast story after story based on simplistic and biased popular speculations about the causes of human development. The careful and responsible discourse found in these chapters contrasts sharply with the typical news story about the role of parents, genes, or schools in children's growth and behavior. There is not much contest as to which source the public looks to for its information and stimulation. But the good news is that scientific truth usually works its way into the public mind over the long run. The way this works would make a good subject for developmental study some day, especially if such a study could find a way to speed up the process. In the meantime, readers of this edition of the *Handbook of Child Psychology* will find the most solid, insightful

and current set of scientific theories and findings available in the field today.

## *Preface to Volume Three*

### *Social, Emotional, and Personality Development*

NANCY EISENBERG

As for the fifth edition, this volume has been a labor of love. When I was a graduate student, we read many of the chapters from the 1970 edition of the *Mussen Handbook of Child Psychology* in our classes. Even then, in my mind it was the "bible" of the field. Moreover, my mentor was Paul Mussen, so I frequently borrowed one of his extra copies of the *Handbook*, and he gave me that copy as a gift when I graduated. When the 1983 edition of the *Handbook* was being prepared, I was fortunate as a young scholar to get to review a couple of chapters; in addition, I heard the occasional grumblings of Paul Mussen about the chapters that were late. At that time in my career it was my dream that I would someday get to contribute a chapter to the *Handbook*.

Thus, I was pleased and honored (as well as a little apprehensive) when I was asked to edit a volume of this very important set of books for the fifth edition, and now the sixth edition. Editing the volume has been an exceptional learning experience. I have had the privilege to work with some of the best people in the field and to read (and reread) a year or two before other people the very exciting work that is in this volume. I have learned much from my fellow contributors to the volume.

The contributors to this volume deserve much thanks. All of the people who were requested to contribute agreed to do so, and all of the chapters were completed. The authors spent tremendous energy and time constructing their very thoughtful and integrative chapters,

and then editing them to fit within the stringent space limitations and page restrictions. The contributors to this volume poured their souls into their chapters; I was fortunate to work with such a talented, cooperative, and personable group of people.

I also thank the many other people who made this volume possible. First and foremost, I thank my husband, Jerry Harris, for his continuing support throughout this and my other time-consuming projects. I also thank Richard Lerner for his assistance in dealing with administrative issues related to the volume. The senior editors, Richard Lerner and William Damon, allowed the volume editors to shape their own volumes, which I greatly appreciated. Numerous colleagues who critiqued the chapters in manuscript form also provided valuable insights and suggestions that enhanced the quality of the final product.

In addition, I thank my colleagues and students who shared their ideas with me in the course of this task. I also appreciate the financial support that I received over the last few years from the National Institutes of Mental Health and the National Institute of Drug Abuse. Finally, I thank Paul Mussen, my friend and mentor, who has provided me with intellectual and emotional support for approximately three decades. His death has left a hole in my life and that of many others. It has been a privilege and joy to carry on the tradition of the *Handbook* that he edited twice in his career, and I dedicate this book to him.

Contemporary Work on Regulation	8
The Development of Emotion-Related Regulation	9
Modes of Regulation	10

The sixth edition of the *Handbook of Child Psychology* was written approximately 8 years after the 1998 fifth edition. As was true for the last edition, the goal of the authors in this volume of the *Handbook* was to present state-of-the-art reviews of conceptual and empirical work on social, emotional, and personality development. Each author or set of authors has provided the reader with an integrative summary of the current status of an important topic within the domain of social and personality development and, to some degree, with a vision for the future. Although research on social, emotional, and personality development is a cumulative endeavor with few abrupt, dramatic changes in knowledge, the field does have a somewhat different look from 8 years ago, and differs greatly from that depicted in the fourth edition of the *Handbook* in 1983. In this chapter, I note some of the themes in this volume, with an eye to changes in themes in the past 20 or so years.

## **AN EMPHASIS ON PROCESS (MEDIATION) AND MODERATION**

As developmental psychologists have produced and accumulated more knowledge about the occurrence and frequency of variables of interest (e.g., descriptive data) as well as about relations among constructs (i.e., correlational data), they have begun to ask more complex questions than in the past. This trend is very evident in this volume of the *Handbook*, even more so than in the fifth edition (1998). For example, in addition to routinely questioning assumptions of directionality of causality, there is evidence in the chapters of an increased concern with *process*, as reflected in questions about mediation. Mediating processes are the processes underlying the relation between two variables (a predictor and a criterion). Mediators help clarify how or why a given relation occurs (Baron & Kenny, 1986; MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002).

---

Work on this chapter was supported by a grant from the National Institute of Mental Health. Thanks to Mary Rothbart

---

for her comments on a draft of this chapter and to Joseph Campos for his discussion with me of some of the ideas therein.

## 2 Introduction

In addition, based in part on the contemporary concern with context, diversity, biological substrates and predispositions, and indices of individual differences (see later discussion), there is considerable interest in moderating variables, that is, in variables such as sex, socioeconomic class, race/ethnicity, personality, prior socialization experiences, and type of situation that affect the direction or strength of the relation between an independent or predictor variable and a dependent or criterion variable (Baron & Kenny, 1986). To study moderation, investigators generally examine the interaction of the independent variable with the potential moderator (e.g., age, high or low level of regulation) when predicting an outcome or criterion variable or comparing the equivalence of structural models for different groups.

Mediating or moderating processes are discussed directly or indirectly by all chapter authors, but are a more central focus in some chapters. For example, in their discussion of relations of temperament to children's adjustment, Rothbart and Bates (Chapter 3, this *Handbook*, this volume) explicitly discuss two types of indirect relations: mediated linkage, as when temperament influences transactions with the environment, which, in turn, shape the child's developing adjustment, and moderated relations, as when temperament and some facet of the environment affect children's adjustment. Bugental and Grusec (Chapter 7, this *Handbook*, this volume) also explicitly emphasize moderation in the socialization process, and Dodge, Coie, and Lynam (Chapter 12, this *Handbook*, this volume) review studies of moderating effects, concluding that such research is essential for delineating the combinations of factors that predict antisocial behavior.

A few more specific examples of how authors discuss mediation and moderation illustrate the types of issues that are the focus of contemporary work in developmental psychology and related disciplines. First, consider mediation. Collins and Steinberg (Chapter 16, this *Handbook*, this volume) conclude that the impact of pubertal maturation on adolescent psychosocial development is more likely to be interpersonally mediated than due to the direct action of hormonal changes on mood or emotional functioning. Similarly, multiple authors note that the quality of relationships or social interactions likely mediates between distal environmental factors (e.g., economic resources, quality of the neighborhood), family structure, or social institutions and youths' adjustment and other socioemotional developmental outcomes (e.g., Dodge et al., Chapter 12; Parke & Buriel, Chapter 8; Thompson, Chapter 2, this *Handbook*, this volume). Harter (Chapter 9, this *Handbook*, this volume) argues for mediation by

others' approval of the relation between genes (as expressed, for example, in temperament or attractiveness) and self-esteem. Kagan and Fox (Chapter 4, this *Handbook*, this volume) discuss a number of biological systems that mediate between heredity or biological structures and psychological or behavioral responses, whereas Ruble, Martin, and Berenbaum (Chapter 14, this *Handbook*, this volume) note that genes and hormones are often viewed as proximal mediators of the effect of evolutionary forces on gender differences. Eisenberg, Fabes, and Spinrad (Chapter 11, this *Handbook*, this volume) present data indicating that sympathy at least partly mediates the relations between moral judgment or perspective taking and children's prosocial behavior, whereas children's regulation mediates the relation between parental expression of negative emotion in the family and children's sympathy. They also present a model in which a number of more proximal factors mediate the relations of more distal factors (e.g., biological factors, socialization, and antecedent sociocognitive and dispositional characteristics of the child) to prosocial behavior.

Mediation is invoked repeatedly in discussions of parenting, parent-child attachment, family variables, and developmental outcomes. After a review of the literature on attachment, Thompson calls for additional exploration of the mediators of the relations of attachment security to outcome variables. Rubin, Bukowski, and Parker (Chapter 10, this *Handbook*, this volume) present data indicating that lower levels of parental skill have been associated with higher levels of antisocial behavior and lower levels of academic performance, which in turn have been associated with higher levels of peer rejection. Dodge et al. (Chapter 12, this *Handbook*, this volume) discuss social-cognitive processes as mediators of the relations between parenting (e.g., abuse) and offsprings' externalizing behavior. They also argue that parenting is a mediator of the relation between the macrolevel variable of family poverty and children's aggression. Wigfield, Eccles, Schiefele, Roeser, and Davis-Kean (Chapter 15, this *Handbook*, this volume) suggest that a range of parental beliefs and practices mediate between family demographics and achievement-related outcomes. In their model, specific parental behaviors (e.g., time spent with the child, teaching strategies) at least partially mediate relations between parental general beliefs and behaviors (e.g., locus of control, gender-role stereotypes, parenting style) and children's outcomes (e.g., goals, persistence, performance). Bugental and Grusec (Chapter 7, this *Handbook*, this volume) examine a range of potential mediators in regard to the relation of socialization to developmental out-

comes, including children's acquired ways of cognitively representing their social worlds, hormones (and neurotransmitters) involved in children's responses to socialization experiences, and gene expression in the continuous reorganization of the brain in response to experience. Finally, Caspi and Shiner (Chapter 6, this *Handbook*, this volume) discuss a variety of mediating processes related to personality and note the need for further investigation of both the proximal relationship-specific processes that mediate personality effects on relationship outcomes and mediators (e.g., parental attributions) of the association between parental personality and parenting behavior. The list could go on and on; what is impressive is how mediating processes have become such a central focus in work on socioemotional development.

Moderational processes are also repeatedly emphasized in this volume. For example, Bugental and Grusec discuss the ways that parental goals serve to moderate parental behavior (including their affective responses) on different occasions, as well as the role of culture as a moderator of the relation between socialization experiences and children's development. Collins and Steinberg (Chapter 16, this *Handbook*, this volume) cite evidence indicating that the impact of puberty on psychological functioning is moderated by the social context in which adolescents mature. They also cite research indicating that aspects of parenting—for example, parenting style and parenting practices—may interact with one another in the prediction of outcome variables such as youths' adjustment. Numerous other authors in this volume review empirical interactions between children's temperament (e.g., emotionality or regulation) or personality and their parenting experiences in predicting children's behavior or socioemotional development (e.g., Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3; Thompson, Chapter 2, this *Handbook*, this volume). Components of temperament or personality may also interact with one another: For example, Eisenberg et al. (Chapter 11, this *Handbook*, this volume) summarize data indicating that the interaction of individual differences in emotionality and regulation predicts children's prosocial behavior and sympathy better than the consideration of only the main effects of these predictors.

Demographic characteristics that reflect diversity are other common moderators of predictors of developmental outcomes. Wigfield et al. (Chapter 15, this *Handbook*, this volume) suggest that competence-related beliefs and school performance may predict school performance for White but not African American children and that academic self-concept of ability is less predictive of general self-esteem for at least some African American children

than for White American children. Dodge et al. (Chapter 12, this *Handbook*, this volume) note that harsh discipline (but not abuse) is a predictor of later aggressive behavior for White but not African American children. Further, Ruble et al., Chapter 14, and Turiel and others, Chapter 13, this *Handbook*, this volume, discuss ways in which the sex of the child may moderate the effects of social experience on various social behaviors (although authors did not always use the term *moderation*). Thus, moderators that have received substantial attention include temperament/personality, children's sex, race, culture, and parenting style or support.

One moderator of the effects of the socializing environment that has received relatively little attention in the past is genetic differences between children. Recently, Caspi et al. (2002) reported such moderation for the long-term effects of maltreatment. Those children whose genotype resulted in high levels of MAOA (monoamine oxidase A, an enzyme that metabolizes neurotransmitters such as serotonin, and thus renders them inactive) were more likely than children without this genetic tendency to exhibit antisocial problems if they were maltreated (see Caspi & Shiner, Chapter 6, this *Handbook*, this volume). With the new wave of research on genes, neurotransmitters, and other biological factors, investigators are likely to obtain much more evidence of interactions between biological indices and environmental factors or experiences in the next decade (see Cadoret, Yates, Troughton, Woodworth, & Stewart, 1995). Such research, as well as research on interactions involving the kinds of variables already discussed, is producing a more differentiated understanding of “when” relations and processes occur—an issue that is an essential complement to the more basic mediational question of “why” relations occur (Parke, 2004). Moreover, as dynamical systems approaches become more popular, evidence of indirect, nonlinear relations among multiple variables is likely to be more common than at the present (e.g., Lewis, 2002).

## A FOCUS ON EMOTION

The fifth edition of the *Handbook* (1998) was the first to include a chapter dedicated solely to the topic of emotion (rather than the more general topic of socioemotional development in infancy). The neglect of emotion in prior editions is not surprising given the history of the study of emotion in psychology in the past 50 years. Due to the influence of behaviorism and then cognitive approaches in psychology, emotion was considered a nuisance variable (and something of no relevance) for many

## 4 Introduction

years. In the past 10 to 15 years, however, emotion has become central to the study of social development, as well as to many other topics in psychology.

The current emphasis on emotion is a dramatic departure from the previous view of emotions as intrapsychic events “which do not play a causal role in behavior and which are secondary by-products of more significant processes” (Campos, 1984, p. 148). Today emotions are viewed as motivational forces that play a role in much of our social behavior. As noted by Parke (1994), in contemporary psychology, emotions are viewed as “both products and processes of social interactions, relationships, and contexts” (p. 158).

The central role of emotion in contemporary developmental psychology is reflected in most of the chapters in this volume. This focus is, of course, most evident in Saarni, Campos, Camras, and Witherington’s chapter on emotional development (Chapter 5, this *Handbook*, this volume). Saarni et al. take a functionalist perspective in which emotion is closely linked to the context and what a person is trying to do. Emotion is viewed as synonymous with the significance of a person-event transaction for the individual.

Due to the immense body of work relevant to emotion, Saarni et al. (Chapter 5, this *Handbook*, this volume) limit their coverage, focusing primarily on the conceptualization of emotion, developmental changes in emotion and emotion communication, the role of culture in emotion in emotional development, and the components of emotional competence, their development, and their relations to adjustment and social competence. Saarni et al.’s review of this portion of the emotion literature demonstrates that children’s understanding of emotion and its expression, as well as children’s communication of, and coping with, emotion, change considerably with age. Moreover, emotional understanding and communication seem to have a profound influence on social interaction, although the relation between social interaction and these aspects of functioning is doubtlessly reciprocal. Saarni et al.’s review reflects major domains of interest in recent work on emotion and provides a contemporary, contextually oriented perspective on emotional development.

### Temperament, Personality, and Emotion

Emotion can be viewed in both situationally specific and dispositional terms. In theory and research on temperament and personality, enduring individual differ-

ences in reactivity are fundamental constructs; thus, dispositional emotional tendencies are salient topics in the two chapters that deal with temperament (Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3, this *Handbook*, this volume) and the chapter on personality (i.e., Caspi & Shiner, Chapter 6, this *Handbook*, this volume).

Temperament is defined by Rothbart and Bates as constitutionally based individual differences in reactivity and self-regulation. Reactivity includes emotional responding, both in regard to specific emotions (e.g., fear) and more general constructs of emotion (e.g., negative emotionality or emotional intensity; see Larsen & Diener, 1987; Rothbart & Bates, Chapter 2, this *Handbook*, this volume). Regulation pertains to the modulation of temperamental reactivity (Ahadi & Rothbart, 1994; Eisenberg, 2002; Rothbart & Derryberry, 1981). Research on temperament/personality, and hence on emotional reactivity and self-regulation, has increased greatly in volume in the past 1 to 2 decades.

Kagan and Fox (Chapter 4, this *Handbook*, this volume) view temperament as a “biologically based bias for correlated clusters of feelings, thoughts, and actions that appear during childhood, but not always in the opening months, and are sculpted by varied rearing environments into a large but still limited number of traits that comprise an individual’s personality profile.” Thus, like Rothbart and Bates (Chapter 3, this *Handbook*, this volume), they include emotion in their definition of temperament. However, they do not emphasize regulatory components of temperament to the same degree as Rothbart and Bates, and they tie dispositional biases to thought patterns (Rothbart & Bates view the content of thought as personality rather than temperament), as well as to actions.

Dispositional emotionality also plays an important role in concepts of personality. In fact, Caspi (1998) defined personality as “individual differences in the tendency to behave, think, and feel in certain consistent ways” (p. 312). Personality theorists often include in personality not only traits, but also personal concerns (i.e., a wide array of motivational, developmental, or strategic constructs that are contextualized in time, place, or role) and life stories (McAdams, 1995). As noted by Caspi and Shiner (Chapter 6, this *Handbook*, this volume), “personality is typically seen as including a wider range of individual differences in feeling, thinking, and behaving than is temperament.” Similarly, Kagan and Fox (Chapter 4, this *Handbook*, this volume) assert that, “the stable variation in behaviors and emotions observed in older children, ado-

lescents and adults are personality traits, not temperamental biases, although the latter make a contribution to the profile that emerges later in development.” Analogously, Rothbart and Bates (Chapter 3, this *Handbook*, this volume) note that, “Temperament represents the affective, activational, and attentional core of personality, whereas personality includes much more than temperament, particularly the content of thought, skills, habits, values, defenses, morals, beliefs, and social cognition. Social cognition includes the perception of the self, others, and the relation of self to objects, events, and others.”

Despite these definitional distinctions, as noted by Caspi and Shiner, there is a striking similarity between the constructs of temperament and personality. Both can be observed in animals (at least to some degree) as well as humans; both involve moderate genetic influence but are also affected by experience; and, importantly, “many traits from both domains are characterized by specific habitual positive and negative emotions” (Caspi & Shiner, Chapter 6, this *Handbook*, this volume). If we view temperament as representing the building blocks from which personality develops (Rothbart & Bates, Chapter 3, this *Handbook*, this volume), these similarities are not surprising.

Caspi and Shiner (Chapter 6, this *Handbook*, this volume; Caspi, 1998), as well as Rothbart and Bates (Chapter 3, this *Handbook*, this volume), speculate on how aspects of temperament in childhood are linked to the structure of adult personality (i.e., aspects of the “big five” components of personality). For example, temperamental negative emotionality is believed to contribute to the personality construct of neuroticism and agreeableness (inversely related) whereas temperamental positive affect or surgency (and sociability) are associated with agreeableness and extraversion in adults. In addition, aspects of temperament believed to be involved in the regulation or control of emotionality and emotionally driven behavior have been linked to personality. For example, temperamental behavioral inhibition (see Kagan & Fox, Chapter 4, this *Handbook*, this volume) is viewed as related to adult neuroticism and low levels of extraversion (Caspi & Shiner, Chapter 6, this *Handbook*, this volume). Moreover, temperamental attentional regulation and inhibitory control likely contribute to the adult personality characteristic of constraint, and perhaps also agreeableness (although the latter may also have a more proximal temperamental correlate in childhood; see Rothbart & Bates, Chapter 3, this *Handbook*, this volume).

## Emotion and Social Behavior

In addition to playing a role in later personality, and consistent with much of the review in the Saarni et al.’s Chapter 5 (this *Handbook*, this volume) on emotion, individual differences in temperamental emotionality, including directly experienced negative emotions such as anger and vicariously induced emotion (e.g., sympathy or empathy), frequently have been found to predict variation among children in socioemotional development (see Dodge et al., Chapter 12; Eisenberg et al., Chapter 11; Turiel, Chapter 13, this *Handbook*, this volume). For example, to a much greater degree than 8 years ago, there is empirical support for relations between dispositional emotionality—irritability/anger, fearfulness, and positive emotionality—and social competence or adjustment, including internalizing and externalizing problem behavior (see Caspi & Shiner, Chapter 6; Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3, this *Handbook*, this volume). Moreover, much more often than a decade ago, investigators are identifying distinct relations between different types of negative emotions (e.g., anger versus anxiety or sadness, fear of novelty versus fear of strangers) and the prediction of specific internalizing and externalizing problems or related psychological problems (e.g., Eisenberg et al., 2001, 2005; Rothbart & Bates, Chapter 3, this *Handbook*, this volume).

Ruble et al. (Chapter 10, this *Handbook*, this volume) noted an increased focus on emotion in the peer literature since the fifth edition of the *Handbook*. They list among topics recently introduced to the discipline the relation of jealousy and other emotional processes to the maintenance and dissolution of peer relationships. Dispositional emotionality clearly plays a role in the quality of social functioning in peer interactions and relationships; for example, emotional reactivity has been linked to social withdrawal (Rubin et al., Chapter 10, this *Handbook*, this volume; Spinrad et al., 2004), as well as information processing in social encounters, although there is relatively little research on the latter issue (see Arsenio & Lemerise, 2004; Crick & Dodge, 1994). Researchers have found that cheerful children appear to be relatively popular, whereas children prone to intense negative emotions are lower in social status (see Rubin et al., Chapter 10, this *Handbook*, this volume). Relations between peer interactions/relationships and emotion no doubt are reciprocal; as noted by Rubin et al. (Chapter 10, this *Handbook*, this volume), experiences with peers affect social, emotional, and cognitive

functioning beyond the influences of family, school, and neighborhood.

Contextually specific emotional reactions, in addition to dispositional emotionality, are seen as playing a major role in peer and other types of relationships. Rubin et al. (Chapter 10, this *Handbook*, this volume) define *relationships* as referring to the meanings, expectations, and emotions that derive from a succession of interactions between two individuals known to each other. As noted by Thompson (Chapter 2, this *Handbook*, this volume), “Emotion is a more salient feature of social interaction compared to most encounters with objects—including the emotions that precede social interaction and the changes in emotions that arise from interactive activity.” Thompson also notes that differences in attachment security are believed to affect early emotional development and the style of young children’s emotion regulation, and that these emerging aspects of the individual influence children’s social, emotional, and personality development in subsequent years. Thus, social relationships are affected by dispositional differences in emotionality as well as by emotions experienced when interacting with others, and the quality of social relationships with parents, peers, and others contribute to emerging individual differences in situational and dispositional emotionality.

### Emotion, the Self, and Goals

Emotion is also an integral aspect of conceptions of the self. For example, low self-esteem seems to be highly related to feelings of depression and hopelessness (Harter, Chapter 9, this *Handbook*, this volume). Moreover, emotions tied to attachment status (e.g., Kochanska, 2001) may affect children’s self-esteem and working model of the self in relation to others. In addition, young children’s understanding of emotion (e.g., identification of emotions, knowing when various emotions are likely to occur) is viewed by both Harter and Thompson (Chapter 2, this *Handbook*, this volume) as affecting the child’s construction of the self.

In the 1998 edition of this volume, Eccles, Wigfield, and Schiefele concluded that the highest priority in the research on achievement was closer consideration of the influence of emotion on motivation. Although there is more work on this issue than a decade ago, there is not as much as one might expect. Nonetheless, as noted by Wigfield et al. (Chapter 15, this *Handbook*, this volume), emotional development plays a role in some theories regarding individual differences (and likely de-

velopmental change) in achievement-related beliefs, values, and goals. Success and failure are associated with emotional reactions; level of anxiety can affect performance; and emotion-related self-evaluations play a role in achievement-related behavior and vice versa. For example, high levels of trait-like intrinsic motivation appear to foster positive emotional experience and well-being (Ryan & Deci, 2000), as well as self-esteem (Ryan, Connell, & Deci, 1985). Wigfield et al. (Chapter 15, this *Handbook*, this volume) note that there has been increasing interest recently in the research on relations between motivation and affect, and they expect the volume of work on this topic to increase.

### Emotion and Morality

The role of emotion in the study of morality has varied greatly as a function of the conception of morality. In Kohlbergian work on moral reasoning, emotion traditionally plays a minor role in comparison to cognition (see Kohlberg, 1984; Rest, 1983). In contrast, emotions such as empathy-related reactions or guilt have been highlighted in some work on moral *behavior*, including theory and research on prosocial tendencies (e.g., Eisenberg & Fabes, 1990; Eisenberg et al., Chapter 11, this *Handbook*, this volume; Hoffman, 2000), feelings of guilt (Saarni et al., Chapter 5; Thompson, Chapter 2, this *Handbook*, this volume; Zahn-Waxler & Kochanska, 1990), and conscience (Thompson, Chapter 2, this *Handbook*, this volume). For example, in work on prosocial behavior, both enduring tendencies toward experiencing moral emotions (i.e., dispositional sympathy) and situational emotional reactions (e.g., situational sympathy or guilt) are viewed as motivating altruistic action (see Eisenberg et al., Chapter 11, this *Handbook*, this volume). And in recent work, emotional reactions such as guilt and empathy are one of two components of conscience (Aksan & Kochanska, 2005).

Some contemporary theorists, including Wilson (1993), assume that there is a biologically based emotional basis to morality (see Turiel, Chapter 13, this *Handbook*, this volume). According to Kagan (1984), moral principles are determined by the intensity of the community’s affective reactions to the specific content of the principle. Turiel recognizes the importance of emotion in morality, but also emphasizes cognition more than theorists such as Hoffman, Kagan, and Shweder, concluding, as he did in 1998, “As important as are emotions—especially sympathy, empathy, and respect—for moral functioning, emotions occur in and among persons

who can think about them with regard to other people and in relation to complicated social agendas, goals, and arrangements. The relationships among emotions, moral judgments, reflections, and deliberations require a great deal of attention in research and in theoretical formulations.” Thus, the magnitude of the role of emotion in morality is still an issue of discussion.

### Sex and Emotion

In the past decade, investigators have not examined sex differences in measures of emotional functioning as much as might be expected. As one might expect, there are sex differences in the emotions that boys and girls tend to display—for example, girls tend to display more sadness, fear, shame, and guilt (Eisenberg, Martin, & Fabes, 1996; Ruble et al., Chapter 14, this *Handbook*, this volume)—although little is known about the degree to which boys and girls differ in internally experienced emotion (albeit adolescent girls report more anxiety and depression than do boys). Nonetheless, gender differences in the degree or type of expression of anger and frustration may be a factor in the gender difference in children’s externalizing behavior and aggression (see Dodge et al., Chapter 12, this *Handbook*, this volume). Findings regarding gender differences in empathy or sympathy are weaker, although some measures favor females (Eisenberg et al., Chapter 11, this *Handbook*, this volume). Guilt is another emotion that girls likely experience more than boys; if this is true, there are implications for both the development of conscience and for children’s adjustment (see Zahn-Waxler & Robinson, 1995). In addition, there is evidence that females are better at expressing and decoding emotions than are males (Ruble et al., Chapter 14, this *Handbook*, this volume), which has implications for gender differences in social communication and skills. Because of the centrality of emotion in recent research and theory on the quality of children’s social functioning, it is likely that investigators will attend more to gender differences in the experience and expression of emotion in the near future.

### Emotion in Socialization and the Socialization of Emotion

Socialization is an area of study in which emotion has received increased attention in recent years (Parke & Buriel, Chapter 8, this *Handbook*, this volume). As noted by Parke and Buriel (1998), affect played a relatively minor role in socialization theories until the recent past.

Until the 1980s, affect was discussed primarily in regard to the degree of warmth, support, and harmony versus conflict or hostility in the parent-child relationship or expressed in parents’ “parenting style” (see Collins & Steinberg, Chapter 16, this *Handbook*, this volume). In contrast, the topic of affect/emotion permeates contemporary work on socialization, far beyond the emotional tone of parents’ interactions with their children.

Before highlighting some of the recently emerging topics in regard to emotion and socialization, it is noteworthy that nearly every chapter in this volume contains some discussion of the relation of the emotional climate in the home and/or school—that is, between parents and children, teachers and children, and/or between parents—to children’s social, emotional, or achievement-related development. Most authors of the chapters have noted that the emotional tone of the relationship between the socializing adult and a child is associated with the quality of children’s social behavior (e.g., social competence, prosocial and aggressive behavior, peer interactions), their conceptions of self and emotional autonomy, the quality of their interpersonal relationships, their academic-related outcomes, or their adjustment (e.g., chapters by Bugental & Grusec; Collins & Steinberg; Dodge et al.; Eisenberg et al.; Parke & Buriel; Rubin et al.; and Thompson, this *Handbook*, this volume). Indeed, one of the more consistent findings across domains of socioemotional development is the importance of supportive, positive (versus hostile) relationships with socializing adults for children’s healthy development. Although this is an old topic of study, investigators are still delineating the many ways in which the emotional tone of relationships with other people may affect the course of children’s development.

According to Bugental and Grusec (Chapter 7, this *Handbook*, this volume), emotion is one outcome of socialization: “it [socialization] includes their [children’s] ability and motivation to acquire individual and culturally shared competencies at a social, emotional, and cognitive level.” Thus, in addition to providing an emotional context for socialization, socialization-related interactions are believed to affect the valence and degree of emotionality, in part through influencing children’s felt security and attachment, conceptions of the self, and the associations, interpretations, and attributions they make regarding people, contexts, and events in their lives.

In addition, Bugental and Grusec (Chapter 7, this *Handbook*, this volume) suggest that emotion affects a variety of cognitive processes fundamental to the socialization process, including attentional focus, memory

retrieval, appraisal and response selection, and the capacity for rational or reflective processing. These processes affect, for example, children's responses to socialization attempts and parents' reactions to their children's negative behaviors. Bugental and Grusec's conception of the role of emotion in socialization is more complex, multilayered, and encompassing than in most existing theory.

It is no surprise that emotion plays a central role in both biologically oriented and culturally oriented socialization theories. In biologically-based theories, affect and emotion are conceptualized as basic processes to be regulated, as regulators of relationships (e.g., attachment relationships), or as consequences of socializing relationships. One relatively recent focus has been the long-term influences of socialization practices on the regulation (or dysregulation) of the child's neurohormonal responses, which often co-occur with emotional experience and are part of emotional responses. Emotional processes are also viewed as functional regulators of other processes central to socialization (see Bugental & Grusec, Chapter 7, this *Handbook*, this volume).

In recent sociocultural perspectives, the expression, experience, interpretation, and naming of emotions are derived, at least in part, from the culture (see Bugental & Grusec, Chapter 7, this *Handbook*, this volume; Kitayama & Markus, 1994; Saarni et al., Chapter 5, this *Handbook*, this volume). Thus, socialization by the culture influences emotional reactions, as well as a range of social behaviors. Saarni et al. illustrate this point in their discussion of "how emotion communication accompanies and helps to inculcate cultural values, affects pre- and perinatal emotionality, determines the types of events to which an infant or child is exposed, and creates the 'emotional climate' within which a person is immersed." As a consequence of the recent increased awareness of cultural contributions to emotional experience and expression, a number of our current conceptions of emotional development are likely to be challenged (see the discussion of culture that follows).

In summary, in the past 2 decades, the topic of emotion has moved to center stage in the study of social and personality development. This surge of interest in emotion has been accompanied by, and perhaps is related causally to, elevated interest in biological inputs to development and temperament. In addition, contemporary concern with culture and context has had a powerful influence on thinking about emotional development.

## A FOCUS ON REGULATION

Because emotional experience and expression often involve regulation (or the lack thereof), contemporary discussion and research on emotion regulation also have been revitalized. Until the early 1990s, popular approaches to the topic of regulation included emphases on parental control and discipline; children's compliance, delay of gratification, and resistance to temptation; children's internalization of societal values regarding behaviors such as aggression and prosocial behavior; and the role of fear, anxiety, and guilt in fostering internalization or at least compliance (e.g., Hoffman, 1970, 1983; Maccoby & Martin, 1983; see Dodge et al., Chapter 12; Eisenberg et al., Chapter 11; Turiel, Chapter 13, this *Handbook*, this volume). Although there is still considerable interest in these topics, in recent years investigators concerned with regulatory processes also have focused on mechanisms by which children regulate their emotion and emotion-driven behavior, and the relation of individual differences in regulation to social competence and adjustment. Even though children's regulation was clearly an important emerging topic in the fifth edition of the *Handbook* (1998), more authors discuss this topic in this edition of the *Handbook*, and in considerably greater depth. Perhaps this is because many view the regulation of emotion, as much as the emotion itself, as related to quality of social behavior and relationships (Rubin et al., Chapter 10; Saarni et al., Chapter 5, this *Handbook*, this volume).

## Contemporary Work on Regulation

Contemporary thinking on the aforementioned topics has diverse origins in the discipline. The work of the Blocks (Block & Block, 1980) on ego control has had an important impact on this topic of study. Also important is work by temperament theorists on constructs such as attentional control (e.g., the ability to shift and focus attention), impulsivity, and effortful control (i.e., superordinate self-regulatory systems that can assert control over the reactive and self-regulatory processes of other temperament systems; Rothbart, Ahadi, Hershey, & Fisher, 2001; Rothbart & Rueda, 2005). Similarly, mechanisms for adaptation discussed by coping theorists (e.g., Carver, Scheier, & Weintraub, 1989; Lazarus & Folkman, 1984) for decades can be viewed as modes of dealing with, or regulating, emotion and behavior in stressful contexts. In addition, some of the

adult personality work on constructs such as constraint or conscientiousness (Caspi & Shiner, Chapter 6, this *Handbook*, this volume) is relevant to developmental scientists interested in regulatory processes.

Self-regulation is discussed, in one form or another, in most of the chapters in this volume. For example, Kagan and Fox (Chapter 4, this *Handbook*, this volume), as well as Rothbart and Bates (Chapter 3, this *Handbook*, this volume), discuss the temperamental (including physiological) basis of regulation of reactivity; in addition, Rothbart and Bates emphasize the attentional basis of some forms of self-regulation and review parts of the growing literature pertaining to the relations of temperamental regulation to adjustment. Caspi and Shiner (Chapter 5, *Handbook*, this volume) note that constraint is a component of all contemporary systems of personality, and highlighted the role of temperamental regulation in the emergence of personality traits such as constraint (or conscientiousness) and neuroticism. Saarni et al. focus on social communicative mechanisms used by infants to regulate their behavior (e.g., social referencing), as well as on the relation of emotion regulation to adjustment, coping, and emotional competence. They also discuss emotion and language as regulators of behavior.

Thompson (Chapter 2, *Handbook*, this volume) reviews the early development of self-regulation, whereas Rubin et al. (Chapter 10, this *Handbook*, this volume) summarized literature on the role of self-regulation in peer competence. The latter also note that peer interactions, especially friendships, provide opportunities to develop and use emotion regulation capacities. In addition, Dodge et al. (Chapter 12, this *Handbook*, this volume) discuss the role of children's emerging regulatory abilities in age-related changes in aggression; they also note the association of individual differences in children's aggression with problems in emotion regulation, attentional deficits, and impulsivity. Similarly, Eisenberg et al. (Chapter 11, this *Handbook*, this volume) report findings consistent with the view that regulatory processes are intimately involved in the vicariously induced emotions of sympathy and personal distress, as well as in the performance of prosocial behavior. Further, Wigfield et al. (Chapter 15, this *Handbook*, this volume) consider links between motivation and self-regulation and how motivation is translated into regulated behavior. They also discuss the importance of internally (versus externally) regulated motivation and behavior in the

achievement of goals and learning, as well as academic performance.

Bugental and Grusec (Chapter 7, this *Handbook*, this volume), Parke and Buriel (Chapter 8, this *Handbook*, this volume), Dodge and Coie (Chapter 12, this *Handbook*, this volume), and Collins and Steinberg (Chapter 16, this *Handbook*, this volume) focus, to varying degrees, on the socialization correlates of the development of children's self-regulation—a topic that has flourished in the past decade. For example, Bugental and Grusec note the increasing interest in the long-term effects of socialization practices on the regulation (or dysregulation) of the child's neurohormonal responses. They, as well as other authors (e.g., Collins & Steinberg, Chapter 16; Thompson, Chapter 2, this *Handbook*, this volume; also see "A Focus on Relationships" that follows), discuss the co-regulation of the protective care (attachment) system by parent and offspring. This protective care relationship (especially parental warmth), in turn, is viewed as facilitating the acquisition of self-regulation skills. Moreover, Bugental and Grusec briefly discuss socialization practices and behaviors most associated with children's autonomous regulation. In addition, Parke and Buriel review literature on the potential role of emotional and attentional regulation as mediators between parenting and child outcomes and the likely mutual causal relations between socialization experiences and individual differences in children's regulation.

### The Development of Emotion-Related Regulation

Based on the literature reviewed in various chapters (e.g., Saarni et al., Chapter 5; and Thompson, Chapter 2, this *Handbook*, this volume), several developmental trends in emotion-related regulation are evident (also see Eisenberg & Morris, 2002; Thompson, 1994; Walden & Smith, 1997). First, with increasing age in early infancy and childhood, regulation of emotion and behavior is shifted gradually from external sources in the social world (e.g., socializers) to self-initiated, internal (i.e., child-based) resources. Caregivers soothe young children, manage young children's emotion by selecting the situations they are in, and provide children with information (e.g., facial cues, narratives) to help the child interpret events (Thompson, Chapter 2, this *Handbook*, this volume). With age and cognitive development, children are better able to manage emotion themselves. Second, mentalistic strategies for emotion regulation, such as thinking

about situations in a positive light, cognitive avoidance, and shifting and focusing attention, increase with use in age. The use of such strategies is probably facilitated by the development of children's understanding of emotion, including the factors that elicit, maintain, and modulate emotion, as well as by other cognitive advances and physical changes. Third, with greater maturity, children develop greater capacity to modulate the course of their physiological and emotional arousal, for example, the intensity and duration of arousal, an ability that would be expected to have dramatic effects on behavior (e.g., aggression, venting of emotion, emotional expression). Fourth, with age, individuals likely become more adept at selecting, managing, and construing situations and relationships in a manner that minimizes the need to deal with negative emotions and stress (Carstensen, 1991; see Saarni et al., Chapter 5, this *Handbook*, this volume). Fifth, the ability to match strategies with the nature of stressors appears to improve with development. Thus, children improve in the ability to select appropriate coping solutions for everyday problems. Moreover, children appear to become better at distinguishing between stressors that can be controlled and those that cannot, and at choosing the most effective strategies for these stressors (e.g., emotion-management strategies such as blunting or cognitive distraction in uncontrollable contexts; see Saarni et al., Chapter 5, this *Handbook*, this volume). These developmental changes are likely to impact development in many aspects of social, emotional, and academic functioning.

Neurological changes, especially in the prefrontal cortex and cingulate gyrus, likely account for some of the age-related changes in self-regulation and executive attention (see Rothbart & Bates, Chapter 3; Thompson, Chapter 2, this *Handbook*, this volume). A topic of recent interest has been the continued growth and change in multiple regions of the prefrontal cortex throughout the course of adolescence, especially with respect to processes of myelination and synaptic pruning (both of which increase the efficiency of information processing; see Collins & Steinberg, Chapter 14, this *Handbook*, this volume). These changes are believed to underlie improvements in executive functioning (long-term planning, metacognition, self-evaluation, and the coordination of affect and cognition; Keating, 2004), which plays a central role in self-regulation. Research on the neurological bases of self-regulation is clearly an important emerging area of work.

## Modes of Regulation

Conceptual issues or empirical data related to different types of regulation or control were not discussed much in the 1998 *Handbook* (except in this introduction), and Rothbart and Bates note that this state of affairs has changed. Numerous authors at least address implicitly or explicitly, several types of children's regulatory/control capacities, including the regulation of attention, physiology, or behavior, as well as the social context. For example, in the discussion of temperament and/or personality (e.g., Caspi & Shiner, Chapter 6; Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3, this *Handbook*, this volume), authors review findings related to the abilities to effortfully manage attention and to effortfully activate or inhibit behavior as needed when necessary, especially when one is not inclined to do so. Developmental theorists frequently have highlighted constructs such as inhibitory control, self-regulation, constraint, and ego control, which involve the ability to modulate the behavioral expression of impulses and feelings (e.g., Block & Block, 1980; Kopp, 1982; Pulkkinen, 1982; Rothbart et al., 2001), and such abilities are addressed in numerous chapters in discussion of their relations to adjustment and social competence (e.g., Caspi & Shiner, Chapter 6; Dodge et al., Chapter 12; Rothbart & Bates, Chapter 3; Saarni et al., Chapter 5, this *Handbook*, this volume).

Another type of regulation—managing or regulating the stressful situation that elicited the emotional arousal—has been discussed primarily by coping theorists, who view problem-focused coping (efforts to modify the source of the problem) as an important type of coping (Lazarus & Folkman, 1984). This type of regulation generally includes planning and direct problem solving or instrumental coping in response to the experience of emotion. In addition, people often proactively manage situations to reduce exposure to stress and negative emotion in the future (Aspinwall & Taylor, 1997; Carstensen, 1991). An example is when socially anxious individuals choose not to attend social events that elicit discomfort. Unfortunately, few investigators have examined children's efforts to proactively shape or select their experiences; this remains an important gap in our knowledge.

Appropriate regulation depends, in part, on the particular context. Effective emotion-related regulation is viewed as flexible and relevant to one's goals (Cole, Michel, & Teti, 1994; Eisenberg & Morris, 2002). For

example, appropriate expression of emotion depends on the situation, and a person skilled in regulation adjusts his or her behavior accordingly. Moreover, it is important to differentiate between regulation and how it is measured. If regulation is operationalized as control or inhibition of behavior, particularly high levels are likely to be maladaptive (Block & Block, 1980). For example, some children appear to be highly inhibited temperamentally; these children are prone to fears, negative affect, avoidant behavior, and social withdrawal (see Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3, this *Handbook*, this volume), and are more likely than other children to develop anxiety disorders in adulthood (Rosenbaum et al., 1993). We (and, to some degree, Rothbart & Bates, 1998, Chapter 3, this *Handbook*, this volume) have argued that it is important to differentiate between control (i.e., inhibition) that is more effortfully managed and that which is somewhat involuntary and, hence, often rigid and extreme so that only the former should be labeled as *self-regulation* (e.g., Eisenberg & Spinrad, 2004; Eisenberg et al., 2004). In reality, the degree to which various control processes are effortful or not may usually vary on a continuum rather than categorically. Moreover, this distinction may not be as useful in regard to physiological regulation, although physiological processes related to emotion sometimes can be modulated by effortful processes (e.g., focusing attention away from a distressing event, thought, or person) and vagal processes may be involved in effortful regulation (see Rothbart & Bates, Chapter 3, this *Handbook*, this volume).

One important reason for differentiating between more effortful and less voluntary aspects of control or regulation is that they may be combined in various ways that seem to be associated with different types of behavior in children (Eisenberg & Morris, 2002). For example, early in elementary school, externalizing problems have been linked to low levels of effortful attentional control and inhibitory control, as well as with reactive undercontrol (impulsivity). In contrast, younger children with internalizing behavior problems (not comorbid with externalizing) tend to be low in effortful attentional but not inhibitory control, and high on less voluntary overcontrol (e.g., very low in impulsivity; Eisenberg et al., 2001; also see Caspi, 2000; Caspi & Shiner, Chapter 6, this *Handbook*, this volume). As children move through elementary school, however, internalizing problems may no longer be linked to deficits in attentional control (Eisenberg et al., 2005). In contrast, children who are

well adjusted tend to be high in attentional and inhibitory effortful control and moderate in impulsivity (Eisenberg et al., 2001, 2005).

In summary, a recent theme in the developmental literature has been on multidimensional, emotion-related conceptions of regulation. This work is a natural accompaniment to the current emphasis on emotion and temperament, as well as the concern with adjustment, stress, and coping in the larger domain of psychology. However, as is noted by Collins and Steinberg (Chapter 16, this *Handbook*, this volume), the issues of both emotional development and self-regulation have attracted only tangential attention from adolescence researchers. Thus, the role of various aspects of regulation and control in healthy and maladaptive adolescent development is a natural area for future investigation.

## A FOCUS ON COGNITION

Another trend in developmental psychology in recent years has been increased links between work on cognition with theory and empirical research on emotion and social behavior (Parke, 2004). Cognition plays an obvious and fundamental role in most aspects of emotional and social functioning. Saarni et al. (Chapter 5, this *Handbook*, this volume) review the early emergence of a cognitive understanding of facial expressions and others' emotions (e.g., social referencing). They also provide many examples of how cognitive advances in infancy and early childhood are reflected in emotion-related capabilities. For example, they note a number of competencies the child needs to be emotionally competent, including the following that involve social-cognitive skills: (a) awareness of one's own emotional state; (b) the ability to discern and understand others' emotions; (c) skill in using the vocabulary of emotion and expression terms commonly available in one's subculture and at more mature levels skill in acquiring cultural scripts that link emotion with social roles; (d) the capacity for empathy and sympathy (which involves some understanding of others' emotional states); (e) understanding that inner emotional state need not correspond to outer expression and that one's emotional-expressive behavior may impact on another; and (f) awareness that the structure or nature of relationships is in large part defined by how emotions are communicated within the relationship. Related skills discussed by authors in this volume include the abilities to comprehend and take into account unique information

about others' internal states (intentions, emotions, motivations, cognitions), to analyze elements of a social context and the consequences of various modes of action, and to devise appropriate cognitive strategies for sensitive social interaction in relationships, management of aggressive impulses, and altruistic behavior (Dodge et al., Chapter 12; Eisenberg et al., Chapter 11; and Rubin et al., Chapter 10, this *Handbook*, this volume).

In addition, conceptions of the self are in large part cognitive constructions, although they also are imbued with emotion (Harter, Chapter 9, this *Handbook*, this volume). In fact, Harter argued that developmental achievements in understanding others' behaviors and cognitions (e.g., how others view the self), as well as emotional processes, underlie age-related changes in self-conceptions. Similarly Thompson (Chapter 2, this *Handbook*, this volume) argues that a host of cognitive skills underlie the early emergence of the self and the understanding of self in relation to others.

In his chapter on moral development, Turiel (Chapter 13, this *Handbook*, this volume) discusses a range of ways in which cognitions are integral to moral thinking. For example, cognition obviously is critical for differentiating moral from nonmoral (e.g., conventional and personal) concerns, in constructing conceptions about morality, in analyzing information about elements in a specific morally relevant situation, and in making morally relevant decisions based on situational information and values, beliefs, and goals. As is evident from the passage from Turiel's chapter quoted earlier, he argues that cognition is central to moral development.

In his discussion of early socioemotional development, Thompson (Chapter 2, this *Handbook*, this volume) reviews some of the ways in which young children's working models of attachment figures and relationships are modified with the growth of understanding of psychological processes (e.g., work on the theory of mind). Individuals' working models of relationships, which have a cognitive as well as an affective component, are expected to influence relationships not only in childhood (also see Rubin et al., Chapter 10, this *Handbook*, this volume), but later in life (Main, Kaplan, & Cassidy, 1985; see Collins & Steinberg, Chapter 16, this *Handbook*, this volume). In addition, Collins and Steinberg discuss cognitive and sociocognitive changes in adolescence—for example, in executive attention, decision-making processes, problem solving, abstract reasoning, and perspective taking—that are relevant to psychosocial changes during that period of life.

The role of cognition in the motivation to succeed has been a topic of considerable discussion. Wigfield et al. (Chapter 15, this *Handbook*, this volume) organized their review of theory and research on the motivation to succeed around three broad questions: Can I do this task? Do I want to do this task and why? and What do I need to do to succeed on this task? It is obvious that cognition is central to assessing and dealing with all of these questions, although, of course, emotion also plays a critical role in achievement motivation. As an example of how cognitions affect the motivation to succeed, Wigfield et al. reviewed literature concerning the ways in which children's understanding of competence-related constructs (e.g., ability, effort, task difficulty) affect motivation.

Interest in cognitive processes as explanatory mechanisms in socialization has changed markedly in recent years. In the past 2 decades, social learning theory accounts of socialization have become much more cognitive in orientation; in addition, cognitive constructs from the cognitive sciences and social psychology have been assimilated into developmental conceptions of socialization. In their chapter, Bugental and Grusec (Chapter 7, this *Handbook*, this volume) argue that socialization interactions are organized by the ways experiences are represented at a cognitive level. Cognitions often mediate or moderate socialization processes, and cognitive processes involved in socialization may be deliberate and reflective or relatively automatic. They also discuss the role of children's acquired ways of cognitively representing their social worlds (including conceptions of the self, family members, and peers) in mediating the effects of socialization on developmental outcomes, as well as how parental cognitions—for example, biases, attributions—affect the quality of parenting. In brief, socialization is achieved partly through caregivers' influence on the development of children's conceptions of relationships, and parents' beliefs about children likely are influenced by their own working models of relationships (also see Rubin et al., Chapter 10, this *Handbook*, this volume).

Like Bugental and Grusec (Chapter 7, this *Handbook*, this volume), Parke and Buriel (Chapter 8, this *Handbook*, this volume) suggest that the role of cognition in socialization is varied and multilevel: "the role of cognition comes in many guises, including the child's own cognitive capacities as a determinant of socialization strategies, as well as parents' cognitions, beliefs, values and goals concerning their parental role as constraints on their socialization practices. . . . Equally important is the

recognition of the importance of the ways in which parents perceive, organize and understand their children's behaviors and beliefs for appreciating how parent-child relationships are regulated and change." Moreover, like Bugental and Grusec, Parke and Buriel view cognitions as mediators of the relation between socialization or family experiences (parenting, marital conflict) and children's developmental outcomes. Parental cognitions, ideas, beliefs, values—also are viewed as mediating the relation of family socioeconomic status to children's development.

Finally, cognitive perspectives such as cognitive developmental theory and schema-based models are important in contemporary work on gender issues. Among the most fundamental issues in the study of gender are the role of cognition in gender-typed behavior, the development of an understanding of gender-relevant constructs early in life, and the role of social factors in children's gender-relevant cognitions. The current focus on cognition has contributed a conception of gender development in which the child's conceptions play a significant role in his or her own development (see Ruble et al., Chapter 14, this *Handbook*, this volume).

In brief, cognitive processes of many sorts (including those studied in neuropsychology) are being integrated into theory and research on diverse aspects of social and emotional development. This trend, which has likely increased in the past decade, has resulted in richer conceptualizations of children and their social and emotional development, as well as of the socialization process.

## A FOCUS ON CONTEXTUAL AND ENVIRONMENTAL INPUTS TO DEVELOPMENT

Investigation of social and emotional development is becoming more differentiated and sophisticated in its conception of the social context. This change in the field is based, in part, on Bronfenbrenner's (1979) early efforts to increase the field's awareness of the multiple levels of the child's social ecology and the need to consider the interaction between the larger social world (e.g., the neighborhood and culture) and the family and individual. The social environment provides affordances for the expression of individual characteristics—it is the niche for biologically based characteristics to operate (or not). And, as mentioned previously, the field is increasingly recognizing the importance of gene-environment interactions (i.e., when the effect on a person of exposure to

a particular environment varies depending on their genotype or, conversely, when environmental experiences moderate gene expression).

Similarly, life-span psychologists also have heightened our awareness of the interplay of historical, cultural, biological, and psychological influences on behavior (Baltes, Lindenberger, & Staudinger, 1998; Baltes, Reese, & Lipsitt, 1980). From a life-span perspective, changes in the individual's social context across the life span interact with the individual's unique history of experiences, roles, and biology to produce an individualized developmental pathway. Further, increased interest in individual differences in temperament, personality, and social functioning sometimes has contributed to a focus on context as a possible explanation for these differences (e.g., Rothbart & Bates, Chapter 3, this *Handbook*, this volume).

## Diversity

One manifestation of current interest in the context of development is the recent emphasis in the discipline on recognizing and examining diversity (Parke, 2004). This trend is consistent with the life-span emphasis on individual variation in developmental trajectories. An emphasis on diversity can refer to a host of differences among people that are correlated with different life experiences, including differences in sex, sexual orientation, and masculinity/femininity; in culture and subcultural background/experiences; in socioeconomic status and associated living conditions; and in the composition and structure of families.

For years, many developmentalists have acknowledged that research on differences among various groups (e.g., cultures or subcultures) is valuable in delineating factors that influence diverse courses of development. However, in the past decade or two, we have moved beyond solely identifying differences *between* groups on particular variables.

Of particular importance, developmental scientists are acknowledging the value of studying differences in *processes* of development in different groups. Often in the past, the implicit assumption has been that the causes of development were similar or identical across groups but that various groups differed in degree of exposure to various causal agents or in biological predispositions. Thus, gender, ethnicity, and other group-level variables were considered unwanted error variance and were often treated as control variables—nonpsychological and non-behavioral variables of little interest. Investigators are

finding that contributors to development, and the configuration and operation of influential factors, sometimes vary in different contexts and for different groups. Examples were provided in the prior discussion of moderation effects.

### Types and Examples of Contextual Influence

The importance of the various types of contextual influences on social and emotional development is evident in many of the chapters in this volume. Consistent with the past *Handbook* chapters on socialization, Parke and Buriel (Chapter 8, this *Handbook*, this volume) review in some detail the relations of aspects of the proximal family context (e.g., parental socialization-related practices and cognitions) to social, personality, and emotional development. This ongoing interest in the role of the proximal family environment is also reflected in a number of other chapters, such as those focused on early social, self-related and moral development (Thompson, Chapter 2, this *Handbook*, this volume), aggression (Dodge et al., Chapter 12, this *Handbook*, this volume), prosocial development (Eisenberg et al., Chapter 11, this *Handbook*, this volume), peer relationships (Rubin et al., Chapter 10, this *Handbook*, this volume), achievement (Wigfield et al., Chapter 15, this *Handbook*, this volume), and socioemotional development in adolescence (Collins & Steinberg, Chapter 16, this *Handbook*, this volume).

Parke and Buriel's Chapter 8, Bugental and Grusec's Chapter 7 (this *Handbook*, this volume) on socialization processes, and, to some degree, a number of other chapters include content pertaining to other aspects of context. These include family structure and organization (e.g., as assessed by parental employment status, marital status, and number of parents in the home) and subcultural and cultural factors. Although research on socialization in minority families and communities is still quite limited in quantity, such work has been assigned new importance in the past 2 decades (see Parke & Buriel, Chapter 8, this *Handbook*, this volume). Developmental scientists are increasingly acknowledging that the values, socialization goals, and strategies in ethnic minority families may differ in important ways from those in the majority culture. Moreover, there are unique issues and challenges with regard to socialization and development in contexts where children must interact effectively in two cultures (e.g., the cultures of the minority and major-

ity groups), cultures that often conflict in particular values and expectations. Similarly, the context of poverty—a situation in which increasing numbers of families are finding themselves—is a topic of growing interest in the developmental community (see Parke, 2004; Parke & Buriel, Chapter 8, this *Handbook*, this volume).

Although developmental psychology has been influenced by cultural anthropology for a long time (e.g., Whiting & Whiting, 1975), interest in the role of culture in psychological development has increased in the past 15 years, particularly with regard to the study of emotion, the self, and moral development (e.g., Kitayama & Markus, 1994; Oyserman, Coon, & Kemmelmeir, 2002; Turiel, Chapter 13, this *Handbook*, this volume). As one example, Saarni et al. (Chapter 5, this *Handbook*, this volume) proposed that culture plays a role in the construction of the meaning of events that can elicit emotion (e.g., in emotion-relevant appraisals of events and others' behaviors and reactions) and in rendering some emotional responses more probable than others. Culture also influences how members of a society regulate and express emotion through a transactional process. Specifically, culture determines what one notices in the feedback from the body; influences communication patterns and, hence, socially induced affect; determines one's role in society and, consequently, emotional experiences that are associated with roles; and influences the selection and expression of emotional responses. This view of emotion differs somewhat from the common perspective that emotional expression and feeling are strongly rooted primarily in biology and that many emotion-related processes are universal.

Given the links among emotion, perceptions of the self, and relationships (Harter, Chapter 9, this *Handbook*, this volume; Thompson, Chapter 2, this *Handbook*, this volume), it is not surprising that contemporary theorists expect culture to play a role in the development of the self. Harter (Chapter 9, this *Handbook*, this volume) noted that the self is likely culturally saturated. Thus, the Western view of self may differ in important ways from that in cultures in which self-definition is deeply embedded in social relationships and obligations. This proposition is consistent with the contemporary argument that people in different cultures have different construals of the self due to cultural differences in concepts of individuality (Markus & Kitayama, 1991). In some cultures (e.g., many Asian cultures), the self is viewed as interdependent and there likely is more em-

phasis on attending to others, fitting in, and harmony with others. In contrast, some have argued that in many Western cultures, independence from others rather than overt connectedness is valued. Although there may be more diversity within groups in regard to an emphasis on individualism than sometimes is acknowledged (Turiel, Chapter 13, this *Handbook*, this volume) so that distinctions between individualistic and collectivistic cultures do not hold (Oyserman et al., 2002), it appears that there is some variation across cultures in normative self-conceptions. This variation probably is reflected in processes underlying the development of self-perceptions early in life. For this reason and others (e.g., the content of certain items may not be relevant or meaningful; see Harter, Chapter 9, this *Handbook*, this volume), measures of self-perceptions developed in the United States may not be appropriate for use in non-Western or nonindustrialized cultures.

Culture is an especially salient theme in Turiel's Chapter 13 (this *Handbook*, this volume) on moral development. Although coming from a predominantly cognitive perspective, Turiel notes the dynamic interplay among various personal and social (including cultural) goals in moral development. He also acknowledges that social reasoning is flexible and takes into account different and varied aspects of the social world. In discussing contrasting perspectives on cross-cultural findings, Turiel makes the point that differences in assumptions about reality (e.g., assumptions about practices that are harmful to the dead) and in informational assumptions (e.g., regarding the expected effects of physical punishment on children) are important to consider when interpreting cultural differences in moral and social conventional reasoning. As is evident in Turiel's chapter, there is disagreement in the field in regard to the interpretation of some cross-cultural differences in reasoning about moral and social conventional issues, with Turiel viewing moral development as being more similar across cultures than do most cultural psychologists (e.g., Shweder, Mahapatra, & Miller, 1987). However, Turiel emphasizes another aspect of context more than do most cultural psychologists; he argues that a focus on contextual variations between cultures has led to little consideration of variations in moral reasoning associated with contextual differences *within* cultures. Turiel and his colleagues' work (e.g., Wainryb & Turiel, 1995) on the diversity of perspectives within cultures stemming from factors such as gender roles

and status hierarchies is an important direction for research on moral development.

The emphasis on different groups within a society serving as different socialization contexts is echoed in recent work on the separate cultures of girls and boys (Maccoby, 1990). Segregation by sex in childhood seems to be a universal phenomenon, although it varies to some degree with variables such as the availability of same-sex peers and opportunities to choose one's associates (Ruble et al., Chapter 14, this *Handbook*, this volume). Within sex-segregated groups, girls and boys appear to develop different styles of interaction, goals, and values, as well as different perceptions of the self (Harter, Chapter 9; Ruble et al., Chapter 14, this *Handbook*, this volume). These subcultural differences likely have substantial and long-term implications for social, emotional, and personality development.

Also evident in this volume of the *Handbook* is the increased recognition in recent decades of connections among contexts within a society, for example, among family, school, and peer cultures (e.g., Collins & Steinberg, Chapter 16; Dodge et al., Chapter 13; Wigfield et al., Chapter 15; Parke & Buriel, Chapter 8; Rubin et al., Chapter 14, this *Handbook*, this volume). However, these connections are seldom examined in empirical study of development and in theory, or acknowledged in the real world (e.g., there often is little communication between schools and parents). Culture doubtlessly has important effects on the nature of the connections across settings within a culture; for example, the links between parents and schools may be stronger in majority culture families than in some minority groups (especially in some neighborhoods) who feel little connection to the majority culture. However, research on the role of culture in the forging (or inhibiting) of connections across settings within cultures would enrich an ecological perspective of development.

## A FOCUS ON BIOLOGICAL PERSPECTIVES

There can be little doubt that there has been a resurgence of interest in individual differences, and especially the biological and constitutional bases of individual differences. Plomin (1994) noted that 78% of the text pages in the 1983 *Handbook of Child Psychology* were devoted predominantly (more than half the page) to normative or group difference approaches. In contrast, individual

differences were a major focus of attention in the 1998 edition of the *Handbook* and in this edition. Indeed, in three of the chapters in Volume 3, constitutionally based individual differences are the primary focus (i.e., Caspi & Shiner, Chapter 6; Kagan & Fox, Chapter 4; Rothbart & Bates, Chapter 3, this *Handbook*, this volume).

The current focus on constitutionally based individual differences is not unprecedented. After a period of heavy reliance on biological explanations of social behavior earlier in this century, biological perspectives appeared to go out of fashion in developmental and social psychology. Behaviorism and then social learning perspectives became more popular during the middle half of the century, whereas biologically based explanations of social behavior and personality were deemphasized. In the past 25 years, the pendulum has swung back once more.

Noticeable differences in the field between now and when the 1998 edition of the *Handbook* was published are in regard to the degree of acceptance of genetics and biological factors as major contributors to socioemotional development and, of equal importance, in the greater understanding that genetic contributions to development do not preclude environmental contributions. The field is more cognizant that genetic factors usually are moderated or mediated by the environment, including the social environment, and are not independent of environmental inputs to development. Thus, as was noted by Caspi and Shiner (Chapter 6, this *Handbook*, this volume), in the past decade the pitting of nature versus nurture has increasingly come to a halt.

For the most part, developmental scientists now accept that both genetic and other biological factors affect development, and that even behaviors with a strong hereditary basis can be strongly affected by the environment in which the organism develops. Most also are aware of the relevant caveats in interpreting the results of behavioral genetics studies, two of which are aptly spelled out by Dodge et al. (Chapter 12, this *Handbook*, this volume): “it is understood that genetic effects may be mediated environmentally through gene-environment transactions in which genes influence surrounding environments, which, in turn, influence phenotypic expression. . . . In behavior genetics studies, the effects of such transactions are included in the heritability estimates and not counted as environmental effects. Second, all estimates are context specific. That is, the influence of genes on behavior varies across social contexts, and a change in the social context may change the relative im-

portance of genes and environment.” Increased understanding of these issues has led to a more balanced and complex view of the role of nature and nurture in socioemotional development.

Caspi and Shiner (Chapter 6, this *Handbook*, this volume) suggest that the use of molecular genetic techniques is contributing to the trend to replace the nature-nurture conjunction “versus” with the more appropriate conjunction “and.” Other factors that have likely contributed to movement in this regard include sophisticated discussions of interpretational and statistical issues (e.g., Bronfenbrenner & Ceci, 1994; Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Rutter & Silberg, 2002; Turkheimer & Gottesman, 1996) in premier publication outlets, as well as studies demonstrating the complexity of relations between environmental and genetic or biological factors (see Caspi & Shiner, Chapter 6, this *Handbook*, this volume, and the discussion of moderated relations later).

### Biology, Temperament, and Personality

As noted previously, Rothbart and Bates (Chapter 3), as well as Kagan and Fox (Chapter 4, this *Handbook*, this volume), focus primarily on issues related to temperament. It is often assumed that behaviors with a temperamental basis are inherited, but current definitions of temperament are more complex. Rothbart and Bates (Chapter 3) define temperament as “constitutionally based individual difference in reactivity and self-regulation, in the domains of affect, activity, and attention. . . . By the term *constitutional*, we refer to the biological bases of temperament, influenced over time by heredity, maturation, and experience.” Thus, temperament is influenced not only by heredity, but by environmental factors that affect an individual’s biological being (e.g., trauma or drugs) and by the social context.

Similarly, for Kagan and Fox (Chapter 4, this *Handbook*, this volume), temperament “refers to a biologically based bias for correlated clusters of feelings, thoughts, and actions that appear during childhood, but not always in the opening months, and are sculpted by varied rearing environments into a large but still limited number of traits that comprise an individual’s personality profile.” Thus, they emphasize the role of both biological and environmental factors in children’s early dispositional characteristics. Similarly, Caspi and Shiner (Chapter 6, this *Handbook*, this volume) argue that personality, viewed as social and cognitive elaboration

tions on temperament, is moderately influenced by both heredity and environment (especially unshared environmental factors that are not shared by twins or siblings). Thus, there is consensus among these authors on the importance of both hereditary and the environmental influences on temperament and personality.

Developmental scientists increasingly are using physiological/neurological measures of dispositional characteristics, situational reactivity, regulation, approach/avoidance tendencies, and various types of cognitive, attentional, or emotional processing related to temperament. For example, Kagan and Fox (Chapter 4, this *Handbook*, this volume) summarize research on cerebral asymmetry and its association with behavioral inhibition, other physiological correlates of inhibited and uninhibited behavior, and the relation of neurochemical systems in the brain to mood and action. They further note that people with different temperaments will not react in the same way, behaviorally or biologically, to a given experience. Accordingly, they suggest that we invent constructs that capture this fact—that we “replace the current constructs, which describe children and their environments (parents, sibling, school settings) separately, with single synthetic constructs that represent a particular temperamental type growing up in a particular set of contexts. . . . As environments shape children of varied temperaments into different phenotypes, it will be useful to invent new concepts, rather than rely on the language of ANOVA that describes interactions between the temperamental type of child and a rearing environment.”

Rothbart and Bates (Chapter 3, this *Handbook*, this volume) discuss associations of the major dimensions of temperamental reactivity (approach, fear, anger, etc.) and self-regulation (e.g., attention) with the neural systems identified as underlying these dimensions. They discuss neurological processes involved in effortful control, defined as “the efficiency of executive attention, including the ability to inhibit a dominant response and/or to activate a subdominant response, to plan, and to detect errors.” Rothbart and Bates also review research on the behavioral and emotional correlates of autonomic reactivity (e.g., heart rate, vagal tone, skin conductance) and cortisol responding, as well as hemispheric asymmetry, as a way of further examining the biological bases of temperament and their expression in behavior. These measures, which tend to be related to some indices of temperament, are sometimes used as proxies for temperament, and sometimes as separate

constructs that inform us about aspects of temperament that relate to them.

After concisely summarizing the behavioral genetics literature, Caspi and Shiner (Chapter 6, this *Handbook*, this volume) highlight recent work on molecular genetics and personality. They note that individual genes have not consistently mapped onto personality, but that this may be due (among other reasons) to personality being predicted by a combination of genes and gene X environment interactions. Caspi and Shiner believe that developmental psychologists can contribute to this line of work by helping to refine the measurement of psychological phenotypes for inclusion in genetic research and helping to measure developmental contexts and environmental risks that may interact with genetic factors to shape personality (or temperament) and its development.

### Biology and Socioemotional Development

As is reflected in the chapters in this volume, much contemporary work on the biological bases of socioemotional development is based on complex frameworks that posit interconnected causal roles of biological/constitutional and environmental factors in human functioning. For example, Bugental and Grusec (Chapter 7, this *Handbook*, this volume) depict development as the result of a dynamic co-regulation of aspects of the individual (from neural to behavioral) and the environment (from physical to social). The emergence of structure in both people and their environments results from a process of mutual influence and regulation. They present literature consistent with the view that children are biologically prepared for socialization, and argue that biologically based differences in children (e.g., in temperament, physical attractiveness) elicit different socialization experiences from the environment. Similarly, biological factors that affect parenting are discussed, with a recognition that biologically influenced parental characteristics are played out in a social context. They further argue, using an evolutionary perspective, that humans may be designed for preferential receptivity to proximity-maintenance with specific others in the presence of distress (e.g., attachments), for the use and recognition of signals denoting power or dominance, for differentiating between in-groups and out-groups in social life, and for the reciprocal obligations associated with communal life. These biological predispositions are viewed as emerging in a social context in which cultural factors, as well as situational cognitive and emotional factors, act as mediators and moderators of their effects on

the socialization process and its outcomes. Thus, Bugental and Grusec view socialization in a complex process-oriented manner, influenced by the ongoing interaction of biological and environmental factors.

As is evident in Ruble et al.'s chapter (Chapter 14, this *Handbook*, this volume), biological approaches play an increasingly visible role in the study of gender-related development. They discuss possible evolutionary contributions to sex differences, as well as more proximal biological correlates or contributors—such as hormones and brain structure—to gender-related development and behavior. They conclude that prenatal androgens and hormones during early development appear to affect gender-related self-perceptions, preferences, or behaviors, and that the effects of sex hormones in adolescence are evident, but probably more modest. They further note that hormones have different effects on different characteristics; for example, prenatal androgen seems to have a large effect on some aspects of functioning (activities and interests), a modest effect on others (e.g., sexual orientation), and a small effect on others (gender identity). In addition, they conclude that gender socialization processes at home, at school, in interaction with peers, and through the media all contribute to gender differentiation in concepts, preferences, behaviors, and/or values, although relations often are found under some conditions. They conclude that biological and environmental factors interact in complex ways: “There is increasingly sophisticated understanding of biological effects, and recognition that they are not immutable. Genes are activated or suppressed by environmental factors. Hormones and brain functioning are almost certainly influenced by the different environments in which girls and boys are raised, by their different toy and activity choices, and by joint effects of biology and the social environment.”

In their chapter on aggression, Dodge et al. (Chapter 12, this *Handbook*, this volume) conclude that there is indisputable evidence of the role of heredity in aggression (also see Rhee & Waldman, 2002), especially for those who develop aggressive tendencies early and are stable in their aggression into adulthood (also see Caspi & Shiner, Chapter 6, this *Handbook*, this volume). They further conclude that the contribution of shared or common environment is small whereas that of children's nonshared environment is moderate. Thus, “person-specific” experiences of individuals in families appear to be an important environmental factor contributing to aggression and other antisocial behavior. Dodge et al.

also review a large body of work linking environment factors such as family and peer factors to aggression and, more importantly in regard to causal conclusions, research indicating that prevention/intervention programs can reduce the incidence of antisocial behavior. Experimental interventions that involve random assignment are perhaps the best way to demonstrate that environmental factors contribute to antisocial tendencies in youth, despite the strong role of heredity. An issue that merits attention is how partly hereditary factors such as temperament influence the effectiveness of interventions in deterring antisocial behavior.

Dodge et al. (Chapter 12, this *Handbook*, this volume) also discuss evidence for gene by environment interactions. For example, they highlight research demonstrating that children who are genetically predisposed to antisocial tendencies are especially likely to manifest them if they grow up in a risky social environment, such as one in which they are victims of maltreatment. Dodge et al. conclude that some of the most important discoveries in the next decade will come from studies of gene-environment interactions, as well as from experimental prevention/intervention studies.

Eisenberg et al. (Chapter 11, this *Handbook*, this volume) view heredity as contributing to both the development of prosocial and empathy-related responding in the species and to individual differences in aspects of emotionality and regulation (e.g., attentional regulation) that contribute to prosocial behavior and empathy in childhood. Similar to Dodge et al. (Chapter 12, this *Handbook*, this volume), they review studies demonstrating links between environmental factors and prosocial development, as well as experimental prevention studies demonstrating that children's prosocial tendencies can be modified by environmental interventions. However, it is likely that the effects of heredity are not as strong for prosocial as for antisocial behavior (e.g., Krueger, Hicks, & McGue, 2001), although heredity does contribute to empathy/sympathy (see Eisenberg et al., Chapter 11, this *Handbook*, this volume). For example, in a study of step-families, Deater-Deckard et al. (2001) found that most of the variance in adults' reports of children's prosocial behavior was due to environmental rather than hereditary factors, especially aspects of the environment that were not shared by the children (although there was significant variance for shared environmental effects). Unfortunately, there has been little research conducted as yet on the prediction of prosocial tendencies from the interaction between heredity and the environment.

## A FOCUS ON RELATIONSHIPS

As noted by Rubin et al. (Chapter 10, this *Handbook*, this volume), interest in relationships other than the parent-child relationship has grown tremendously in recent decades. In addition, researchers studying the family increasingly have examined not just the parent-child dyad, but also the larger family unit, associations between the quality of parent-parent and parent-child relationships, and links between the quality of familial interactions and quality of sibling and peer relationships (Parke & Buriel, Chapter 8, this *Handbook*, this volume). For example, there is now evidence that marital discord is related to problems with children's adjustment, social withdrawal, and low social competence, all of which compromise the quality of peer relationships. Moreover, investigators have begun to study the role of social relationships outside the family (e.g., as reflected in social support) for quality of interaction within the family (see Parke & Buriel; Rubin et al., this *Handbook*, this volume) and for the provision of social opportunities for children (e.g., adult social networks as a source of potential peer contacts for children). In addition, a relatively new emphasis in the literature in recent years has been the impact of settings such as schools, workplaces, volunteer activities, leisure pursuits, and neighborhoods on developmentally significant interpersonal experiences, especially in adolescence (Collins & Steinberg, Chapter 16, this *Handbook*, this volume).

As is discussed in some of the chapters, it has been suggested that the oft-cited causal relation of emotion-related capacities with quality of relationships can be reversed (or more likely, can be bi-directional)—for example, that early attachment relationships play a role in the development of emotion regulation and reflect strategies for regulating emotion in interpersonal contexts (Saarni et al., Chapter 5; Thompson, Chapter 2, this *Handbook*, this volume). The securely attached infant whose parent is consistently and appropriately responsive to the infant's distress signals is believed to learn that it is acceptable to express distress and to actively seek the assistance of others for comfort when upset. In contrast, avoidant infants, due in part to their parents' nonresponsiveness to their distress signals, may learn to inhibit emotional expressiveness as well as other-directed self-regulatory strategies (e.g., contact-seeking and maintaining behaviors; Cassidy, 1994).

The internal working model developed in the context of early attachment relationships is believed to affect

the quality of children's subsequent relationships because of the assumptions and expectations about relationships that are inherent in internal working models (Bretherton & Waters, 1985; Parke & Buriel, Chapter 8; Rubin et al., Chapter 10; Thompson, Chapter 2, this *Handbook*, this volume). One way early attachment relationships may affect other relationships is through their influence on the developing sense of self in the infant as lovable or unworthy of love (Bretherton, 1991; Harter, Chapter 9, this *Handbook*, this volume).

Clearly, the topic of attachment and early parent-child relationships is still a central issue in the study of relationships in developmental psychology. Attachments are hypothesized to affect the development of the self, a range of cognitions relevant to quality of relationships, emotion regulation and emotions attached to various relationships, sympathetic and prosocial behavior with others, social competence with peers, and personality development (see Collins & Steinberg, Chapter 16; Eisenberg et al., Chapter 3; Harter, Chapter 9; Rubin et al., Chapter 10; Thompson, Chapter 2, this *Handbook*, this volume). However, most researchers no longer believe that working models consolidate in early childhood with little or no further modification. This broader conception of working models is reflected in Thompson's discussion of some of the questions that require attention in the future, including the following: (a) to what extent is security of attachment definitive of the parent-child relationship? Are there important features of this relationship that are outside the scope of attachment? (b) How is it that attachment security becomes increasingly an attribute of the person, rather than of a specific relationship with maturity? Is it possible that both relationship-specific and person-specific features of attachment security coexist within the attachment-related representational systems that exist in adulthood? (c) How are multiple attachment relationships developmentally influential? How do the expectations arising from multiple attachments become integrated into coherent ways of relating to others, representing relationships, and self-understanding? and (d) why should attachment security be related to other features of psychological development? Some of these questions are related to issues raised by Harter (1998, Chapter 9, this *Handbook*, this volume) and merit additional attention in the next decade.

Close peer relationships such as friendships have been increasingly examined by developmental scientists in the past 2 decades and have been viewed as a source of support; a factor affecting self-perceptions; a context for

learning about emotions, conflict, social negotiation, and caring behavior; an impetus for cognitive, social, and emotional development; and an influence on the development of antisocial behavior and substance abuse (Collins & Steinberg, Chapter 16; Dodge et al., Chapter 12; Harter, Chapter 9; Rubin et al., Chapter 10, this *Handbook*, this volume). However, a type of close peer relationship that has received relatively little attention until the last decade is romantic relationships. Collins and Steinberg conclude that relationships with peers are a primary context for the transmission and realization of expectations about romantic relationships. According to the research they review, the quality of romantic relationships, including aggression within them and feelings of rejection, is correlated with the quality of other relationships with peers and family members: Youth with healthy familial and peer (e.g., friendship or peer group) relationships tend to have more positive romantic relationships. They also note that the developmental outcomes of romantic relationships can be positive or negative, depending partly on the quality of these relationships. Consequently, the effects of early family and peer relationships on subsequent adjustment and well-being in adulthood (and in adult relationships) likely are partly mediated through experiences in adolescent romantic relationships. Moreover, partner relationships in late adolescence and early adulthood seem to play an important role in determining an individual's trajectory in antisocial behavior (i.e., its cessation or continuation) in early adulthood (Caspi & Shiner, Chapter 6, this *Handbook*, this volume). Thus, the topic of romantic relationships would seem to be an important one for further study, especially as it relates to success in adult development.

## A FOCUS ON APPLICATION

Another trend in the developmental research in the past 2 decades has been renewed interest in application and real-world problems. This emphasis in the discipline is reflected in the fact that for the first time, one volume of the 1998 *Handbook* (Volume 4) was devoted to applied issues, and that volume is also part of this edition of the *Handbook*. Although much of the applied work on socioemotional development is discussed in that volume, the contemporary concern with application is also reflected to some degree in this volume.

This concern can be seen in both the topics of study and the ways in which people are conducting research

on certain topics. Work on aggression, regulation, coping, and social competence is burgeoning, for example, no doubt in part because of concern in society about children's psychological health, violence, and related social issues (e.g., see Caspi et al., Chapter 6; Collins & Steinberg, Chapter 16; Dodge et al., Chapter 12; Eisenberg et al., Chapter 11; Rubin et al., Chapter 10; Saarni et al., Chapter 5, this *Handbook*, this volume). In the past decade or two, the focus on developmental psychopathology, in particular, has increased in the writings of developmental scientists. Moreover, investigators increasingly have been turning their attention to development in stressful contexts such as families in poverty, one-parent families, and families of divorce (Parke & Buriel, Chapter 8, this *Handbook*, this volume). Concern with clinical issues and prevention is not without precedent, of course; much of the early work in child development grew out of a desire to understand the origins of typical childhood problems.

In addition, work on topics that have been a focus of interest for a long time is increasingly being conducted outside the laboratory in real-world contexts so that findings have direct applicability to prevention, clinical, and policy issues. For example, developmental scientists are becoming involved in the process of obtaining knowledge that can be used to design programs that lessen the probability of negative effects from exposure to stressors (e.g., divorce, poverty) or that promote prosocial behavior or inhibit aggressive tendencies in school settings (Dodge et al., Chapter 12; Eisenberg et al., Chapter 11, this *Handbook*, this volume). Moreover, developmental scientists are deeply involved in evaluating programs such as day care that have implications for both families and policy (see Volume 4). It is likely that the increasing trend for developmental scientists to apply their theory and methods to real-life issues in real-world contexts will continue into the next decade and well into the 21st century.

## SUMMARY

In general, the chapters in this volume highlight the emerging themes, constructs, and methods in the field, and a recent permeability in the intellectual boundaries of the field. Many of the changes in the study of social and emotional development in the past 2 decades can be characterized by increasing integration and differentiation. In this context, I am using the term *integration* to

mean the assimilation (usually with some accommodation) into the study of socioemotional functioning of ideas and methods from diverse approaches and topics in developmental psychology, other subdisciplines of psychology, and even other disciplines such as sociology, genetics, and anthropology. The integration of novel methods, constructs, and theoretical perspectives has broadened not only our understanding of social and emotional development, but also the entire framework on which we design and interpret research findings.

*Differentiation* within the field of socioemotional development may be viewed in terms of contexts, constructs, and causal inferences. As noted previously, the burgeoning interest in context in developmental psychology is reflected in the study of many levels of influence, including diversity in culture and subculture, race and ethnicity, biological sex and gender, types of families and groups, and genetic and constitutional influences. In regard to constructs, our thinking is becoming less global and more conditional, multifaceted, and complex. Similarly, proposed causal influences of various social processes are becoming more multifaceted. Mediated and moderated relations, as well as those based on dynamic systems perspectives, are more central in theory and research.

Moreover (and related), researchers are increasingly acknowledging and examining the multiplicative and covarying contributions of various types of environmental and biologically based influences on socioemotional functioning. Increasingly children are being viewed as producers of their environment as well as the products of socialization; parents and children are viewed as coregulators of each other's behaviors and affective states; and development is characterized as a consequence of social interactions that are shaped by contextual factors and characteristics of all participants in the interaction. Although interactional and reciprocal causal models are not new, they are becoming a part of our everyday thinking about psychological phenomena. As one might expect, implementation of complex interactive models into research designs lags behind conceptual models. However, analytic methods for exploring reciprocal, additive, and interactive causal influences, as well as analyses for examining nonlinear relations and growth curves, are becoming more common, so developmental scientists are increasingly able to test complex conceptions of development empirically. The next decade, like the past one, will undoubtedly be an exciting time for the study of social, emotional, and personality development.

Security of Attachment in the Strange Situation	47
Other Behavioral Assessments of Attachment Security	50
Origins of Attachment Security	52
Consistency and Change in the Security of Attachment	57

What constitutes the development of a person? In moral philosophy, “personhood” is not inherent in human existence but rather is contingent on the achievement of self-awareness, moral autonomy, and other constituents of distinctly human capability. Developmental scientists offer a more nuanced answer to this question, describing how the development of personhood emerges in a continuous relational context in which infants and young children develop their earliest understandings of who they are, who others are, and how to relate to other people.

---

Every author of a *Handbook* chapter should have such an opportunity to write a revision—to try to portray the field more accurately, to correct mistakes and misinterpretations, and to see how far the field can advance in a few years. In the previous edition, I gratefully thanked many colleagues who were willing to contribute to my “meandering ponderings” about the issues of this chapter. I remain grateful to them because they have continued to stimulate my thinking. I am also grateful to a remarkable group of student colleagues: Rebecca Goodvin, Debbie Laible, Sara Meyer, Lenna Ontai, and Abbie Raikes.

Early Attachment and Subsequent Psychological Development	60

<b>CONCLUSION</b>	84
<b>REFERENCES</b>	85

This chapter is concerned with early sociopersonality development. Because other chapters of this *Handbook* are devoted to temperamental individuality, the development of emotion, peer relationships, and other processes related to personality, the goal is not to comprehensively describe the emergence of early personality or to identify individual characteristics that foreshadow adult personality traits. Instead, and consistent with a developmental perspective, the goal is to describe how central facets of social and personality

---

They have contributed to the ideas considered here, and the chapter is dedicated to them. My deepest appreciation also to Nancy Eisenberg, whose patience and good heart made it easier to complete this project during a period of personal challenge. Although I have sought to identify major contributors to each of the topics reviewed here, the length limitations prohibited appreciative citations to all relevant and important papers. Consequently, I offer an apology to respected colleagues whose work is not explicitly noted as frequently as they merit, but whose thinking and research have been influential.

development emerge through the growth of social understanding, self-awareness, early conscience and cooperation, and the relationships that infuse these early achievements. These are some of the most important ways that make a 6-year-old a fundamentally different person from a newborn and form the foundation for individuality and social relatedness in the years to come. The development of social understanding, relationships, self, and conscience constitute the most important ways that developing individuality intersects with the social world. These topics have also provoked the most concerted research attention in the study of sociopersonality development during the past decade.

The research literatures surveyed in this chapter identify several themes about early sociopersonality development and developing persons. First, relationships are central. Indeed, this chapter is a study of relationships and their developmental influence, whether considering face-to-face interaction and the growth of social expectations, parent-child discourse and autobiographical self-awareness, the growth of a mutually cooperative orientation between parent and child, security of attachment, or children's representations of self and relational processes. This chapter reflects an emerging view that relational experience is generative of new understanding, whether of emotions, self, morality, or people's beliefs, and highlights the need for a developmental relational science of the future that focuses on relational influences across diverse developmental domains. Such a developmental relational science could integrate the most valuable perspectives offered by attachment theory, neo-Vygotskian thinking, sociolinguistic approaches to cognitive growth, and other perspectives into a thoughtful understanding of how early relational experience contributes to fundamental competencies and the emergence of individual differences in thinking, sociability, and personality development.

Second, because relational experience is important, early sociopersonality development is best understood not as socialization or constructivism but rather as the appropriation of understanding from shared activity (Rogoff, 1990). The literatures reviewed in this chapter describe how psychological development arises from the powerfully inductive capacities of the young mind interacting with the conceptual catalysts of social exchange, whether in the conflict of wills between parents and a locomoting toddler, interactions about broken toys and mishaps, or conversations about the day's events that reflect cultural values. Integrating understanding of the

constructivist mind with the influence of relationships in early sociopersonality development requires comprehending the nature of the shared activity of young children and those who care for them. This is an important research challenge because a model of appropriated understanding through shared activity can potentially further understanding of many features of early sociopersonality growth. In attachment theory, research on the shared activities and conversations of young children and their caregivers can help to clarify how specific representations of experience and self (or internal working models) develop from relational security or insecurity. In theory of mind, studies of shared experiences and discourse can elucidate some of the conceptual catalysts fostering preschoolers' understanding of people's desires, feelings, beliefs, and thoughts (Thompson, 2006a). A model of appropriated understanding from shared activity offers, more than traditional socialization or constructivist views, the opportunity to integrate social and cognitive aspects of early sociopersonality development.

Third, thinking and understanding in early childhood is a conceptual foundation for what develops afterward. Although this seems a truism, it was not long ago that characterizations of young children as egocentric, concrete, preconventional, and preconceptual made this developmental period seem discontinuous with the conceptual achievements of middle childhood and later. If early childhood establishes the foundations for the development of social cognition, moral judgment, and self-understanding of the years that follow, then relationships and other influences experienced in the early years set the context for the growth of an empathic, humanistic orientation toward others, balanced self-concept, capacities for relational intimacy, social sensitivity, and other capacities conventionally viewed as achievements of middle childhood and adolescence. Understanding how this occurs is a current and future research opportunity.

In the contemporary climate of developmental science, relational influences in the family are understood in concert with heritable influences shared by family members. Although students of early sociopersonality development have been slow to enlist genetically sensitive research designs into studies of family influences (see Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000), research on genetic and shared and non-shared environmental influences on the security of attachment and other relational variables has advanced

understanding of the interaction of heredity and environment. Contemporary scholarship also benefits from a far less polarized view of the influences of nature and nurture than what was true only a few years ago. Heritability estimates, while important, are now recognized as being both sample- and context sensitive and having little implication for the potency of environmental influences (Committee on Integrating the Science of Early Childhood Development, 2000; Rutter, 1997). Equally important have been the contributions of developmental behavioral genetics for conceptualizing the differentiating experiences of siblings in the family (nonshared environment) and for understanding how children's characteristics are evocative of parenting practices (gene-environment correlation), both long integrated into developmental theory but now receiving renewed attention. At the same time, an expanding body of research is underscoring the importance of studying long-neglected gene-environment interactions—by which children with different heritable characteristics are affected differently by the environment—for informing developmental theory concerning family relationships (see, e.g., Ge et al., 1996, and O'Connor, Caspi, DeFries, & Plomin, 2003, for illustrations). Such studies highlight that the interaction term in the quantitative model for partitioning heritable and environmental influences on behavior may be the most important one. Molecular genetics research has the power to elucidate gene-environment interactions and the probabilistic nature of genetic effects (Rutter, Silberg, O'Connor, & Simonoff, 1999), and comparative studies highlight the influence of the environment in gene expression in studies of rats and primates (see Gunnar & Vasquez, *in press*, for a review). Taken together, contemporary research is affirming the wisdom of the lesson repeatedly learned by prior generations of developmental scientists: the inseparability of nature and nurture. What has advanced significantly is the technology for elucidating their interaction.

This is an exciting time for studying the development of the person because of a new appreciation of the generative influence of relational experience and respect for what young individuals bring to these relationships.

## SOCIAL UNDERSTANDING

Understanding the world of people—the psychological processes that guide behavior and relationships, the na-

ture of social roles and institutions, group processes, and other social phenomena—is essential to psychological growth. At each age, social cognitive understanding contributes to social competence, interpersonal sensitivity, and an awareness of how the self relates to other individuals and groups in a complex social world. Social cognition is also central to the development of emotion understanding, moral awareness, and self understanding. Early social cognitive development creates a foundation to these achievements as young children begin to comprehend how human behavior is related to mental goals, intentions, feelings, desires, thoughts, and beliefs, and how social interaction is affected by the juxtaposition of these mental states in two or more individuals. Moreover, attachment theory and other theories of social development view early childhood as the period when individual differences in social beliefs and dispositions emerge from children's social experiences, especially in close relationships. Taken together, the study of early social cognitive development offers the opportunity to understand how young children derive their initial insights into the psychological world of people, and why children begin to create markedly different expectations for this social world. These early developmental processes color social understanding throughout life.

Developmental study of social cognition has traditionally been the stepchild of research on cognitive development, based on the assumption that the same conceptual processes organize children's thinking about the social and nonsocial worlds. Beginning with the Piagetian era, when the study of social-cognitive development began in earnest, this meant that relatively little attention was devoted to social cognition in infancy and early childhood because this period was theoretically characterized as one of egocentrism, concrete thinking, and a focus on appearances rather than underlying, invisible realities. Students of social cognitive development also inherited from Piagetian theory the constructivist model, with its emphasis on the autonomous child's induction of understanding from individual experience.

The current post-Piagetian era of cognitive developmental research has offered new opportunities to explore early social cognitive development because of a new view of the developing mind. The assumption of early childhood egocentrism has been replaced by the realization that understanding the mental world of other people, and the differences between people's mental states, is one of the early and consuming interests of infants and

young children. In their investigations of the growth of joint attention; inferences of intentionality, desires, and beliefs; theory of mind; and other conceptual processes, researchers have highlighted how remarkably early and apparently easily young children acquire insight into the psychological world and the relevance of these achievements to later social understanding.

Contemporary study of early social cognition also contributes to a more sophisticated understanding of the processes by which social understanding develops in early childhood. At a time when cognitive developmental scholars are questioning the adequacy of explanations of conceptual growth that focus solely on the inductive, constructivist mind and are exploring the social origins of psychological understanding (e.g., Carpendale & Lewis, 2004; Hobson, 2002), research into early face-to-face interaction, the impact of locomotor experience on parent-infant relations, social referencing, parental socialization of social domain understanding, and parent-child conversation contribute new insight into the developmental catalysts to early psychological understanding. By exploring these social catalysts, the ideas of social and cognitive developmentalists are usefully integrated in contemporary social cognitive research. This is especially so because inquiry into early social cognitive development can help to clarify central constructs in social developmental theories (such as the “internal working models” of attachment theory) while also providing insight into the consequences of differences in early social experiences for children’s understanding of mental states. Therefore, contemporary research on early social cognitive development is not only an instantiation of the traditional view that conceptual achievements are applied to the social and nonsocial worlds alike but also a new opportunity to explore how the scaffolding of everyday social experience provides uniquely social catalysts to the development of psychological understanding.

The study of early social cognition encompasses developments in social skills, general knowledge of the social world (including the psychological functioning of people), and person-specific social expectations. In each of these areas, infancy and early childhood is a period of significant advance.

### Early Social Discriminations and Expectations

In traditional developmental theory, a fundamental conceptual challenge for the newborn is to distinguish the

internal world from the surround. From this perspective, early social cognition requires the emergence from initial symbiosis or egocentrism. But an alternative view is offered by contemporary perceptual theory (e.g., Gibson, 1995), which argues that the integrated perceptual experiences yielded by movement and activity contribute to a fundamental distinction between internal experience and surrounding stimulation from shortly after birth. According to this view, the tight synchrony of multimodal experience (e.g., integrated visual, tactile, kinesthetic, and auditory experiences) that arises from self-initiated movement is perceptually different from incoming stimulation arising from objects that are acted on or that move of themselves. Gibson and others (e.g., Neisser, 1995) have argued that, in this way, perception distinguishes self-initiated action from surrounding activity and gradually contributes to self-awareness. Indeed, Gibson goes on to argue that the development of new behavioral capabilities coincides with the perception of new affordances of objects in the surrounding world, such as how flat surfaces begin to be perceived as traversible when infants can locomote, and how people begin to be perceived as arousing and responsive when infants can interact socially. In this sense, social cognition and self-awareness each arise from the new perceptual experiences yielded by action, including social activity.

The social and inanimate worlds are potentially distinguishable early in life in several ways. People are spontaneous agents and act in a self-initiated manner, but this is not true of inanimate objects. People interact in a reciprocal, contingent, coordinated, and communicative fashion with the infant, predictably responding to the baby’s signals but responding with considerable variability. Emotion is a more salient feature of social interaction compared to most encounters with objects—including the emotions that precede social interaction and the changes in emotions that arise from interactive activity. Most important, the locus of causality for people’s behavior is intentional goal-directed mentality for which no comparable sources of causality exist for objects.

During the 1st year, infants begin to discriminate between the social and animate worlds in many of these ways (see Raikson & Poulin-Dubois, 2001). These discriminations are founded on early perceptual preferences that orient young infants toward social events. Newborns visually track facelike stimuli, reflecting the influence of dedicated subcortical neural circuits that

affect the development of, and are later supplanted by, cortically mediated facial preferences at 2 to 3 months of age (Johnson & Morton, 1991; Mondloch et al., 1999). Newborns exhibit a visual preference for their mothers' faces based on global perceptual discriminations that will later become more refined when infants begin scanning interior facial features at 2 to 3 months of age (Pascalis, de Schonen, Morton, Deruelle, & Fabre-Grenet, 1995; Walton, Bower, & Bower, 1992). By 3 months, when infants' facial scanning has moved to the interior of faces, infants also begin to discriminate the pictures of familiar persons (Barrera & Maurer, 1981; but see Bartrip, Morton, & de Shonen, 2001, for evidence of earlier recognition ability). Newborns are also capable of recognizing the sound of the mother's voice based on prenatal auditory experience (DeCasper & Fifer, 1980; DeCasper & Spence, 1986). This may be related to newborns' preference for the sounds of human speech and, in particular, for "infant-directed speech" that is characterized by exaggerated prosody, repetition, and simple syntax (Cooper & Aslin, 1990). Infants' preference for infant-directed speech endures throughout the early months and adult vocalizations can evoke emotional responses in the infant that are consistent with the positive or negative tone of the adult voice. Infants respond positively to vocalizations signaling affirmation or warmth (with exaggerated melodic contour) and negatively to vocalizations signaling anger or prohibition (with sharp, staccato intonations; Fernald, 1985, 1996). People are, in short, uniquely compelling elements of the newborn's world: The constellation of stimulus properties they possess captivate the young infant's attention and arouse emotion, perhaps owing to the developing brain's preparedness to respond to human stimulation.

People are captivating to infants not only because of their stimulus properties but also because of their behavioral propensities. Young infants discover that people respond to their initiatives in ways that create excitement and generate positive arousal. This becomes especially apparent after 2 to 3 months of age when, with the behavioral state fluctuations of the neonatal period subsiding and longer periods of awake alertness emerging, infants and their caregivers begin to engage in episodes of face-to-face play. These episodes are typically characterized by focused social interaction without competing caregiving goals or other demands on either partner, with infant and adult facing each other in close proximity and interacting facially, vocally, tactily, and with

behavioral gestures. Developmental scientists have been interested in episodes of face-to-face play not because of their ubiquity or universality, but rather because they constitute some of the earliest experiences of focused social interaction that contribute to the growth of social skills and the development of social expectations for familiar caregivers.

Detailed microanalyses of the course of infant and adult behavior during social interaction reveal several characteristics of face-to-face play that underscore the complexity and richness of this social experience for young infants. First, in responding contingently to the baby's socioemotional expressions, adults do not merely mimic or mirror the infant's actions. In addition, they express emotion in ways that are comparable to the baby's own but using different expressions, such as responding with a smile and a lilting voice when the baby coos. Moreover, adults also model positive expressions and differentially reinforce the baby's emotional responses. Malatesta's elegant microanalyses of maternal and infant emotional expressions during face-to-face play revealed that mothers maintained a generally positive demeanor and, while they matched the emotion of most infant emotional expressions (including joy, interest, surprise, and even sadness and anger), the baby's negative expressions (such as pain or "knit brow") were likely to be ignored or, in the case of anger, evoke the mother's surprised response (Malatesta, Culver, Tesman, & Shepard, 1989; Malatesta, Grigoryev, Lamb, Albin, & Culver, 1986). Mothers seemed committed to maintaining the baby in a positive emotional state and, over a period of weeks, maternal modeling and contingent responding to infant emotional expressions helped to account for increased rates of infant joy and interest expressions in face-to-face play. Adult contingent responsiveness is complex and often involves responses that do not match the infant's own but instead are intended to alter or guide the baby's emotional responding.

Second, although face-to-face play is commonly characterized as the establishment and maintenance of well-coordinated synchrony, with adults sensitively scaffolding their initiatives to accord with the baby's signals, it is mistaken to portray this social activity so simply. Tronick and his colleagues, based on their own microanalytic studies, have concluded that well-coordinated interactions occur only about 30% or less of the time that mothers and infants engage in face-to-face interactions, with nonsynchronous or uncoordinated exchanges occurring when infants become fussy,

mothers are distracted, or for other reasons (Gianino & Tronick, 1988; Tronick, 1989). They argue that other interactive goals—such as interactive reparation and self-regulation—accompany the goal of maintaining interactive coordination. Therefore, infants are faced with a more complex interactive activity than merely responding to a sensitively scaffolded social situation. In their earliest experiences of social play, infants are also learning that social interaction is dynamic and changing, and are acquiring the social skills of managing its dyadic course and its emotional effects. They are discovering that their social and emotional responses have effects on the adult's behavior—sometimes highly predictable effects—and that their emotions are central to the dynamics of interaction with a human partner. They are also discovering that their own emotional experience is affected not only by the initiatives of the caregiver but also by the interaction that arises from mutual responsiveness.

These experiences may help to explain why, by 2 to 3 months of age, infants respond differently to people compared to objects, directing more positive facial expressions and vocalizations to responsive people than toward interactive objects (e.g., puppets), and showing distress to nonresponsive people but rarely toward non-interactive objects (Ellsworth, Muir, & Hains, 1993; Legerstee, 1997; Legerstee, Pomerleau, Malcuit, & Feider, 1987). By 2 to 3 months of age, infants appear to expect that people will respond to them and interact with them. This conclusion is supported by studies of the “still-face” effect in infants in which mothers alternate episodes of face-to-face interaction with an episode in which they look at the infant but are impassive and unresponsive. Studies of infants age 2 to 6 months show that babies reliably respond with diminished positive affect, withdrawal, self-directed behavior, and sometimes with social elicitation (e.g., brief smiles, momentarily increased vocalizing and reaching) and negative affect during the still-face episode. When mothers subsequently respond normally, infants become more sociable but also remain subdued (see Adamson & Frick, 2003, for a review of this literature). The still-face effect is robust: It has been observed in response to strangers as well as to parents (Ellsworth et al., 1993; Kisilevsky et al., 1998), in comparisons of infants from Western and non-Western cultures (Kisilevsky et al., 1998), and in conditions when the adult's reasons for ceasing social interaction were systematically varied such as turning away to look at another person (Striano, 2004). This sug-

gests that the expectation that people will be responsive is not person specific and seems to be generalized to a range of interactive experiences in the early months.

The still-face procedure was originally designed to simulate the infant's interactive experience when mothers are depressed. Individual differences in maternal behavior and affect are significant influences on how infants respond socially (Adamson & Frick, 2003). Several studies have found that depressed mothers are less responsive and emotionally more negative and subdued in face-to-face play with their infants, for example, and the offspring of depressed mothers are also less responsive and emotionally less animated as early as 2 to 3 months (e.g., Cohn, Campbell, Matias, & Hopkins, 1990; Field, Healy, Goldstein, & Guthertz, 1990; Field et al., 1988). Field and her colleagues (1988) found that 3- to 6-month-old infants of depressed mothers remained more subdued and less animated when subsequently interacting with a nondepressed stranger. Dawson and colleagues did not replicate this finding with 13- to 15-month-old infants, but reported that the atypical patterns of frontal brain activity characteristic of the infants of depressed mothers during social interaction with their mothers were also apparent when these infants subsequently interacted with a nondepressed familiar adult (Dawson et al., 1999). Differences in early social experience seem to be important, therefore, for how infants interact with other partners, which may reflect the early emergence of generalized and specific social expectations. This may help to explain why early differences in infant affective and self-regulatory behavior in the still-face paradigm predict later attachment security (Braungart-Rieker, Garwood, Powers, & Wang, 2001; Cohn, Campbell, & Ross, 1992) and other psychosocial sequelae. Much more research on the origins and outcomes of individual differences in infant behavior in the still-face procedure is needed to clarify the specific social expectations it reflects. However, by 2 to 3 months of age, infants have begun to expect that people will respond positively to their initiatives, and marked differences in adult responsiveness have significant effects on the infant's social and emotional reactions that generalize to other partners.

As these studies suggest, adult responding that is contingent on the infant's initiatives contributes to the socially and emotionally engaging quality of early social interaction. By 2 to 3 months of age, infants respond with positive emotion to contingent responding but become affectively negative if the contingency is interrupted (Lewis, Alessandri, & Sullivan, 1990; Rovee-Collier,

1989; J. Watson, 1985). Contingency in an environmental response is positively arousing perhaps because it contributes to the infant's sense of agency. Initiating actions that have a predictable effect is a salient indication that one can exert control over important outcomes, whether social or nonsocial. J. S. Watson (1995) has argued that young infants are especially sensitive to perfectly response-contingent events because these indicate self-generated outcomes (e.g., movement of a mobile contingent on the baby's leg kicking) and that such experiences contribute to self-awareness. Later, at about 2 to 3 months, he argues, infants become sensitized to imperfect response-contingent events that are more likely to be social in nature (see also Gergely & Watson, 1999). In each case, contingency is salient because of the sense of control and effectance it creates. Murray and Trevarthen (1985) showed that a small sample of 2- to 3-month-olds responded animatedly when viewing live images of their mothers talking to them through closed-circuit television but later, when the same images of their mothers were replayed (and were thus noncontingent), infants turned away in apparent disinterest or distress (see Bigelow, MacLean, & MacDonald, 1996; Hains & Muir, 1996; and Legerstee & Varghese, 2001, for partial replications and extensions; but note also Rochat, Neisser, & Marian, 1998, for a failure to replicate this effect). The contingency of face-to-face interaction thus seems important to the social and emotional potency of early social play.

There are other advances in social cognition and social skills emerging from early face-to-face play and related experiences of social interaction. First, because social play is so richly affective, infants learn about the emotional expressions of people. By 3.5 months, infants can discriminate the dynamic, multimodal expressions of different emotions enacted by their mothers and they prefer congruence between facial and vocal expressions (Kahana-Kalman & Walker-Andrews, 2001; Montague & Walker-Andrews, 2002; Walker-Andrews, 1997). This is not observed, however, in response to the emotional expressions of unfamiliar women until 5 to 7 months of age. This suggests that partner familiarity may be important to the earliest comprehension of emotional expressions and their meaning, with some evidence that infants respond in an emotionally resonant manner to the dynamic emotional expressions of their mothers by 3 months (Haviland & Lelwica, 1987). Infants as young as 5 months also react in an emotionally differential manner to positive and negative emotions conveyed through speech alone (Fernald, 1996). Regular experiences of

face-to-face play in which these emotional expressions are salient features of social communication would contribute to these forms of nascent emotion understanding. Second, social play also provides opportunities for infants to learn about the distinctive behavioral characteristics of familiar partners. Fathers play differently than mothers in face-to-face encounters with young infants, for example, and infants later show differentiated expectations for the social behavior of each parent (see M. Lamb, 1997, for a review). Finally, to the extent that in the early months, infants begin to represent others' actions as "like me" when they can also be performed by the self (Meltzoff & Gopnik, 1993), the coordination of the socioemotional initiatives of the self and a sensitive partner during early episodes of social play is likely to consolidate this nascent representational capability by 3 months of age.

Social play is not the only interactive context for the development of early social discriminations and expectations. In light of the salience of distress, the association between parental soothing and subsequent relief is likely to be meaningful and easily learned by an infant, contributing to expectations that an adult's arrival will bring distress relief (M. Lamb, 1981). In this context, differences in adult responsiveness are again likely to be important, at least to the extent that they affect developing expectations for the caregiver's arrival and soothing when infants are upset. Several research groups have found that by 6 months, distressed infants began quieting in apparent anticipation of the arrival of their mothers when they could hear the adult's approaching footsteps; infants also protested loudly if the adult approached but did not pick them up (Gekoski, Rovee-Collier, & Carulli-Rabinowitz, 1983; M. Lamb & Malkin, 1986). These studies suggest that during the initial months of the 1st year, infants are learning the association between their distress, a caregiver's approach, soothing ministrations, and subsequent comfort. Much more research is needed to understand the effects of reliable differences in the caregiver responsiveness (such as differences in the adult's efficacy in soothing the infant) on these emergent social expectations related to distress relief, especially as they are mediated by the infant's emotional tendencies.

### **Intentions and Inferring Intentionality**

Interest in face-to-face play wanes after 7 months as infants become more mobile and interested in more active

forms of interaction. The growth of self-produced locomotion not only changes infant-parent interaction but also is, according to Campos and his colleagues, a setting event for a variety of socioemotional and conceptual advances in the child (Campos, et al., 2000; Campos, Kermoian, & Zumbahlen, 1992). These advances occur because locomotor experience dramatically changes the relation of the infant to the environment. Rather than merely reaching toward objects or responding to events that appear before them, infants are now capable of approaching objects and people of interest and initiating independent exploration. As a consequence, self-produced locomotion is associated with a cascade of conceptual changes related to person-environment relations (such as postural compensation to changes in peripheral optic flow perception, advances in distance perception and increased wariness of heights, and more sophisticated spatial search strategies), which include advances in referential communication, means-ends understanding, and social interaction across a distance.

The onset of locomotor experience is also associated with socioemotional changes in the infant and challenges for the family system. The infant's independent locomotion means that the child is becoming capable of wandering away from the parent, acting in a dangerous or disapproved manner, and pursuing independent goals, together with the feelings of self-efficacy of doing so. Parents respond to these changes by more vigilantly monitoring the infant's activity (and childproofing the house), using distal communicative modes (such as calling across a distance), and intervening more often with distractions, prohibitions, and sanctions and thus, at times, frustrating the infant's goal-directed efforts. The stage is set, therefore, for a significant conflict of intention between the infant and parent. Indeed, at the same time that attachment security is emerging, infant-parent relationships are being shaped by how each partner is negotiating the challenges associated with the onset of infant locomotor activity. Parental reactions to this developmental transition are likely to vary significantly. The evolution of offspring from immobile to self-propelled excites most parents, but many also find that the monitoring, intervening, and proaction required to supervise a mobile child is a significant new challenge for them, along with the conflict of wills and testing of limits that accompanies infants' responses to their efforts. A parent's capacity to re-

main sensitive to and supportive of the infant's emergent competencies during this period contributes to maintaining parent-infant harmony just as parental coercion and frustration are likely to undermine it.

There are thus many reasons to perceive the locomotor transition as a catalyst for early socioemotional and conceptual development and for parent-infant relationships. But the social consequences of this transition have been little studied thus far. In an exploratory study, Campos and colleagues (1992) interviewed the mothers of locomotor and prelocomotor 8-month-olds and found that mothers' perceptions of the child and reports of their own activities varied significantly based on the child's locomotor status. The parents of locomotor infants indicated that they used more verbal prohibitions, had higher expectations for the child's compliance, and engaged in greater disciplinary activity than did the parents of prelocomotor infants. Parents also reported that their offspring showed greater sensitivity to the parents' location and emotional signals, and exhibited increased expressions of anger and frustration, but also showed more intense affectionate behavior.

Observational studies provide some support for these interview results. Biringen, Emde, Campos, and Appelbaum (1995) reported—in an age-held-constant observational study—that the onset of walking was accompanied by greater “testing of wills” between mothers and infants in prohibition contexts, and by diminished maternal praise of the child, although there were no differences in infant emotionality. Zumbahlen and Crawley (1996) observed a greater number of parental prohibitions directed to crawling than nonlocomotor infants, and that crawling infants showed greater anger and also more often visually checked back with the parent across a distance. In another age-held-constant observational study, Hendrix (2004) reported that the mothers of locomotor infants used “no” more often in a prohibitive context compared to mothers of prelocomotor infants, but there were no group differences in proactive discipline (such as using distractors), child compliance, or infant emotional reactions. The parents of locomotor infants also reported using a greater number of discipline practices at home. Some of these studies have also reported changes in parental behavior over time *regardless* of the child's locomotor status, such as greater childproofing of the home (Hendrix, 2004). This suggests that the anticipation of the baby's self-produced locomotion is important to parents, helping them to prepare for the physical

maturation and behavioral competence of their young offspring and the new requirements of their parenting.

That the growth of independent locomotion during the second half of the 1st year is associated with significant changes in parent-child interaction derives, in part, from how locomotion contributes to a more agentic and goal-directed infant. The emergence of intentional, goal-oriented behavior has been a familiar characterization of the 8- to 12-month-old infant from Piaget's (1952) description of the fourth sensorimotor substage. As Campos and his colleagues (2004) have noted, locomotion spurs more sophisticated means-ends behavior because infants must maintain a specific goal in mind (such as moving toward an interesting object) while assembling the specific movements and secondary strategies necessary for achieving it. Not only are infants becoming more volitional during this transition but also, as a consequence, they are being exposed to a range of social responses that underscore the discordant intentions of others, whether they consist of parental prohibitions, verbal admonitions (conveyed in the tone of voice), cautionary facial expressions in response to social referencing, or other forms of referential communication. Self-produced locomotion enhances the expression of infant volition, and also contributes to an awareness of others' intentions (Campos et al., 2000). Indeed, these may be developmentally allied achievements because of how parental interventions over conflicting goals enhance the salience of the volition of another as it contrasts with the infant's own, and motivates efforts to comprehend the difference (see also Tomasello, Carpenter, Call, Behne, & Moll, *in press*; Tomasello & Rakoczy, 2003).

There are many indications that by 9 to 12 months, infants begin to perceive peoples' actions as intentional and goal directed as infants interpret actions in relation to the objects to which they are directed. In a study by Woodward (1998), for example, infants were habituated to a scene of a hand reaching across a stage to grasp one of two toys. After habituation, the positions of the toys were reversed and the hand either reached to grasp the original toy in its new location (requiring a different trajectory) or a new toy in the original location (using the same reaching motion as before). Six-month-olds and 9-month-olds each looked longer to the latter trials, suggesting that infants had encoded the original action as directed to a particular toy. In this study, infants did not respond comparably when a mechanical arm rather than a human hand reached to grasp the objects, consistent

with infants' differential encoding of human and nonhuman activity. At least by 7 months of age, for example, infants distinguish the movement of people as being self-initiated whereas objects move by external force (Spelke, Phillips, & Woodward, 1995), and this may occur even earlier (Legerstee, 1994). Using a similar habituation procedure, Woodward has also shown that by 12 months, infants understand the object directedness of a person's gazing (Woodward, 2003) and pointing (Woodward & Guajardo, 2002) and have also begun to comprehend the distinction between goals and the actions enacted to achieve them (Woodward & Sommerville, 2000). Baldwin, Baird, Saylor, and Clark (2001) have likewise shown that 10- to 11-month-olds organize their perceptions of people's actions by the completion of goal-directed activity (see Baird & Baldwin, 2001).

Inferences of the intentions underlying actions like reaching, gazing, and pointing are easy for infants to comprehend because they are the same actions that often express their own intentions. By 6 months of age, infants are familiar with the sight of their own hand reaching toward an object and may be more likely, as a consequence, to interpret other object-directed reaches they observe as similarly goal oriented. Understanding the object directedness of gazing and pointing emerges later with growing comprehension of referential communication and joint attention. Moreover, when caregivers respond to the intentionality they infer in the behavior of their infant offspring, they also scaffold emergent comprehension of the intentional structure of behavior (Meins, Fernyhough, Fradley, & Tuckey, 2001; Meins et al., 2003). When mothers punctuate their verbal responses to the infant's goal-directed activity with affirmative utterances when the goal is achieved, for example, they help to parse the sequence of behavioral acts in terms that organize the perception of behavior in goal-oriented units. Caregivers who are attuned to the intentional orientation of infant behavior (or "mind-minded," according to Meins and her colleagues; see Meins et al., 2001, 2003) are especially likely to interactively scaffold early comprehension of the goal orientation of behavior in these ways.

The perception of people as subjective, intentional agents is a signal accomplishment for early social cognitive development. By the first birthday or shortly thereafter, there are further indications that infants are responding in a more sophisticated manner to the actions of people as subjective, intentional agents (see

Carpenter, Nagell, & Tomasello, 1998, Tomasello, 1995a, 1999, and Tomasello & Rakoczy, 2003 for reviews). Infants create joint attentional states with adults by looking in the direction of the adult's gaze or looking from a toy to the adult's face and back to the toy again. They not only follow an adult's gaze but also look in the direction of the adult's pointing or gesturing. They produce protodeclarative gestures (such as pointing to or holding up an object while alternating gaze between the object and the adult's face) and protoimperative gestures (such as reaching for an object while alternating gaze between the object and the adult's face), each apparently intended to alter the adult's subjective orientation and elicit a desired response. They also exhibit social referencing behavior (discussed later). To be sure, there has been some debate over whether these behaviors reflect true perceptions of intentionality rather than conditioned learning of social behavior (Moore & Corkum, 1994) or affective sharing (Baldwin & Moses, 1996). However, the intercoordinated developmental emergence of these achievements suggests that a more fundamental transition has occurred in the infant's person perception. By the first birthday, infants have begun regarding people as intentional agents with subjective viewpoints that can be altered. Later in the 2nd year, further evidence of this transition emerges with the ability of 14- to 18-month-olds to imitate adults' intended rather than accidental actions (Carpenter, Akhtar, & Tomasello, 1998; Meltzoff, 1995), their enlistment of inferences concerning the intentions of adult speakers in learning new words (Baldwin, Markman, Bill, Desjardins, & Irwin, 1996; Tomasello & Barton, 1994), and their use of intention inferences in new social learning (Carpenter, Call, & Tomasello, 2002). There are many further advances in intentionality understanding after age 2. Young children have much to learn about how intentions connect to other mental states, the influences that mediate the transition from intention to action, and the nature of nonintentional action, as well as other psychological processes.

Understanding people's behavior as goal directed and intentional takes the infant a long way toward a mentalistic comprehension of human behavior, but observing rather prosaic behaviors like reaching and pointing does not provide much insight into how infants begin to understand the salient experiences of social interaction. Little is known of how a dawning appreciation of other people as subjective, intentional agents alters other features of developing social cognition and the growth of infant-

parent relationships. How much does the emergent "testing of limits" of the toddler period, for example, arise from the young child's perception of the adult's intentionality when blocking, deterring, or otherwise frustrating the child's goal-directed activity? How does a 1-year-old interpret an adult's emotional behavior in relation to objects in the framework of intentionality inferences? How does this infant regard the intentionality of the adult's emotional behavior toward herself? Are a caregiver's nurturant actions perceived by a 1-year-old as intentional and goal directed, and how is this related to emergent social expectations and the developing security of their relationship? Twelve- to fourteen-month-old infants enlist emotional demeanor and gaze direction in their inferences of the intentions of an adult actor toward toy kittens (Phillips, Wellman, & Spelke, 2002). Do toddlers derive similar intentionality judgments in their observations of everyday social behavior?

### Social Referencing

Limited answers to such questions can be gleaned from the research on social referencing (Campos & Stenberg, 1981; Klinnert, Campos, Sorce, Emde, & Svejda, 1983). Social referencing describes the use of another's emotional cues to clarify the interpretation of an ambiguous or uncertain event. The enlistment of this emotional information may derive from active information seeking (such as when one adult looks to another's face to clarify the meaning of an ambiguous statement) or may capitalize on the availability of another's emotional cues in the course of affective sharing or seeking reassurance (Baldwin & Moses, 1996). In either case, the importance of social referencing is twofold. First, it indicates that by the first birthday, infants are fairly good consumers of the emotional cues of others and can enlist this information in their own responses to events. Second, social referencing inaugurates the processes by which young children vicariously acquire an understanding of events through the signals provided by others and thus appropriate socially constructed meaning systems. Both are lifelong features of social development.

The research on social referencing indicates that it has important but modest effects on infant behavior (Feinman, Roberts, Hsieh, Sawyer, & Swanson, 1992). The influence of social referencing is especially apparent when infants are uncertain how to respond, but another's emotional cues can be influential even when they are not unsure (Feinman et al., 1992; Zarbatany &

Lamb, 1985). Hertenstein and Campos (2004) have demonstrated the retention of social referencing influences for up to 1 hour in 14-month-olds, but much more research into the longer-term effects of social referencing is needed. Infant responses to uncertain situations can be influenced by facial expressions alone (e.g., Klinnert, Emde, Butterfield, & Campos, 1986; Sorce, Emde, Campos, & Klinnert, 1985; Zarbatany & Lamb, 1985), vocal cues alone (Mumme, Fernald, & Herrera, 1996), multimodal emotional cues (sometimes including gestures; e.g., Hirshberg & Svejda, 1990; Hornik, Risenhoover, & Gunnar, 1987; Walden & Ogan, 1988), and even televised images (Mumme & Fernald, 2003). In everyday situations, infants commonly have access to the unsolicited multimodal emotional cues of their caregivers as they traverse, experiment, and explore the limits of their known universe.

Consistent with the research on infants' understanding of the subjectivity of others' actions, social referencing studies have also shown that as young as 12 to 14 months of age, infants understand the object specificity of another's emotional message (Hornik et al., 1987; Repacholi, 1998; Walden & Ogan, 1988), and can use that person's referential cues, such as gaze direction, to guide the interpretation of the person's emotional expressions (Moses, Baldwin, Rosicky, & Tidball, 2001). This suggests that another's emotional message has considerable informational value for 1-year-olds because they can comprehend its referential intent. But the emotional cues of an adult also have emotional impact, and studies have shown that the adult's signals influence the infant's general emotional demeanor, especially toward the object of referential focus (Hirshberg & Svejda, 1990; Klinnert et al., 1986; Moses et al., 2001; Mumme et al., 1996; Sorce et al., 1985). These dual influences of social referencing are not inconsistent. When reading another's emotional expressions in the presence of an ambiguous event, infants are emotionally alerted by the adult's affective demeanor at the same time that they are interpreting the meaning of this demeanor for the event of shared referential focus.

Social referencing illustrates, therefore, the sensitivity of 1-year-olds to the meaning underlying an adult's emotional orientation. By the beginning of the 2nd year, 1-year-olds comprehend that another's emotional expressions can be evoked with reference to a specific object or event, and this knowledge influences their interpretation of that event. This awareness is enlisted not only in situations when infants are uncertain about

ambiguous events but also in circumstances when caregivers' emotional expressions serve to alert, caution, interest, reassure, or otherwise motivate their young offspring in relation to events of shared attention. In these circumstances, the same understanding of object specificity and referential intent enables infants to comprehend that the adult's sharp, imperative voice is with reference to the potted plant that the child is reaching toward, or that the caregiver's smiling expression provides reassurance with respect to the kitten they are stroking.

In light of these early achievements in referential understanding and emotional communication, it is somewhat surprising that there has not been exploration of further development in these processes during the 2nd and 3rd years, when a young child's interpretation of the psychological meaning of an adult's emotional expressions becomes more insightful. Studies of early language acquisition show that as early as 18 months, for example, toddlers' inferences of the intentions of adult speakers—usually gleaned from their emotional displays—provide a basis for initial word learning (e.g., Baldwin, 2000; Baldwin et al., 1996), and future research might be devoted to examining other conceptual achievements that are facilitated by early emotional communication. For example, what does it mean for a young child's perception of other people, especially other family members or peers, when they are the targets of a caregiver's emotionally referential focus? When do young children begin to comprehend that they can themselves be objects of an adult's emotional responding, and what is the impact of this awareness for early self-concept and the development of security in close relationships? Variations in emotional communication appear to be relevant to the earliest feelings of self-confidence and pride when the adult's referential focus on the child or the child's accomplishments is accompanied by emotionally affirmative cues (Stipek, 1995). Conversely, emotional communication can be enlisted by parents in conveying behavioral standards (such as looking sternly at the child who is initiating disapproved activity) and in inducing shame or guilt when these standards are violated (Emde & Buchsbaum, 1990).

The impact of social referencing experiences on the adult also merits further research attention. Informal observations of spontaneous referencing behavior in my laboratory indicate that parents are acutely aware of the social referencing of their young offspring and often deliberately pose salient emotional expressions to reassure, instill caution, and provide other socioemotional

messages. If this is true, it suggests that social referencing should be viewed as a dyadic process of referential communication through which infants and young children appropriate an understanding of events of significance to them, and caregivers facilitate that understanding through deliberate emotional cuing.

### Understanding Social Events

After 18 months, a transition occurs in psychological development when young children strive to comprehend normative standards for the social world. Developmental scientists have observed this in many behavioral domains. With respect to early conscience, for example, this is the period when toddlers respond with heightened interest and concern to objects that are damaged or flawed, applying normative standards for the wholeness, appearance, and integrity of objects (Kagan, 1981, *in press*; S. Lamb, 1993). As discussed later, this subsequently becomes manifested in an intuitive morality that causes young children to regard rules as obligatory, even though children commonly violate them (Wellman & Miller, 2003). With respect to the development of self-awareness, the responses of 18-month-olds to the familiar rouge task not only reveal self-recognition before a mirror but also their evident embarrassment when detecting a spot of red on their noses (Lewis, 2000; Lewis & Brooks-Gunn, 1979). Toddlers have internalized a normative standard for their physical appearance that does not include a rouge-marked nose. One of the most important manifestations of the young child's search for normative standards at this age is in language development, where they strive to comprehend the appropriate nominal reference of the words they are acquiring at such a rapid pace (Tomasello & Rakoczy, 2003).

With respect to event representation, young children reveal further their search for normative standards. By the end of the 2nd year, they begin to create generalized scripts for familiar social experiences such as bedtime rituals, mealtimes and other regular family routines, arrivals and departures from child care, and other common events (Hudson, 1993; Nelson, 1978, 1989; Nelson & Gruendel, 1981). These scripts provide a conceptual scaffold for knowledge of general routines and for memory of specific experiences that incorporate routine events, and they constitute the young child's normative expectations for how those routines should occur in the future. Indeed, young children can be inflexible in their fidelity to scripted expectations (Hudson, 1990, de-

scribes one 2-year-old who became distressed when she was given her bath before—rather than after—dinner because she thought this meant that she would not be fed that evening). These scripts increase in complexity and scope throughout the preschool years as they become integrated into broader knowledge systems.

Studies by Nelson and her colleagues indicate that the content, organization, and structure of early event representation is shaped not only by the child's prelinguistic representation of experiences but also by the verbal structure applied to them in parent-child discourse. In the context of shared conversations, beginning as soon as children can talk about events, parents help to review, reconstruct, and consolidate young children's memory of generalized routines and specific experiences (Fivush, 1993; Hudson, 1990; Nelson, 1989, 1993a). Furthermore, parents often help children to anticipate future events, and the verbal structure they provide may help to organize the child's representation of that experience as it subsequently occurs (Nelson, 1989, 1993a). There is also evidence that the style of parental discourse is important. Parents who are more elaborative in their conversational style provide considerable background and contextual information in their shared discussion of events in the child's life. Several studies have found that the offspring of more elaborative mothers have a more complete and sophisticated representation of their past experiences (including representations of routine events) not only owing to the direct impact of parental discourse style but also because of the child's appropriation of the adult's narrative approach (Hudson, 1990; Nelson, 1993a; Reese & Fivush, 1993).

Generalized event representations, or scripts, provide a foundation for young children's understanding of social events. However, with researchers' focus on rather prosaic routines (such as restaurant visits), little is known about how young children represent everyday experiences that involve greater emotional and relational depth such as separations and reunions, bedtime routines, and distress relief. Such events are important in how young children comprehend emotion and relationships, the quality of parental nurturance, and the reliability of care. The child's direct experience of these events, as well as the verbal structure of parental discourse in subsequent conversation, are each important to how children comprehend these experiences. Further study of children's representations of these experiences may also contribute to understanding the origins of the differences in relational security and trust that underlie parent-child attachment.

### Feelings and Desires

Social referencing research is important because it illustrates the significance of emotion to the infant's behavioral regulation and to social understanding. Social referencing is important also because processes of emotional communication are ubiquitous in child-parent interaction, including the routine events that are the foundation for generalized event representations. Not surprisingly, among the most important subsequent advances in early social cognition is developing understanding of people's desires, beliefs, and feelings (Thompson & Lagattuta, 2005).

Toddlers display a remarkable comprehension of the differences between people in what they desire, contrary to the traditional portrayal of early egocentrism. In an important study, Repacholi and Gopnik (1997) presented 14- and 18-month-olds with two snacks: goldfish crackers (which the children liked) and broccoli (which the children disliked). Then the adult tasted each snack, smiling and exhibiting pleasure ("mmmm!") with one, and frowning and saying "ewww!" with the other. In the "match" condition, the adult's preferences were the same as the child's; in the "mismatch" condition, the adult preferred the broccoli and disliked the crackers. Then the adult extended her hand and said, "I want some more, can you give me more?" The 18-month-olds (but not the younger toddlers) reliably gave the adult the food she desired in both the match and mismatch conditions. By contrast, the 14-month-olds overwhelmingly gave the adult more goldfish crackers. The sensitivity to differences in desire among 18-month-olds is consistent with evidence that spontaneous verbal references to desire emerge by 18 months, and somewhat later children use contrastive statements about desire (e.g., comparing what one person wants with what another desires; Bartsch & Wellman, 1995).

By age 2, toddlers can be overheard making spontaneous verbal references to emotions, the causes of emotion, and even emotion regulatory efforts (e.g., "I scared of the shark. Close my eyes" at 28 months; Bartsch & Wellman, 1995; Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986; Brown & Dunn, 1991; Dunn, Bretherton, & Munn, 1987; Wellman, Harris, Banerjee, & Sinclair, 1995). The emergence of expressive emotion-related utterances is preceded by months of receptive comprehension of emotion-related discourse (Ridgeway, Waters, & Kuczaj, 1985). Careful analysis of the content of young children's emotion references has shown that even in their initial utterances,

children regard emotions not just as behavioral events but as subjective, psychological conditions, distinct from the situations and behaviors with which they are associated. By contrast with their descriptions of pain, for example, children as young as 2 describe emotion as referential (e.g., sad *about* something) and involving volition, consistent with their developing understanding of intentionality and referentiality. Moreover, even in these initial utterances, toddlers explicitly differentiate people's feelings, often contrasting another's emotions with their own in a nonegocentric manner (Bartsch & Wellman, 1995; Wellman et al., 1995). By age 2.5, young children comprehend better the connections between desire and emotion: People are happy when they get or see what they want and unhappy when their desires are denied (Repacholi & Gopnik, 1997; Wellman & Woolley, 1990).

It appears that early childhood witnesses the growth of young children's intuitive theories of emotion that incorporate not only the belief-desire reasoning described by theory of mind researchers but also their dawning understanding of the internal (including visceral) and external determinants of emotion, the subjectivity and referentiality of emotional experience, the outcomes of emotional arousal, and emotional regulatory processes. These intuitive theories of emotion expand markedly during the preschool years (Denham, 1998; Fabes, Eisenberg, Nyman, & Michaelieu, 1991). In their efforts to comprehend the causes of emotion, preschoolers begin to conceptually map the typical situations and goal states that are associated with different feelings, such as that blocked goals elicit anger and loss is associated with sadness (Harris, 1989; Stein & Levine, 1989). This reflects their awareness that both situational and internal factors are relevant to eliciting emotion (Dunn & Hughes, 1998; Fabes et al., 1991). For example, 3-year-olds know that feelings are associated with beliefs and expectations about events such as the surprise a visitor feels after seeing giraffes on a farm (Wellman & Banerjee, 1991). Young children's understanding of the connection between emotion and thought is also revealed in their appreciation that feelings can be evoked by mental reminders of past emotionally evocative experiences. By age 5, for example, children understand that someone can feel sad when seeing a cat who reminds her of a pet who ran away (Lagattuta, Wellman, & Flavell, 1997; see also Lagattuta & Wellman, 2001). Young children are thus beginning to comprehend the personal and idiosyncratic influences on emotional responding (Dunn & Hughes, 1998).

As a consequence of these causal understandings, and perhaps also because they are more motivated to do so, young children better understand the causes of negative than positive emotions they observe in others (Dunn & Hughes, 1998; Fabes et al., 1991). Their understanding is limited, however. Young children have considerably greater difficulty understanding how emotions can be based on *false* belief, for example, and it is not until about age 6 that they appreciate that someone will feel delighted before opening a box of candy because she thinks it contains chocolates rather than the pebbles her older brother has substituted (de Rosnay & Harris, 2002; de Rosnay, Pons, Harris, & Morrell, 2004; Harris, Johnson, Hutton, Andrews, & Cooke, 1989). Moreover, consistent with the younger child's straightforward association of emotions with specific mental states, it is not until middle childhood that children begin to grasp that multiple emotions of different valence can be experienced simultaneously, and that ambivalence and emotional equivocation can occur (Harter & Buddin, 1987; Wintre & Vallance, 1994).

Young children's developing understanding of how to manage or regulate their emotions reflects these conceptions of the origins of emotional experience (see reviews by Thompson, 1990, 1994). In early childhood, preschoolers believe that emotion can be managed by fleeing, removing, restricting perception of, or ignoring emotionally arousing events, revealing an awareness of the connections between emotion, perception, and thought. Children also recognize that emotion can be managed through reassuring self-talk, seeking nurturance, ceasing to think about emotionally arousing events, distraction, or other strategies that change the mental states that contribute to emotional arousal (Harris, Guz, Lipian, & Man-Shu, 1985; Lagattuta et al., 1997). Consistent with their developing comprehension of the distinction between appearance and reality, older preschoolers also begin to understand the value of managing emotional expressions to dissemble one's feelings or protect the feelings of others, and they begin to use display rules in everyday circumstances (Banerjee, 1997; Cole, 1986). The intuitive theories of emotion that guide young children's understanding of the origins of emotions are also enlisted in their efforts to regulate emotional arousal.

Young children are highly motivated to understand emotions because their desires and feelings are compelling experiences and others' emotions are salient and significant influences on them. Although desires and emotions may seem conceptually simple (especially by

comparison with other mental states), they are actually quite challenging for young children to understand because they are invisible, multidetermined motivators of behavior. Emotions have complex internal causes and can be manifested in diverse facial, vocal, and behavioral expressions that are not always intercoordinated, which makes understanding the associations between desires, feelings, perceptions, beliefs, and behavior a conceptually daunting task.

Young children are assisted in developing coherent intuitive theories of emotion, however, by their conversations with adults who label, describe, and explain the causes and consequences of the emotion to them (Thompson, Laible, & Ontai, 2003). The influence of these verbal references to emotion begins early: In one study, references to feelings by mothers and older siblings when toddlers were 18 months were positively correlated with the child's emotion-related utterances at 24 months (Dunn et al., 1987). With increasing age, emotion-related discussions are integrated into conversations of recent events or current experiences, story reading, talking about upcoming events, personal storytelling, or other conversational forums. The influence of these conversations on emotion understanding derives from (a) the growth of language competence that provides a lexical foundation to shared understanding of psychological experiences that are otherwise difficult to define, comprehend, or convey to another; and (b) adult mind-mindedness that causes them to induct young children into the psychological world they inhabit whenever they talk with the child about people. Thus, whenever young children ask "why" about the feelings and behavior they observe in others, they are tutored about the mental world by adults who cannot help but do so because psychological understandings of people have become intuitive to mature thinkers. Moreover, language also enables thought about emotional experience outside of its immediate context, when young children (and often their parents) are more capable of thoughtful reflection and discussion. Indeed, language content and structure has many potentially important influences on the growth of psychological understanding in children (see Budwig, 2002, for a review of these), but the essential feature of these linguistic contributions is that they are also social.

Parent-child conversation about desires, feelings, behavior, and thought thus helps to organize psychological understanding through the lexicalization of mental and emotional life: Words categorize psychological experience in ways that provide coherence and a basis for

shared reference and understanding. They help to make explicit the implicit knowledge that young children have intuited. When preschoolers discuss desires and feelings with an adult, they also begin to comprehend that the same event can be experienced differently by people who may feel differently about it (Levine, Stein, & Liwag, 1999). Conversational discourse enables young children to compare their own representation of an experience with that of the adult, and by comparing primary and secondary representations (the latter conveyed in shared conversation) young children are likely to derive new ways of understanding and thinking about personal experiences. More broadly, conversations about emotions provide a forum for the transmission of cultural values, causal attributions, moral evaluations, and other belief systems of the caregiver that are also part of the adult's intuitive understanding of the psychological motivators of people's behavior. As a consequence, young children learn about emotion in conversations that can link emotion to standards of conduct and social awareness. This may explain why parental conversational references to feelings are a more significant predictor of early conscience development than are parents' explicit references to rules (Laible & Thompson, 2000).

Parents who discuss emotions more frequently and with greater elaboration, therefore, have children with more accurate and richer conceptualizations of emotion (Brown & Dunn, 1996; Denham, Zoller, & Couchard, 1994; Dunn, Brown, & Beardsall, 1991; Dunn, Brown, Slomkowski, Tesla, & Youngblade, 1991; Fivush, 1993; Jenkins, Turrell, Kogushi, Lollis, & Ross, 2003; Laible, 2004a, 2004b; Ontai & Thompson, 2002). There are many elements of elaborated, emotion-related discourse that are likely to provoke young children's emotion understanding, including the adult's descriptive statements, explanations of the causes of emotion or its consequences, linking emotion in another person to the child's experience, asking questions of children that further their understanding of emotion, and coaching children in strategies of emotion management (Ontai & Thompson, 2002). The frequency of mothers' and children's emotion references and, in particular, their talk about the causes of emotion are especially influential for the development of emotion understanding (Brown & Dunn, 1996; Dunn & Brown, 1993; Dunn, Brown, & Beardsall, 1991; see also Dunn, Brown, Slomkowski, et al., 1991), although more research on this issue is necessary. Parents and young children tend to discuss negative emotions more frequently than positive feelings

because the former are conceptually more complex and are also more troubling to the child, and thus there is a stronger inherent need to understand, regulate, and/or prevent intense negative feelings (Lagattuta & Wellman, 2002). Parents also talk about emotions differently with daughters than with sons, using more elaboration, reassurance, and a greater relational focus in their emotion-related conversations with daughters (Fivush, 1998).

Research on the influence of parent-child conversation on the early development of emotion understanding also highlights two other conclusions. First, conversations with adults are not the only important conversational catalysts to emotion understanding. Young children talk about feelings and thoughts more frequently with friends and siblings than they do with their mothers (Brown, Donelan-McCall, & Dunn, 1996), and these conversations also contribute significantly to children's developing understanding of emotion (Hughes & Dunn, 1998). Sibling interactions (especially interaction with an older sibling) offer unique contexts for the growth of emotion understanding, such as in pretend play that permits animated role taking of feelings and coping strategies (Dunn et al., 1991; Youngblade & Dunn, 1995), and sibling conflict that involves negotiating desires and needs with other family members (Dunn & Herrera, 1997; N. Howe, Patrakos, & Rinaldi, 1998). These contexts for emotion conversation among co-equals may be even more provocative of developing emotion understanding because young children can be more direct in conveying their own desires and emotions and their reasons for feeling these ways.

Second, by contrast with simple constructivist or socialization models of the development of knowledge, the growth of emotion understanding derives from an interaction of a child's comprehension of psychological realities with the catalysts of the adult's psychological references in shared conversation. Both the child's constructivist effort and the adult's provocation are important, and probably necessary. Young children clearly have powerful inductive capacities for comprehending psychological states in themselves and others, but to assume that children build theories about mental states independently of the scaffolding of child-parent discourse and other relational incentives may overstate either the insightfulness of the child's inductive inferences or the clarity of the observational material on which the young child relies. Considerably more research is needed, however, to understand how these discourse elements interact with the child's conceptual capabilities and other

social influences in helping children to develop more sophisticated understanding of the psychological world.

Because of this, an essential future research task is to understand the broader network of relational influences that are associated with differences in parent-child conversational discourse about emotion. It seems likely that individual differences in the richness of adult speech about psychological states would be complemented by other affective dimensions of the parent-child relationships. Securely attached children are more advanced in emotion understanding (Laible & Thompson, 1998; Ontai & Thompson, 2002; Raikes & Thompson, 2005a), for example, and the broader family emotional climate, the adult's emotional expressiveness, and other features of early emotion socialization have important influences on young children's developing emotion understanding (Denham, 1998; Raikes & Thompson, 2005a). The few studies that have assessed the importance of emotional influences in the family in relation to conversational discourse find that each are important to emotion understanding (e.g., Denham et al., 1994). Further study of this question is necessary, however, for understanding how developments in young children's conceptual comprehension of emotion are facilitated by language, elements of the family emotional climate, and their interaction.

### Understanding Psychological Characteristics and Social Roles

After age 3, other significant advances occur in young children's understanding of the psychological world. Most notably, children develop a more fully representational view of the mind that incorporates an awareness that beliefs can be inconsistent with reality (Wellman, 2002; Wellman, Cross, & Watson, 2001). Young children's dawning understanding of false belief is significant not only because it reflects an awareness of the potential independence of mental events from objective reality but also because it is a gateway to the comprehension of other psychological realities such as the privacy of personal mental experience, the induction of mistaken beliefs in others, and the mind's activity independent of experience (e.g., interpretations, expectations). For these reasons, there has been a significant research literature exploring the origins of this developmental achievement that is more extensively reviewed in another chapter of this *Handbook*.

Individual differences in children's understanding of false belief are strongly correlated with differences in

emotion understanding (Cutting & Dunn, 1999; de Rosnay et al., 2004; Hughes & Dunn, 1998). Both capacities rely on an awareness of the subjectivity of psychological states: People can share the same experience but be psychologically affected in different ways, thus the potential privacy of psychological experience. However, the association between emotion understanding and false belief awareness may also derive from their common association with differences in language ability, family background, or children's experiences in family relationships (Cutting & Dunn, 1999; Ruffman, Slade, Rowlandson, Rumsey, & Garnham, 2003). As with the research on conversational discourse and emotion understanding, for example, many studies have found that children's conversations with parents and peers about mental and emotional themes predict later differences in false belief understanding (Bartsch & Wellman, 1995; Brown et al., 1996; Dunn, Brown, & Beardsall, 1991; Dunn, Brown, Slomkowski, et al., 1991; Hughes & Dunn, 1998; Ruffman, Slade, & Crowe, 2002; Ruffman et al., 2003; Sabbagh & Callanan, 1998; Welch-Ross, 1995; see generally Astington & Baird, 2005). Sabbagh and Callanan (1998) found that when 3- to 5-year-old offspring initiated conversational references to the mind by implicitly contrasting different mental states or saying "I don't know," their parents often responded by highlighting the representational aspects of mental states, which commonly elicited further explicit mental state talk from their children. Other researchers have also found that parents' mental state causal language (Dunn, Brown, Slomkowski, et al., 1991) and explicit mental state discourse are especially important to the development of false belief understanding in children (e.g., Ruffman et al., 2002). A recent training study with 3-year-olds showed that only training conditions involving language improved children's subsequent performance on false belief tasks, and that language conditions involving both perspective-shifting discourse (i.e., discussing mental deception using deceptive objects, such as a pen that looks like a flower) and syntactic prompts (e.g., sentential complements such as "*Peter knows* that Mommy's home") were each independently effective (Lohmann & Tomasello, 2003).

These findings are consistent with the general view that adult discourse about phenomena that interest young children is influential in conceptual growth, especially when the phenomena are otherwise elusive or difficult for children to comprehend. Harris (in press; Harris & Koenig, 2005) has argued that children accept

the testimony, or claims, of adults on a wide range of issues of importance to them, from understanding the shape of the earth and other natural phenomena, to the association between mind and brain and other psychological phenomena, to the nature of God, the afterlife, and other metaphysical phenomena. Children early develop understanding of these phenomena based on their acceptance of the truthfulness of what they are told but cannot independently confirm, he argues, and this knowledge is readily integrated into knowledge systems based on personal experience. Young children are not passive recipients of this knowledge, of course, because their inquiries about animals, people's beliefs, or God provoke the conversations that inform them, and as they attempt to juxtapose their current conceptions with what they learn, children's comments, queries, and objections further guide the discussion. Research on the early growth of social and emotional understanding, and of mental states, is consistent with this view.

Recent studies indicate that individual differences in mental state understanding have surprisingly early origins. Wellman, Phillips, Dunphy-Lelii, and LaLonde (2004) reported that 14-month-olds who showed greater sensitivity to intentional human activity in a habituation procedure (see Phillips et al., 2002, and described earlier) were more proficient on a battery of theory of mind tasks at age 4. The source of the continuity over several years was unexplained, but relational influences may be pertinent. Meins and her colleagues (2002) found that 6-month-olds whose mothers commented on their actions in ways that reflected awareness of the baby's intentions, goals, or other psychological states (i.e., "mind-mindedness") were more advanced on false belief assessments at age 4. Ruffman, Perner, and Parkin (1999) noted that preschoolers' false belief understanding was even predicted by mothers' use of disciplinary procedures that involved asking the child to reflect on the victim's feelings. These findings suggest that individual differences in social cognitive development across the early years are related to the quality of early relational experience in ways that merit further study. Thus, the preschooler's inductive reasoning about psychological experiences in others has developmental antecedents from early in life.

The developmental outcomes of these differences in social cognitive competence are potentially important. Dunn, Denham, and their colleagues have found that individual differences in false belief understanding and emotion understanding each predict young children's

social competence in friendship with peers in contemporaneous and longitudinal assessments (Brown et al., 1996; Denham et al., 2003; Denham, Caverly, et al., 2002; Dunn, 1995; Dunn, Cutting, & Demetriou, 2000; see also Cutting & Dunn, 2002; Schultz, Izard, & Ackerman, 2000). Understanding the features of parent-child interaction and later conversation that contribute to these differences in psychological understanding—especially in the broader context of the emotional climate of the family—can contribute to a better grasp of the influences that contribute to the growth of interpersonal sensitivity in early childhood.

As with the research on conversation and emotion understanding, the contexts and partners with whom young children share their understandings of the mind are also important. Children commonly discuss their own feelings and mental states in conversations with their mothers, but when talking with peers or siblings *both* children share their views about mutual interests or concerns in positive, cooperative contexts (Brown et al., 1996; Dunn, 1999) or in negotiation or dispute resolution (Howe et al., 1998). False belief understanding was predicted, in one study, by mental state discourse between siblings and friends involving contrastives (i.e., differentiating one person's preferences from another's), activity suggestions involving mental terms (e.g., "*I think I'm gonna . . .*"), and assertions involving mental referents (Brown et al., 1996). In their encounters with peers and siblings, therefore, young children are likely to encounter discrepancies between their own mental states and those of another, and differences between another's descriptions of reality and the reality that the child knows.

Understanding false belief is complemented by other advances in psychological understanding in the late preschool years. By ages 5 and 6, for example, young children begin to perceive others in terms of psychological motives and traits and can predict future behavior on the basis of the traits they infer, including differences in ability (Heyman, Gee, & Giles, 2003; Heyman & Gelman, 1999, 2000; Yuill & Pearson, 1998). They have much to learn about traits as psychological entities, however, and this is revealed in their optimism concerning the controllability and changeability of traits in others that is also reflected in self-perception, as discussed later in this chapter (see Lockhart, Chang, & Story, 2002). By age 3 or 4, as discussed later, young children distinguish behavioral violations that are moral from those that are social conventional, regarding moral

violations as more serious due, in part, to their harm to others (Smetana, 1981, 1997; Smetana & Braeges, 1990). In making this distinction, they are tutored by their mothers who justify moral rules because of their interpersonal consequences (Smetana, Kochanska, & Chuang, 2000). Mother-child conversations also contribute to young children's essentialist thinking about gender differences (Gelman, Taylor, & Nguyen, 2004). Finally, older preschoolers also begin to consider fairness issues in relation to ingroup-outgroup relations, particularly associated with gender exclusion, although major advances in their comprehension of social roles and group processes awaits middle childhood (Killen, Pisacane, Lee-Kim, & Ardile-Rey, 2001; Theimer, Killen, & Stanger, 2001).

### Summary

At least three conclusions emerge from these literatures that point to future directions in research on early social cognition.

First, social experiences are uniquely generative of new understanding of people and the psychological world. Early infant-caregiver interactions contribute fundamentally to the development of generalized social expectations and specific expectations for the behavior of familiar partners. Emotional exchanges in infant-parent interaction contribute to the multimodal discrimination of emotional signals and later, in the context of social referencing, understanding of the referentiality of emotional cues. Changes in parent-child interaction associated with the growth of self-produced locomotion may help to foster developing perceptions of the intentionality and subjectivity of other people. Comprehension of everyday social events is aided by the organization and structure provided by adult discourse about these events. Emotion understanding is fostered not only by everyday emotional interactions between young children and their caregivers but also by parent-child and peer conversations that embed insight into the psychological world—people's desires, feelings, intentions, and thoughts—into discussions of everyday experiences. The semantics and structure of such conversations also usher young children into a broader appreciation of how mental events can be shared or divergent, beliefs can be accurate or inaccurate, and psychological experience can be hidden or disclosed. As parents naturally treat their offspring as psychological beings from infancy, commenting on their intentions and

feelings, punctuating their activity with nonverbal affirmations of goal achievement, and talking with them about the psychological world they inhabit, they induct the child into the world of the mind through their testimony. Contrary to a long tradition of social cognitive research, social cognition is not only the generalization of intellectual skills that children have independently constructed but also the unique developmental catalysts embedded into the everyday experience of social interaction from early in life.

Second, individual differences in social experience are important for differences in early social understanding. Differences in infants' experience in face-to-face interaction (such as when mothers are depressed) affect how they respond to the social overtures of other partners and may have more generalized influences on social expectations. Differences in early parental sensitivity and "mind-mindedness" during the 1st year may be important for how young children begin to comprehend the nature of others' intentions as they are gradually constructing a theory of mind. Differences in the content, richness, and structure of parent-child conversations are important for individual differences in the growth of emotion understanding, comprehension of false belief, and other elements of psychological understanding that are predictive of important dimensions of socioemotional competence in the preschool years and beyond. Although the tenor of research on developing social cognition (particularly theory of mind) has little attended to individual differences in these developmental processes and their implications, recent research shows how important early social influences are for the emergence of differences in social expectations, dispositions, and beliefs in the early years. Further study along these lines is warranted.

Third, integrating understanding of early social cognitive development from cognitivist perspectives and social viewpoints is important to theories of socioper-sonality development, especially those that emphasize the representational dimensions of early relational experience. The developmental account of early psychological understanding is the account on which a theory of the development of "internal working models" derived from early attachments, for example, should be based. More generally, such an integrative approach to further research on early social cognition is likely to contribute added insight to the growth of sociability and the understanding of mind by highlighting how the powerful inductive capacities of the young child's thinking

juxtapose with the incentives of social experience to yield conceptions of the psychological world that are rich, informed, and individualized (Dunn, 1996; Harris, 1997, 1999).

## RELATIONSHIPS

Young children develop in an environment of relationships.<sup>1</sup> Their experiences over time with people who know them well, and whose characteristics and tendencies children begin to comprehend, are core influences on early conceptual and sociopersonality development (Committee on Integrating the Science of Early Childhood Development, 2000). This theme runs across the literatures surveyed in this chapter and in many other developmental formulations. These include the viewpoints of neo-Vygotskian theorists and other students of cognitive growth, discussed in the previous section, who emphasize relational influences on the construction of early thinking and understanding (e.g., Nelson, 1996; Rogoff, 1990). They include research on parent-infant interaction, parent-child relationships, and inquiry into the influence of sibling relationships, peers, and other social partners discussed elsewhere in this *Handbook* (e.g., Dunn, 1993, 2004). They include the work on social networks and social support that highlights how relationships are developmental catalysts and avenues for enhanced knowledge and information, skill acquisition, and emotional support through their stress buffering, scaffolding of new competencies, social exchange, and other influences from an early age (e.g., Cochran, Larner, Riley, Gunnarsson, & Henderson, 1990; Thompson, 1995; Thompson, Flood, & Goodvin, 2005). Current work in developmental psychopathology also emphasizes the centrality of close relationships to the constellation of risk and protective factors that predict the emergence of child pathology or psychological well-being (Cicchetti & Cohen, 1995; Cicchetti, Toth, & Lynch, 1995). Indeed, it is time for developmental scientists to begin integrating these multifaceted perspectives into a coherent developmental relational science.

Relational processes have been extensively studied in early development. In parent-child interaction, these processes include the caregiver's warmth, sensitivity, and contingent responding, the scaffolding of shared ac-

tivity, the emotional climate of the home, the verbal richness of family interaction, incentives for exploratory competence, expectations for mature behavior, imitative learning, conceptual catalysts in parent-child conversational discourse, parent's flexibility and adaptability, the use of proactive discipline, processes of negotiation and bargaining between parent and child, family routines and rituals, the effects of physical punishment, the child's construals of the adult's behavior, and the dyad's attachment security, shared positive affect, emotional synchrony, and mutual responsiveness (Baumrind, 1973, 1996; Grusec & Goodnow, 1994; Grusec, Goodnow, & Kuczynski, 2000; for general reviews, consult Laible & Thompson, in press; Maccoby & Martin, 1983; see also Parke & Buriel, Chapter 8; Saarni et al., Chapter 5, this *Handbook*, this volume).

The outcomes of these multifaceted relational influences on social and personality development are equally diverse and include the development of social skills, social expectations, emotion regulation, behavioral self-control, relational schemas, self-confidence, trust in others, social and emotional understanding, conscience development, and the enhancement or deterioration of emotional well-being and psychological competence. The relational influences of parents, siblings, child-care providers, peers, teachers, extended kin, and others contribute to these important developmental outcomes.

At the center of this relational network is the parent-child relationship, which is important because its influences are unique, comprehensive, ubiquitous, and potentially enduring. Ever since Freud's (1940) famous dictum that the infant-mother relationship is "unique, without parallel, established unalterably for a whole lifetime as the first and strongest love-object and as the prototype of all later love-relations" (p. 45), developmental theorists have in concert emphasized this relationship as the foundation of personality growth. In now-classic formulations, developmentalists like Baumrind (1978, 1989) and Hoffman (1983, 2000) integrated multiple dimensions of warmth, authority, responsiveness, and demand into parenting patterns that were significantly predictive of the competence and adjustment of offspring. More recent perspectives have emphasized the direct and indirect effects of family members on each other (Belsky, 1981), transactional models of family influences extended over time (Sameroff & Chandler, 1975), the embeddedness of family processes in larger social, cultural, and economic systems (Bronfenbrenner, 1979), and the significance of children's constructions of experience in their interactions with

<sup>1</sup>I am indebted to my colleagues on the National Scientific Council on the Developing Child for helping me to develop this concept for the Council's working paper, which can be found at [www.developingchild.net](http://www.developingchild.net).

family members (Grusec & Goodnow, 1994; Rogoff, 1990). Each of these perspectives provides significant continuing catalysts to new thinking about early sociopersonality development in family relationships.

For more than 3 decades, developmental thinking about parent-child relationships has also been guided by attachment theory (Ainsworth, 1973; Bowlby, 1969/1982, 1973, 1980). It is not difficult to account for its influence. Attachment theory explores some of the most compelling questions about early sociopersonality development and its later consequences. How significant are early experiences (especially in intimate relationships) for psychosocial growth? What processes guide continuity and change in personality characteristics throughout life? How are childhood experiences of care linked to later social relatedness? In what ways do early experiences in relationships contribute to psychological vulnerability and strength? Such questions are central to developmental theory, and the creation and validation of the Strange Situation and other assessment procedures has enabled developmental scientists to investigate these questions with growing sophistication and scope. Several decades of research on child-parent attachment have yielded provisional answers to these central questions of developmental theory, and have yielded more questions to ponder.

This section is concerned with theory and research on early parent-child attachment, not because attachment theory is the only important theoretical approach to understanding early relational influences, but because the breadth of its theoretical scope and the body of empirical literature it has produced are uniquely generative of new ideas concerning the impact of early parent-child relationships on sociopersonality development. The continuing vitality of attachment theory will derive, however, from its inclusion of other conceptual and empirical approaches to early relational influences. A number of recent, authoritative reviews of research in attachment (Cassidy & Shaver, 1999; Colin, 1996) reflect the breadth of developmental, personality, and clinical research directions inspired by attachment formulations. The following review focuses on the early development of child-parent attachment and its enduring influence.

### Attachment and Its Development

Attachment can be defined as an enduring affectional tie that unites one person to another over time and across space (Ainsworth, 1973). Attachment figures are a source of security that permit confident exploration and

mastery, a safe haven in stress or danger, and who contribute to self-regulation in difficult or anxious circumstances. Sustained separation from the attachment figure is a source of stress and disruption. Parents are typically the first and primary attachment figures for infants, but other reliable, enduring caregivers can also become attachment figures such as grandparents, stepparents, or sometimes child-care providers. In light of typical conditions of infant care in the United States and elsewhere, multiple attachment relationships are normative, although the development of such relationships is based not on the adult's role or responsibilities but rather on the nature of the child's expectations for that person's behavior from past experience. Given the functions of attachment figures in early childhood development, occasional babysitters, older peers, and teachers are unlikely to be attachment figures and, at later ages, close friends and romantic partners may assume attachment-like functions but are not attachment figures in the same sense (compare Ainsworth, 1989 with Hazen & Shaver, 1994).

Attachment theory offers multilevel explanations for why attachments develop in infancy. On a developmental level, attachment emerges from the variety of social cognitive advances that enable infants to develop individualized expectations for the partner's behavior that help to define the affective quality of their relationship. These advances, discussed in the preceding section, include:

- The recognition of the partner's face, voice, and other features
- The growth of expectations for the partner's behavior (especially related to distress relief and pleasure in sociability) that contribute to an affective preference for that person
- A developing awareness of the partner as a person (with subjective, mental states, and an intentional stance toward the infant) with whom a relationship gradually develops

These and other conceptual achievements contribute to the consolidation of initial attachment relationships by the first birthday.

Attachment relationships continue to develop after the first birthday as the child becomes psychologically more sophisticated and can regard the partner and the relationship in more complex ways (Ainsworth, 1990; Crittenden, 2000). In early childhood, for example, young children increasingly rely on mental representations of the partner's characteristics, especially his or

her physical and psychological accessibility when children are stressed. Children also acquire, as earlier noted, enhanced capacities for understanding the mental and emotional perspectives of the partner, comprehending and accommodating to the partner's goals and interests, and communicating more effectively their own needs and concerns (Harris, 1997). This development of attachment was described by Bowlby (1969/1982, 1973) as the "goal-corrected partnership." In later years, this partnership becomes more complex, mutual, and dynamic as the children mature psychologically. In middle childhood, children understand relationships to be based on psychological sharing between partners, enduring despite conflict, and children begin to explicitly conceptualize relational processes for the first time while seeking psychological support as well as physical proximity to their attachment figures (Raikes & Thompson, 2005b). They may also begin deriving security from the broader network of family relationships they share as well as specific parent-child relationships (Davies & Cummings, 1994; Davies & Forman, 2002). In adolescence, attachment relationships are transformed by a young person's efforts to clarify and differentiate self from others, reflect on complex abstract realities (such as the nature of human relationships), and develop capacities for emotional reflection and self-regulation (Allen & Land, 1999). Attachment relationships develop, in short, with the child's developing psychological sophistication.

On an ethological or evolutionary level, attachments are believed to have evolved to promote infant survival (and inclusive fitness) by maintaining the protective proximity of adults, especially in conditions of alarm or danger. Seeking physical closeness to a caregiver helped to ensure (in the environment of evolutionary adaptedness) that infants were protected and were not lost or abandoned, and that they would also be nurtured and could learn from the adult behavior they observed until they reached maturity.

Complementary biologically based motivational systems fostering nurturance in adults are also believed to have arisen from this evolutionary legacy (Thompson et al., 2005). But the inclusive fitness considerations of the mother are more complicated than those of the infant because maternal energy, time, and other resources must be divided between the needs of several offspring and the mother herself, including her survival and future reproductive potential. From a biological perspective, maternal solicitude is contingent on many factors,

including the number of siblings, environmental resources (e.g., food, social support), the adult's health and age, and the age, health, and other characteristics of the child (Blurton-Jones, 1993; Clutton-Brock, 1991; Hrdy, 1999). In some circumstances, maternal withdrawal or psychological abandonment may be associated with an inability to invest adequate nurturance in offspring. This is consistent with the report of Valenzuela (1990, 1997) that 93% of a sample of chronically undernourished, low-income toddlers were insecurely attached (compared with 50% of a comparison sample of adequately nourished, low-income toddlers) and that their mothers were significantly less sensitive than the mothers of adequately nourished toddlers during observations with the child. It is also consistent, unfortunately, with high rates of infanticide in circumstances and cultures characterized by resource deprivation and other obstacles to adequate early care (Hrdy, 1999). In more typical conditions, there is likely to be greater maternal investment but also significant differences between the mother's willingness to invest in a child (through nurturance and attention) and the child's demands for further investment, such as when weaning conflicts occur (Bateson, 1994; Trivers, 1985). In these circumstances, the mother's insensitivity and rejection are as biologically adaptive for her as are the child's efforts to entice greater nurturance adaptive for the child. Parental solicitude is, in short, a biologically contingent phenomenon, with maternal insensitivity and child-parent conflict not only normative but also biologically adaptive at times in light of the different fitness considerations of each partner.

In addition to developmental and ethological perspectives, Bowlby's (1969/1982, 1973, 1980) theory included two other levels of explanation for the development of attachment relationships that contribute to the conceptual richness of attachment theory. First, he borrowed concepts from cybernetic control systems theory to explain the flexible organization of specific attachment behaviors into a behavioral system characterized by continuous goal-correctedness, hierarchical organization, and the functional interrelations among specific behaviors. Thus, attachment develops as a behavioral system when the child has psychologically matured sufficiently that the functional goals underlying the system (e.g., protective proximity to a caregiver) can organize specific attachment behaviors (e.g., reaching, locomotion to the adult, or crying). This functionalist approach to behavioral organization has been an impor-

tant contribution to assessing attachment in the Strange Situation and other procedures. Second, Bowlby's developmental theory was also significantly influenced by his psychoanalytic orientation. His concept of the "internal working model" of self and attachment figure, arising from early relational experience and coloring later relationships, is similar to central features of object relations theory. In addition, his formulations concerning unconscious defensive processes in children, the influence of inconsistent mental representations arising from different experiences of care, and the importance of the therapist as an attachment figure all derive from his orientation as a psychoanalytic therapist. These influences contribute to the depth of attachment formulations although, like many concepts deriving from the psychoanalytic tradition, their heuristic power is accompanied by some conceptual ambiguity and difficulty in assessment.

### Differences in Attachment Security

Attachment theory is important as a normative theory of the development of early relationships, but the majority of research attention has been devoted to individual differences in the security of attachment and their broader influence. The characterization of these differences in terms of security is consistent with Bowlby's ethological view of the protective functions of attachment relationships, and with Ainsworth's observations of the importance of maternal sensitivity to the infant's emotional well-being. Moreover, the concept of security is also consistent with other well-known characterizations of early psychosocial growth (especially the Eriksonian concept of "basic trust versus mistrust" in infancy) and recasts the meaning of infant behaviors earlier described as "dependent" in a more positive, psychologically constructive light. Although attachment as a species-typical phenomenon has biological origins, individual differences in the security of attachment do not appear to have strong genetic foundations. Three recent studies—two large twin studies of infants (Bokhorst et al., 2003) and preschool children (O'Connor & Croft, 2001) and the third a study of the concordance of foster infants' attachment security with the foster mothers' attachment states of mind (Dozier, Stovall, Albus, & Bates, 2001)—together suggest that nongenetic processes are predominant in the development of secure or insecure attachments. Evidence for the influence of both shared environment (environmental influences that make sib-

lings similar) and nonshared environment (influences that make siblings different) was stronger than evidence for genetic influences in explaining differences in attachment security.

Attachment theory portrays individual differences in the security of attachment as the outcome of variations in maternal sensitivity to the infant during the 1st year. Moreover, differences in attachment security are believed to influence emergent features of social, emotional, and personality development in the years that follow. But in this general formulation there are a number of specific issues related to the interpretation of differences in the security of attachment and their broader significance. The following four receive particular attention here: (1) the concept of security as definitional of the child-parent relationship, (2) the developmental transition from security as relationship specific to security as a personal attribute, (3) the integration of multiple relational experiences into attachment security, and (4) the association between the security of attachment and psychological development.

First, to what extent is the security of attachment definitive of the parent-child relationship? Are there important features of this relationship that are outside the scope of attachment? Bowlby believed that even in infancy attachment is only one of several dimensions of the parent-child relationship and is supplemented by their complementary roles in feeding, play, instruction, and other activities that are guided by other behavioral systems. The parent's skill as a playmate or teacher does not necessarily have consequences for the attachment system. Moreover, there exists a rich literature describing other features of parent-infant relationships that underscore the importance of parental teaching and guidance, the intellectual richness of the home environment, and the adult's sensitivity and responsiveness in fostering the child's conceptual and language development (see Dunn, 1993, and Bornstein, 2002, for reviews). Despite this, few researchers have sought to study the development of parent-child relationships more inclusively, such as by exploring how the emergence of attachment security intersects with other relational influences. This would be a valuable goal in light of recent evidence that the security of attachment moderates the influence on the child of parenting practices such as discipline approach (Kochanska, Aksan, Knaack, & Rhines, 2004) and maternal conversational discourse (Thompson et al., 2003). In addition, understanding the developing dynamics of parent-infant

relationships may provide added insight into the origins of attachment security. As earlier described, at the same time that the security of attachment is emerging during the 1st year, the quality of the parent-child relationship is also being influenced by the growth of self-produced locomotion and the conflict of wills that occurs as infants become more agentic and goal directed. How parents manage conflict with the child may be important, along with sensitive responsiveness in other contexts, to the development of security in offspring.

Second, attachment theorists agree that with growing maturity, attachment security becomes increasingly an attribute of the person, rather than of a specific relationship. In infancy and early childhood, we typically think of children as secure or insecure with respect to a specific caregiver; in adolescence and adulthood, we commonly think of secure or insecure persons. But how and why does this developmental transition occur? Investigating this theoretically crucial question is impaired, to some extent, by assessment procedures: Measures of attachment security for older persons have predominantly incorporated the assumption that attachment styles or states of mind are characteristic of the person, and researchers have rarely considered whether adolescents or adults also maintain relationship-specific forms of security or insecurity with particular partners. Yet, when the findings of studies using different procedures for assessing attachment security are compared, there is evidence for *both* security as a relationship-specific quality and security as a personal attribute in studies of children in middle childhood and adolescence (see Raikes & Thompson, 2005b, and contributors to Kerns & Richardson, 2005). This suggests that security as a personal attribute may develop over an extended period as personality development becomes influenced by the representational systems inspired by multiple attachment relationships throughout childhood and youth. But these findings also raise another question. Is it possible that both relationship-specific and person-specific features of attachment security coexist in the attachment-related representational systems that exist in adulthood?

Third, how are multiple attachment relationships developmentally influential (Thompson, 2005)? Attachment theorists agree that in infancy and at later ages, attachments commonly develop with more than one caregiver, and the security of these relationships is independent of the others. How do the expectations arising from multiple attachments become integrated into coherent ways of relating to others, representing relationships, and self-understanding? Do children acquire

multiple, perhaps somewhat inconsistent, representations of self and relationships if their security varies with different attachment partners? Or are these representations integrated or harmonized in some way? Over the years, there have been different ways of responding to this issue. Attachment relationships are believed by some to be hierarchical in influence (with mother-child attachments primary), while others believe that attachment security affects psychosocial growth in a domain-specific fashion (such that maternal attachments influence different aspects of sociopersonality development than do relationships with fathers or child-care providers; see, e.g., Main & Weston, 1981; Oppenheim, Sagi, & Lamb, 1988). At present, however, neither empirical evidence nor theory offers a clarified picture.

Fourth, why should attachment security be related to other features of psychological development? Thoughtful theoretical attention to this question should guide research into the sequelae of early attachment security and enable researchers to interpret expected and unexpected associations between attachment and later behavior. Attachment researchers have been guided, however, by a broad expectation that secure attachment predicts more positive social and personality functioning. Empirically, this has resulted in a large research literature in which attachment has been studied in relation to a dizzying variety of later outcomes, including cognitive and language development; frustration tolerance; self-recognition; behavior problems; relations with peers, friends, and siblings; interactions with unfamiliar adults; exploration and play; competence in preschool and kindergarten classrooms; curiosity; ego resiliency; and math achievement (see Thompson, 1999, and following). As Belsky and Cassidy (1994) asked, one might wonder if there is anything to which attachment security is *not* related.

Why has there been a search for so many diverse sequelae of attachment security? One reason is that attachment theory provides a conceptual umbrella for broad and narrow constructions of the developmental impact of attachment relationships. The most narrow view, and the one that is best supported by empirical evidence, is that security of attachment should predict the child's later trust and confidence in the attachment figure and other close relational partners. Waters, Kondo-Ikemura, Posada, and Richters (1991) have broadened this view with their argument that because attachment security indexes the continuing harmony of the parent-child relationship, a variety of socialization outcomes should result from attachment security related to identification,

imitation, learning, cooperation and compliance, and prosocial motivation. A yet broader perspective is that attachment security should foreshadow cognitive competence, exploratory skill, and communication style through its effects on the child's self-confidence, initiative, and other broader personality processes, together with the support afforded by continuing sensitive parenting. Weinfield, Sroufe, Egeland, and Carlson (1999) have further proposed that attachment influences later development as it affects (a) neurodevelopment, (b) affect regulation, (c) behavioral regulation and relational synchrony, and (d) early representations (e.g., the internal working models proposed by Bowlby and discussed later). Although they argue that attachment relationships should be most strongly predictive of sequelaelike psychological adjustment, interpersonal competence, and self-understanding, it is easy to see how a much wider variety of outcomes can be encompassed in the four sources of influence they describe. Adding further complexity is the view (now current in evolutionary biology and behavioral ecology) that different attachment patterns are each evolved behavioral strategies that are adapted to different conditions of environmental resources and parental solicitude (see Chisholm, 1999). Whether attachment patterns predict adaptive or maladaptive later behavior depends, in part, on whether the environmental conditions characterizing early development endure or change over the child's life.

Whether conceptualized in a developmental or evolutionary framework, theoretical clarity concerning the association between attachment security and psychological development is essential. When attachment researchers are unclear or disagree over the hypotheses that can be reasonably derived from the theory, it is difficult to determine whether empirical findings confirm, disconfirm, or do not directly address theoretical claims at all. As a consequence, both convergent and discriminate validities are obscured. Moreover, theoretical precision is necessary to guide expectations for whether the association of attachment with other psychological developments will be strong or weak, direct or mediated, moderated by other variables, or nonexistent. Once expectations are clear, then unexpected relations between attachment security and other variables can be examined more incisively (e.g., by exploring for mediating variables). The need for theoretical clarity is perhaps the most important challenge facing attachment theory and research in the next decade of its development (Thompson & Raikes, 2003). Attempting to bootstrap theory development on the findings of empirical re-

search conceived under the umbrella of many different conceptions of attachment outcomes risks both theoretical obscurantism and holding attachment theory accountable for formulations it should not and perhaps cannot embrace (Sroufe, 1988).

### Security of Attachment in the Strange Situation

The Strange Situation has been an empirical and a conceptual anchor for attachment research because of the careful validation work of Ainsworth and her followers (see Ainsworth, Blehar, Waters, & Wall, 1978, for procedural and coding details). By linking detailed longitudinal observations of the secure-base behavior of infants at home with patterns of attachment in the Strange Situation, Ainsworth demonstrated that a straightforward 20-minute laboratory procedure could capture important and reliable dimensions of relational security in infancy. As evidence accumulated for the moderate stability and predictive validity of attachment classifications derived from the Strange Situation, a large body of research was generated to explore the origins, correlates, and sequelae of individual differences in attachment using this procedure. To be sure, the reliance on a single attachment assessment had disadvantages: The identity of the security of attachment construct with Strange Situation behavior made it impossible to examine how prior experiences might affect Strange Situation behavior independently of attachment security (Lamb, Thompson, Gardner, & Charnov, 1985). But the reliance on a single procedure also enabled researchers to integrate a wide variety of research findings because each used the same assessment. The Strange Situation has also had broader significance for attachment research. Attachment assessments for older children and adults are often validated by showing that they yield classifications that are longitudinally consistent with earlier Strange Situation classifications, and attachment researchers still rely on adaptations of the threefold (later fourfold) Strange Situation classification categories when they are studying attachment in older children, adolescents, or adults.

The strategy of the Strange Situation is to create conditions of moderately escalating stress to activate the attachment behavioral system of 1-year-olds. Based on the infant's behavior throughout the procedure, but especially during reunions with the partner after brief separation episodes, an attachment classification is assigned. Infants who are considered securely attached (Group B) organize their behavior around the caregiver

as a secure base throughout the procedure and show fairly unequivocal pleasure at the adult's return. Infants who are insecure-avoidant (Group A) show relatively little secure-base behavior and exhibit avoidance of the partner during reunions either by failing to greet or delaying in greeting the adult. Infants who are insecure-resistant (Group C) also show little secure-base behavior during preseparation episodes (during which they remain preoccupied with the adult) and mingle their efforts to achieve proximity to the caregiver during reunions with angry resistance. Although these dual insecure groups are different in their behavioral characteristics, understanding the distinctive origins and sequelae of these groups has been hindered by the longstanding tendency of researchers to combine avoidant and resistant classifications in their analysis, together with the enlistment of sample sizes that are too small to permit reliable comparisons between these groups.

Although these three groups constituted the extent of the classification options for Strange Situation research for many years, a new insecure classification category emerged in the late 1980s as the result of difficulties in appropriately characterizing the attachment behavior of certain infants, especially those in at-risk conditions. Main and Solomon (1986, 1990) created the classification of disorganized/disoriented (Group D) to describe infants who, for a time, appear to *lack* an organized, coherent strategy for interacting with the caregiver in the Strange Situation. This can be manifested in many ways, most notably in contradictory behavior (e.g., strong avoidance combined with strong contact-seeking), but also in undirected, incomplete, or interrupted movements, inexplicable freezing or stilling, stereotyped or other anomalous postures, apparent fear of the adult, and other indications of disorganization or disorientation. These behaviors can be fleeting and initially difficult to detect, although with training and experience reliable assignment of the D classification can be accomplished. In a sense, infants in the D classification are distinct from those in both the secure classification (group B)—because infants are distinctly insecure—and from the two insecure (groups A and C) classifications, because infants are disorganized rather than exhibiting an organized (albeit insecure) behavioral strategy. Even so, classification as D is often accompanied by a secondary assignment to one of the three organized attachment groups reflecting a “best fitting” alternative classification. Although the D classification originated in efforts to describe the attachment behavior

of infants who had been maltreated, were growing up in difficult family conditions, or were otherwise at risk for later problems, infants in the disorganized/disoriented group are often found in nonclinical middle-class samples, although in widely varying rates, with one meta-analytic estimate that 15% of the infants from middle-class samples are classified in the D group (van Ijzendoorn, Schuengel, & Bakermans-Kranenberg, 1999). By contrast, roughly 25% of the infants in lower-income samples are in the D group, with much higher proportions in some clinical samples. In low-risk, middle-class samples the secondary classification for D-group infants is predominantly secure, while in higher-risk samples the secondary classification is more commonly insecure (Lyons-Ruth & Jacobvitz, 1999; Lyons-Ruth, Repacholi, McLeod, & Silva, 1991).

Why do infants become disorganized or disoriented in the Strange Situation? In a return to Bowlby's clinical interests in the enduring effects of early trauma, Main and her colleagues (Main & Hesse, 1990; Main & Solomon, 1990) have argued that infant disorganization develops in response to the frightening or frightened behavior of the caregiver, which can occur when the adult has an unresolved personal history of traumatic or frightening experiences, especially when memories of these experiences are evoked by current circumstances (e.g., domestic violence). When caregivers act this way, it puts the infant in the terrible paradox of fearing the person from whom they must also find comfort in stress, and disorganized behavior can be the result. In support of this view, the incidence of infant disorganized attachment is much higher in samples characterized by sociodemographic risk, especially child maltreatment (in which the parent necessarily acts in a frightening manner). However, parental depression or marital discord is not necessarily associated with increased frequency of infant disorganization, suggesting that the conditions of family risk that are most generative of the D classification are those that most directly imperil infant-parent relationships and the child's emotional well-being (e.g., Barnett, Ganiban, & Cicchetti, 1999; Carlson, 1998; see Lyons-Ruth & Jacobvitz, 1999, and van Ijzendoorn et al., 1999 for reviews). There is also a significant association between parental classification as “unresolved/disorganized” in the Adult Attachment Interview and infant disorganized/disoriented attachment, which is important because of the belief that this adult state of mind reflects continued difficulty over past experiences of trauma or loss

(Hesse, 1999; van Ijzendoorn, 1995).<sup>2</sup> The more important question, however, is whether the parent's stresses and attachment state of mind are manifested in frightening or frightened conduct in the presence of the infant. The few studies that have directly addressed this question have revealed a modest but inconsistent association between maternal frightening behavior and attachment disorganization in infants, often depending on the form of disorganization the infant exhibits (Lyons-Ruth, Bronfman, & Parsons, 1999; Schuengel, Bakermans-Kranenburg, & van Ijzendoorn, 1999). This suggests that further research is necessary to fully elucidate the origins of infant disorganized/disoriented attachment in the infant-caregiver relationship.

The D classification in infancy is distinguished from the other attachment classifications because it is not an organized strategy. But surprisingly, when attachment security is assessed in separation-reunion procedures in preschoolers, the manifestations of disorganization for most children appear to be highly organized in the form of controlling strategies for managing and regulating mother-child interaction (Moss, Bureau, Cyr, Mongeau, & St.-Laurent, 2004; Teti, 1999). A variety of controlling (group D) subgroups in preschoolers, including controlling-caregiving and controlling-punitive strategies, reflect different behavioral and affective approaches to the caregiver. Because these categories for classifying disorganization in preschoolers were derived

inductively from two small longitudinal follow-up studies of infants earlier deemed disorganized/disoriented (Main & Cassidy, 1988,  $N = 12$ ; Wartner, Grossmann, Fremmer-Bombik, & Suess, 1994,  $N = 13$ ), there is no clear theoretical explanation for why children who are so distinctly *disorganized* in infancy should become preschoolers who are so organized that they seek to control the caregiver's behavior. The extent to which this reflects sequelae of disorganized attachment, changes in parent-child interaction, psychological development in the child, or the influence of other variables is still being explored. This developmental transition remains an empirical and conceptual challenge for attachment theory and research and, together with the need for a better understanding of the origins of infant disorganization, suggests the urgent need for further prospective longitudinal research on these issues.

Taken together, in typical, nonclinical middle-class samples, approximately 62% of infants are deemed secure, 15% avoidant, 9 to 10% resistant, and the remaining 15% disorganized. The proportion of insecure and disorganized groups is larger in lower-income samples, clinical groups, and families at sociodemographic risk (van Ijzendoorn et al., 1999). Multiple classification subgroups associated with each category reflect considerable variation on each classification theme, but little research has been devoted to understanding these differences. There have also been challenges to the suitability of the Strange Situation as an attachment assessment for infants with distinct experiential backgrounds, such as those with substantial experience in child care, which highlight the importance of understanding the backgrounds of infants in the Strange Situation when interpreting their responses to the separation episodes and encounters with a stranger (Clarke-Stewart, Goossens, & Alhusen, 2001).

Attachment researchers have long recognized the analytic limitations of a categorical outcome measure like attachment classification and, over the years, have proposed modifications or adaptations of the classification system to permit continuous scores (e.g., Gardner, Lamb, Thompson, & Sagi, 1986; M. Lamb et al., 1985; Richters, Waters, & Vaughn, 1988) or dimensional approaches to assessing attachment security (e.g., Waters & Deane, 1985). More recently, Fraley and Spieker (2003) have proposed that attachments are fundamentally ordered along two continua (proximity-seeking versus avoidance and high versus low anger/resistance) and have urged attachment researchers to use

<sup>2</sup> Although findings such as these are commonly interpreted as supporting the predictive validity of the Adult Attachment Interview (AAI), they should be interpreted cautiously because the AAI was developed explicitly to predict infant attachment classifications. The AAI was developed from a sample of interview responses of parents for whom the attachment classifications of their infant offspring from Strange Situation assessments conducted several years earlier were known (Hesse, 1999). The AAI coding and classification system were developed by searching for commonalities in the interview responses of parents whose infants shared the same attachment classification. This helps to explain why AAI classifications so closely parallel infant Strange Situation classifications and why many researchers have reported a correspondence between parental AAI groups and their infants' Strange Situation classifications. Predicting infant attachment status was what the AAI was originally created to accomplish. But documentation of the predictive validity of the AAI in this manner is not the same thing as if the adult attachment assessment had been developed completely independently of knowledge of the attachment security of offspring.

a dimensional rather than a taxonomic approach to studying differences in attachment security. Although the use of multiple continua can have important advantages in attachment research, the Fraley and Spieker analysis is limited because they excluded infants in the D classification, rendering their conclusions of limited applicability in light of growing interest in infant disorganization. More generally, a dimensional strategy would require far more than two continua to capture the richness of the organizational approach to attachment assessment and its sequelae, and it requires further research to determine whether a dimensional approach can do so without undermining many of the other advantages of this approach.

### **Other Behavioral Assessments of Attachment Security**

As children mature, attachment assessments must also change to accommodate the child's developing behavioral sophistication. Two other behavioral assessments of attachment security have been developed for preschoolers (representational assessments are discussed later in the section on internal working models). Each has presented attachment researchers with the challenge of mapping heterotypic continuity in attachment security: How can age-appropriate manifestations of a secure attachment be identified that capture the same attachment construct as is assessed in the infant Strange Situation (see Solomon & George, 1999)?

One approach is the Cassidy and Marvin (1992) procedure for preschoolers (i.e., 3- to 5-year-olds), based on an earlier approach by Main and Cassidy (1988) for 6-year-olds, which focuses on reunions with the parent after one or more separations. Preschool attachment classification categories closely parallel those of the Strange Situation. A similar separation-reunion procedure by Crittenden (1992, 1994; see also Crittenden, 2000) uses somewhat different classification categories for older children, including secure, insecure-defended, insecure-coercive, and other insecure groups. Each approach borrows the strategy of the Strange Situation that preschoolers' attachment organization is activated by the stress of separations from the caregiver, and sometimes separation episodes are lengthened to better ensure that this occurs for older children. Although they are similar, the two approaches differ from each other, and from the Strange Situation coding procedures, in how secure behavior is

indexed. The Cassidy-Marvin procedure focuses on body position, affect, speech, gaze, and physical proximity and contact, whereas Crittenden's classification procedure also encompasses affect regulation and open communication with the parent. The Cassidy-Marvin procedure is widely used, and individual differences in security assessed in this procedure are modestly but reliably associated with prior measures of maternal sensitivity and responsiveness and are also modestly associated with infant Strange Situation classifications<sup>3</sup> (Barnett, Kidwell, & Leung, 1998; Moss, Bureau, Cyr, Mongeau, & St.-Laurent, 2004; Moss, Cyr, Bureau, Tarabuley, & Dubois-Comtois, 2004; National Institute of Child Health and Human Development Early Child Care Research Network, 2001; Stevenson-Hinde & Shouldice, 1995). But by contrast with their careful attention to the standardized use of the Strange Situation with infants, attachment researchers have tended to modify the procedure and scoring conventions of the Cassidy-Marvin procedure in different studies, sometimes using the Strange Situation, sometimes extending the separation episodes and eliminating episodes with the stranger, and sometimes including other assessments in the midst of the procedure (e.g., Moss, Bureau, Cyr, Mongeau, & St.-Laurent, 2004; National Institute of Child Health and Human Development Early Child Care Research Network, 2001; Stevenson-Hinde & Shouldice, 1995). This

---

<sup>3</sup> It is important to note that the classification of preschool attachment behavior in the Cassidy and Marvin (1992) and Main and Cassidy (1988) assessments is based on procedures created explicitly to identify early childhood correlates of infant attachment classifications. In a procedure resembling the development of the Adult Attachment Interview, Main and Cassidy (1988) created the preschool attachment categories in an iterative process involving samples of young children for whom their attachment classifications in infancy were known throughout measurement development. By searching for commonalities in the preschool separation-reunion behavior of children who, as infants, shared the same attachment classification, the close parallel between infant Strange Situation and preschool attachment classifications was ensured. However, this approach makes the consistency between infant and preschool classifications less impressive than if preschool classifications had been derived independently, and because it is based on inductive rather than deductive procedures, this approach to measurement development also creates theoretical challenges (e.g., explaining why infants who are deemed disorganized become highly strategic, controlling preschoolers).

makes it difficult to know how comparable the findings are from the different variations of the procedure and how far the validity evidence can extend to significant alterations of the Strange Situation.

A different strategy for assessing attachment security in preschoolers is the Attachment Q-Sort (AQS; Waters & Deane, 1985). Based on extensive home observations, a well-trained observer or the mother sorts 90 descriptive statements into nine groups based on how accurately each statement describes the child. This distribution is then correlated with a criterion sort to yield a correlation coefficient that is the child's security score. The AQS seeks to describe secure base behavior at home rather than provoking attachment behavior in the laboratory, based on an effort to directly assess the secure base behavior that is, to some attachment theorists, the gold standard of any attachment assessment (Waters & Cummings, 2000). Consequently, children are observed under a variety of conditions, but inevitably less often in circumstances that deliberately heighten the activation of attachment behavior. The criteria for secure attachment are thus broader than for Strange Situation-based procedures. In addition to secure base behavior, for example, items that are high in the security criterion sort include:

- "Child follows mother's suggestions readily, even when they are clearly suggestions rather than orders."
- "Child uses mother's facial expressions as a good source of information when something looks risky or threatening."
- "Child recognizes when mother is upset. Becomes quiet or upset himself. Tries to comfort her."
- "Child is strongly attracted to new activities and new toys."

By incorporating into the security criterion sort many of the hypothesized correlates of attachment security (such as the child's obedience, social referencing, empathy, and exploratory interest) the AQS enlists a much broader operationalization of attachment security that is perhaps better suited to a home observational measure, in contrast with the more narrow focus on secure base behavior of the laboratory separation-reunion procedures. The AQS is also an assessment of security alone; there are no consistent procedures for distinguishing secure from insecure attachments on the continuous security score, nor does the procedure yield differentiated forms of insecurity such as those provided by assessments based on the Strange Situation.

The AQS is suitable for use with children from 1 to 5 years of age.

A meta-analysis of research using the AQS by van Ijzendoorn, Vereijken, Bakermans-Kranenburg, and Riksen-Walraven (2004) showed that the average security score for nonclinical samples was .32, with an average score of .21 in clinical samples. With a theoretical range of security scores (like correlation coefficients) from  $-1.00$  to  $+1.00$ , this is consistent with Strange Situation evidence that most infants are secure, but that there is variability in security. They also reported that AQS security scores were moderately associated with security assessed in the Strange Situation (combined effect size .23) and with measures of maternal sensitivity (effect size .31), but were also negatively associated with assessments of temperamental reactivity (effect size .27), conclusions that are consistent with narrative reviews of this literature (e.g., Thompson, 1998). These findings were consistent for security scores derived from observers and from maternal report, although van Ijzendoorn and his colleagues (2004) concluded that research findings better support the validity of observer sorts. Their conclusion is consistent with the greater likelihood of report bias from mothers, but Teti and McGourty (1996) have delineated procedures designed to minimize this influence, and maternal sorts may be more valid with the training and supervision they suggest (the meta-analysis did not distinguish maternal-report studies employing the Teti and McGourty procedures from those that did not).

Do these behavioral assessments capture the same attachment construct that is assessed in the infant Strange Situation procedure? The careful design of these measures, their predicted associations with differences in maternal sensitivity, and their modest associations with infant Strange Situation classifications each suggest that their shared variance indexes a consistent attachment construct. However, differences in external correlates (such as temperament), operationalizations of security, and measurement strategy each indicate that these assessments capture significant sources of independent variance as well. This is perhaps inevitable in light of the challenges of mapping heterotypic continuity in behavior during a period of rapid developmental change. But this means that attachment theorists are wise to be cautious in generalizing findings across research studies using different measures of the security of attachment. As one illustration, a recent report from the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care found different

associations between mother- and caregiver-reported child behavior problems at age 3 and attachment assessments at 15 months (using the Strange Situation), 24 months (using the AQS), and 36 months (using the Cassidy-Marvin procedure), and there was very modest consistency in security and disorganization scores derived from these attachment assessments at each age (McCartney, Owen, Booth, Clarke-Stewart, & Vandell, 2004). As we shall see, the interpretive cautions of generalizing across attachment assessments are also required when generalizing to representational measures of attachment in early childhood and later years.

### Origins of Attachment Security

To attachment theorists, the caregiver's sensitivity to the infant is the adult's core contribution to the development of a secure attachment. Sensitivity is a broad conceptual rubric for the quality of adult caregiving that has diverse consequences for offspring, and it can have different meanings in different theoretical traditions. In Vygotskian theory, for example, sensitivity entails the careful scaffolding of shared activity to foster conceptual growth within the child's readiness for new challenges (Rogoff, 1990), while a learning theorist would emphasize the construction of environmental contingencies that foster adaptive behavior. To attachment theorists, sensitivity consists of a constellation of response attributes that includes attention to the infant's signals, accurate interpretation of their meaning, and appropriate and prompt responsiveness to promote the infant's trust in the caregiver (Ainsworth, 1973; Ainsworth et al., 1978). Empirically, sensitivity tends to be operationalized in ways that also include caregiver warmth, cooperation, interactional synchrony, and other related processes (Belsky, 1999; De Wolff & van Ijzendoorn, 1997; Thompson, 1998). Bowlby himself characterized sensitivity as "respect for the child."

A 1997 meta-analysis by De Wolff and van Ijzendoorn on the association between maternal sensitivity and infant attachment security concluded that there is a modest but reliable association (combined effect size .22) between sensitivity and security (De Wolff & van Ijzendoorn, 1997), which is consistent with the results of several other reviews of this literature (Belsky, 1999; Thompson, 1998) and with findings from the large, longitudinal NICHD Study of Early Child Care (NICHD Early Child Care Research Network, 1997, 2001). This is true whether the infant Strange Situation, the AQS,

or the Cassidy-Marvin procedure is used to assess attachment. Paternal sensitivity is also reliably associated with security of attachment, but more weakly than for mothers (van Ijzendoorn & De Wolff, 1997), and sensitivity is also a predictor of security with nonparental caregivers (Howes, 1999). A meta-analytic review of the results of intervention studies designed to improve maternal sensitivity concluded that carefully designed interventions could be effective in increasing sensitive responsiveness, especially when they were relatively short, behaviorally focused programs. Moreover, these interventions also had a small but significant effect in enhancing the security of attachment, supporting the causal role of maternal sensitivity in fostering attachment security (Bakermans-Kranenburg, van Ijzendoorn, & Juffer, 2003). Parental sensitivity is an important and reliable but modest predictor of the security of attachment.

De Wolff and van Ijzendoorn (1997) concluded that other dimensions of parenting are also important in fostering security, and suggested that researchers look to the contexts of parent-child interaction for clues about these influences. Attachment researchers have responded to their suggestion. Not surprisingly, they have found that the caregiver's psychological attributes are predictive of attachment security. In the NICHD Study of Early Child Care, for example, the mothers of securely attached infants were higher than mothers of insecure infants on a composite of measures of psychological adjustment that indexed depression, neuroticism, and anxiety (each reverse scored), sociability, extraversion, and other variables (NICHD Early Child Care Research Network, 1997). Attachment researchers have also explored other psychological resources of the mother that might foster secure attachment. Meins has reported that maternal "mind-mindedness," which describes mothers' tendencies to impute mental and psychological states to their infant offspring, is associated with sensitive responding and predicts attachment security in 1-year-olds (Meins et al., 2001, 2003). In a similar vein, Oppenheim and his colleagues explored differences in maternal "insightfulness" into the infant's internal experiences and motives and found that mothers deemed positively insightful were rated as more sensitive during mother-infant play sessions, and their offspring were more likely to be securely attached in the Strange Situation (Koren-Karie, Oppenheim, Dolev, Sher, & Etzion-Carasso, 2002; Oppenheim & Koren-Karie, 2002). Both mind-mindedness and insightfulness assessments explained

variance in infant security beyond the effects of maternal sensitivity.

Such studies are helpful in bridging the “transmission gap” highlighted by van Ijzendoorn (1995) in his meta-analytic review of studies associating adult attachment representations, parental responsiveness, and infant attachment security. His review focused on the adult representations of early childhood care, including recollections of feeling loved and secure and perceptions of the feelings and motives of caregivers, which are characterized as attachment “states of mind” and are assessed in the Adult Attachment Interview (see Hesse, 1999, for a review of this literature). Reviewing an extensive body of research, van Ijzendoorn (1995) concluded that these adult attachment representations are significantly associated with independent measures of parental responsiveness (combined effect size .34), with adults in the autonomous (secure) group responding more sensitively to their offspring than adults in the insecure, preoccupied, and dismissing groups. Furthermore, adult attachment representations are also strongly associated with the attachment classifications of infant offspring in the Strange Situation, even when adult attachment was assessed prenatally (combined effect sizes .31 to .48). Autonomous adults tend to have children who are securely attached, and adults in the preoccupied and dismissing groups have offspring who are more likely to be insecure.<sup>4</sup> Thus, one important contribution to the security of attachment are caregivers’ personal representations of the care they received as young children and its influence on the sensitivity of care they provide to their own offspring. As van Ijzendoorn (1995) pointed out, however, a substantial proportion of the association between adult attachment representations and infant attachment security is *not* explained by differences in parental sensitivity, and he suggested that this “transmission gap” warranted further exploration by attachment researchers. What other influences do adult attachment representations have on the development of security in offspring that are not mediated by sensitive care? Studies of maternal mind-mindedness and insightfulness may provide one response to this question (see Meins, 1999).

Beyond the mother-infant dyad, the amount and quality of child care has not been found to be a significant influence on the security of infant-mother attachment, according to the NICHD Study of Early Child Care, al-

though there was some evidence that when maternal sensitivity was low, greater amounts of child care and/or poorer quality care increased the risk of insecure attachment (NICHD Early Child Care Research Network, 1997, 2001). In other cultural settings where the quality of child care is very poor, there is evidence that child care can have a directly adverse impact on infant-mother attachment as well as interacting with maternal insensitivity (Sagi, Koren-Karie, Gini, Ziv, & Joels, 2002).

The quality of the marital relationship has also been found to predict attachment security in several studies, with mothers who report greater marital satisfaction and harmony having infants with more secure attachments, although this association is not found consistently across the research literature (e.g., Belsky & Isabella, 1988; Howes & Markman, 1989; Owen & Cox, 1997; see Belsky, 1999). Marital conflict is likely to have direct and indirect implications for the security of attachment. Maritally conflicted couples may have greater difficulty maintaining sensitivity to infant signals and needs in the midst of their own emotional turmoil. Owen and Cox (1997) also found that marital conflict and sensitive responding each made independent contributions to attachment security, such that conflict was negatively related to attachment security even among young children whose mothers or fathers remained sensitive when interacting with them. The negative emotional climate of the home may be one influence that can account for the impact of marital conflict independently of parental sensitivity: Young children may be made anxious by parental arguing and conflict even when each parent is a sensitive caregiver.

This conclusion is consistent with Cummings and Davies’ (1994; Davies & Cummings, 1994) portrayal of how young children’s security is affected not just by their relationships with each parent but also by their emotional experience in the family system as a whole. Their “emotional security hypothesis” argues that marital conflict can threaten young children’s security in the family and can provoke distress, motivate children’s efforts to regulate conflict, and instill hostile representations of family life—qualities that resemble insecure attachment (see Davies & Forman, 2002; Davies, Harold, Goeke-Morey, & Cummings, 2002). Security may, in short, be a function not just of the child-parent relationship but of children’s experience of the broader family emotional climate. Understanding the direct and indirect influences of the family environment, especially as it is affected by marital conflict, domestic violence, and

<sup>4</sup> See note 2, p. 49.

other negative family experiences, is particularly significant in light of the relatively weak association between measures of parental sensitivity and infant disorganized attachment (van Ijzendoorn et al., 1999). Family influences that are related to angry and frightening parental conduct may, independently of sensitivity, be important to the genesis of infant disorganization and possibly also other forms of attachment insecurity.

Insecure attachment is more frequent in lower-income and socioeconomically stressed samples owing, in part, to the greater incidence of stresses within and around the family that can affect parental sensitivity and the security of attachment (Barnett et al., 1999; van Ijzendoorn et al., 1999; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001). Furthermore, De Wolff and van Ijzendoorn (1997) noted in their meta-analysis that the socioeconomic status of the family is also a significant moderator of the influence of sensitivity on attachment. Thus, there is a weaker association between maternal sensitivity and attachment security in lower-income than middle-income families. A study by Raikes and Thompson (2004c) explored this further by showing, in a sample of low-income Early Head Start families, that while the impact of economic risks (associated with poverty) on attachment security was mediated by its effects on maternal responsiveness, the effects of emotional risks (such as domestic violence, alcohol or drug abuse) had direct effects on the security of attachment that were unmediated by maternal behavior. These risk factors, which altered the broader emotional climate of the family, were associated with lower attachment security independently of variations in maternal sensitivity. Emotional risk factors also moderated the association between maternal behavior and child security such that maternal responsiveness was less strongly associated with attachment security in families with many emotional risks. In short, in homes with many stresses and risk factors, sensitive responsiveness is less likely to shape the security of attachment and the difficulties of family life are likely to have a greater direct impact on the child's sense of security. Further research of this kind, especially research that distinguishes different kinds of risk, is essential to understand better the effects of family stresses and buffers on the security of attachment in socioeconomically stressed and middle-income families as a way of better comprehending the influences on attachment beyond parental sensitivity.

Taken together, the literature on the origins of attachment security not only highlights new directions for

further research but also compels a reconceptualization of the nature of parental sensitivity in a manner that is consistent with De Wolff and van Ijzendoorn's (1997) call for attention to context. Attachment researchers have tended to portray differences in sensitivity as characterological and traitlike, deriving from the enduring legacy of childhood experiences captured in the Adult Attachment Interview. But contemporary approaches to parenting also emphasize the situationally adaptive, flexible nature of caregiving (Grusec & Goodnow, 1994; Grusec et al., 2000; Kuczynski, Marshall, & Schell, 1997). Parents approach their children with consistent values and goals, but their parenting is also affected by the child's immediate behavior, situational and long-term goals, the constraints of the circumstances, and the behavior of other people (such as a spouse or sibling). Their parenting is adapted to characteristics of the child but also of the family, marital relationship, and circumstances as well as the parent's relational history. Such a view is consistent with the conclusions of a meta-analysis by Holden and Miller (1999) on the stability of parenting across time, children, and situations. They found that although child-rearing practices are fairly consistent across different children and over time, parents are much less consistent in their behavior across situations, and they suggested that developmentalists must increasingly view parenting practices as both enduring (rooted in adult values, goals, and beliefs concerning child care) and different (adapting to situational demands and children's immediate needs). The same is likely to be true of the variations in parental sensitivity that contribute to attachment security.

Viewed in this light, variations in parental sensitivity may not be uniformly influential on attachment security, but rather in particular contexts and circumstances relevant to developing security. For example, sensitivity may be an important influence when it is exhibited in the contexts most relevant to attachment—when the child is distressed or alarmed—than during nonstressful episodes of play, teaching, or feeding (Thompson, 1997). The sensitivity with which caregivers manage conflicts of will with their offspring may also be important in light of the growth of parent-child limit testing when children become locomotor, as earlier noted. Sensitivity may be influential in relationships when the parent can be a reliable, protective haven of support, in contrast to conditions in which marital conflict, neighborhood violence, or poor child care impose emotional threats that a sensitive parent cannot buffer. Moreover,

sensitivity may be especially influential when sensitive care is maintained over time as a continuing source of emotional support for adaptive functioning (Belsky & Pasco Fearon, 2002a, 2002b). In these situations, sensitivity is developmentally important because the conditions of care make sensitivity more salient to the infant.

This suggests that the baby's construal of the adult's responsiveness is also an important part of the context influencing the impact of sensitive care on developing attachment security. As Watson (1979) noted, the contingency perception that forms the basis for an awareness of sensitive responding is affected by the base rates of both the child's behavior and the adult's response: Infants who are temperamentally fussy may, for example, have a more difficult time detecting a caregiver's responsiveness to their cries than infants who are temperamentally more pacific (Thompson, 1986). But research on the association between infant temperament and attachment security has yielded a fairly consistent conclusion in studies using the Strange Situation procedure: There is not a reliable, direct association between temperament and attachment security (see Thompson, 1998, and Vaughn & Bost, 1999 for reviews). There is also no reliable association between temperament and the infant disorganized/disoriented classification (van Ijzendoorn et al., 1999). However, research using the Attachment Q-Sort has shown that infants who are temperamentally more negatively reactive and difficult are likely have low security scores (van Ijzendoorn et al., 2004; Vaughn & Bost, 1999), which probably arises from the manner in which attachment security is operationalized in the AQS. Taken together, the research literature does not support the view that attachment security derives from antecedent differences in infant temperament.

This desirably straightforward conclusion is, in some senses, unfortunate because it has caused researchers to fail to explore further a number of indirect associations between temperament and attachment (see Thompson, Connell, & Bridges, 1988). Mangelsdorf, Gunnar, Kestenbaum, Lang, and Andreas (1990) reported that patterns of maternal care had different consequences for the development of security when infants who were high or low in temperamental proneness-to-distress were distinguished. Nachmias, Gunnar, Mangelsdorf, Parritz, and Buss (1996) reported that toddlers who are behaviorally inhibited may especially benefit from a secure attachment relationship when coping with stressful challenges. Taken together, these findings suggest that temperament may interact with maternal caregiving in the

development of attachment security and in the sequelae of attachment in ways that merit further exploration.

Finally, an important influence on the development of attachment security is culture. Cultural practices influence normative conditions of early childhood care, and cultural beliefs and values shape the characteristics that parents value and seek to foster in offspring. Theory and research on attachment has, from the beginning, grown within the conceptual tension of recognizing the importance of culture to the development of attachment while also appreciating the evolutionarily adaptive, species-typical process shaping attachment in humans and other animals. Understanding attachment as a universal developmental phenomenon shaped by cultural influences continues to be one way that research on attachment remains sensitive to context.

This conceptual tension was initially manifested in efforts by researchers in several Western and non-Western nations to use the Strange Situation to determine whether infants in their societies exhibited the same patterns of security and insecurity that were initially identified in the United States. The findings of this research literature, including studies in Israel, Japan, China, Africa, Chile, Sweden, Great Britain, and the Netherlands, yielded several conclusions (see Thompson, 1998, and van Ijzendoorn & Sagi, 1999, for reviews). First, when the Strange Situation is used inappropriately (e.g., allowing separation episodes to endure despite heightened infant distress) or inconsistently with normative child-rearing practices, infant behavior in the procedure does not necessarily reflect attachment security. Infants living on Israeli kibbutzim who rarely encountered strangers and children in Japanese homes who had rarely been separated from their mothers responded with unusual distress in the Strange Situation because the procedure entailed experiences with strangers and separation that were more atypical for their background than for infants living in the United States. This is important because the Strange Situation was designed to be a *moderately* stressful assessment based on the experiences of typically developing children in the United States, and when the procedure is highly stressful it is unlikely to yield a valid assessment of attachment security. These findings underscore the significance of ensuring that assessments of attachment are based on a thoughtful appreciation of the typical conditions of early childhood care for the samples under study.

Second, especially when these considerations are taken into account, studies from a wide variety of

nationalities indicate that infants develop attachments to their parents and other caregivers. Moreover, with a few exceptions (e.g., Grossmann, Grossmann, Huber, & Wartner, 1981), the most common attachment classification in nonstressed, nonclinical samples is secure. Attachment is indeed a universal phenomenon and, although infants may manifest security through distal, proximal, or contact-seeking behaviors, most infants appear to be securely attached. Furthermore, researchers who examined parental perceptions of desirable child behavior found that in most countries, parents endorse a profile of behavior that is consistent with that of securely attached children, although parents from different countries often differ in their reasons for this preference, their preferred manifestations of security, and their evaluations of various patterns of insecurity (Harwood, Miller, & Irizarry, 1995; Posada et al., 1995). It appears that secure attachment is both broadly desirable and normative. Third, when multiple studies were conducted within a single national group (such as in Japan, Israel, Germany, and the United States), they indicated that there is often considerable variability in patterns of attachment *within* nationalities. This within-national variability suggests that cultures are not homogeneous in how they influence the development of attachment security, and the values and practices shared within any nationality are significantly adapted to local conditions (e.g., rural versus urban, kibbutz versus city, or middle-income versus lower-income).

Finally, cultural research on the security of attachment indicates that there is somewhat less consistency across national samples in how the quality of care contributes to attachment security, and in the outcomes of a secure or insecure attachment (Thompson, 1998; van Ijzendoorn & Sagi, 1999). These are the ways in which cultural differences in child care and values concerning children are most likely to be influential. None of a battery of measures of parental attitudes and behavior and parent-child interaction obtained throughout the 1st year succeeded, for example, in discriminating infants who were securely attached from insecure in Sweden (M. Lamb et al., 1985). Likewise, in a study of Israeli infants raised in the kibbutz, Oppenheim et al. (1988) found that attachment security to mother or father had no association with measures of later sociopersonality development. To be sure, the association between parental sensitivity and security of attachment is only of moderate strength in U.S. samples, as noted earlier, and research concerning the sequelae of attachment security

in the United States has yielded a mixed pattern of findings as well. But there is also considerably greater diversity in cross-national findings concerning the origins of attachment security and its outcomes.

Based on these considerations related to attachment research in Japan, Rothbaum, Weisz, Pott, Miyake, and Morelli (2000) have questioned the universal applicability of three core claims of attachment theory: (1) caregiver sensitivity leads to secure attachment, (2) secure attachment leads to later social competence, and (3) children who are securely attached use the caregiver as a secure base for exploration. They argue that these conclusions reflect Western beliefs about the nature of the child and of infant-parent relationships and thus cannot properly be generalized to non-Western cultures (see also Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000). The answer, according to Rothbaum and his colleagues (2000), is to develop unique, indigenous theories and methods of studying parent-child attachment relationships. Indeed, given the amount of variability in attachment observed within nationalities, their recommendation might be extended to the creation of context-specific attachment research for different subgroups within cultural settings.

By contrast, the conclusions yielded by research on attachment and culture suggest a less extreme solution. Hypotheses concerning the origins and outcomes of attachment security derived from attachment theory should be evaluated with attention to the cultural contexts of child care and the values guiding parent-child interaction in specific groups. This includes constant attention to the validation of measures derived from studies of children in the United States for use with non-Western groups and, when necessary, the creation of new assessments. To evaluate whether parental sensitivity predicts attachment security in non-Western contexts, for example, it is important to develop culturally appropriate assessments of sensitivity. Theoretical predictions concerning attachment outcomes must also be evaluated with regard to the contexts and values of early care. Indeed, even the documentation that secure attachment is normative in different nationalities is not necessarily evidence that the Strange Situation procedure is valid until convergent evidence (such as confirming an association between the child's attachment behavior at home with secure behavior in the Strange Situation) is obtained. However, the existing research literature suggests that rather than abandoning the theory and methods of contemporary attachment research, these tools

may continue to be useful as they are adapted to work in specific cultures and settings in which child-parent relationships develop. If such inquiry can be conducted in a culturally sensitive manner, it might be a preferable alternative to the generation of a collection of indigenous attachment methods and theories and would also inform the development of attachment theory.

Indeed, further studies on attachment and culture can usefully enable research into the origins of attachment security to become more context sensitive whether or not it is used to evaluate the generality of attachment theory. Sagi, van Ijzendoorn, Aviezer, Donnell, and Mayseless (1994), for example, compared the attachment security of Israeli infants in two kibbutz arrangements: (1) a “familist” arrangement in which infants returned home for the night after spending the day in group care, and (2) a “traditional” arrangement entailing communal sleeping conditions involving supervision by professional caretakers. From attachment theory they predicted and subsequently confirmed that infants in the latter group would be more insecurely attached to their mothers because of the inconsistent responsiveness of the professional caretakers and their mothers’ inaccessibility to them at night. In another kibbutz study, Oppenheim and colleagues (1988) found that the security of attachment of young children to their *metaplot* (communal caretakers) predicted which children were later more empathic, purposive, dominant, achievement oriented, and independent, even though mother-child attachment security did not predict these dimensions of later psychosocial competence. The importance of the child-*metaplot* attachment relationship to these outcome measures (which were assessed in the context of communal care) may have heightened the influence of these attachments to context-relevant psychosocial skills. In each case, research on attachment in a different cultural setting permitted researchers to test hypotheses that could not be readily evaluated in the United States. These are examples of how further studies of attachment and culture can contribute to a greater understanding of the ways that context influences the early development of security in close relationships.

### Consistency and Change in the Security of Attachment

The current era of attachment research emerged out of a desolate period in which researchers had difficulty devising reliable measures of infant-parent interaction and,

as a result, could not identify stable, meaningful individual differences in interactive quality (Masters & Wellman, 1974). One of the first studies of the stability of attachment classifications contributed to the validation of the Strange Situation by showing that when evaluated within the organizational perspective of Ainsworth’s coding system, individual differences in infant-parent attachment could be highly stable over a 6-month period (Waters, 1978). This finding was consistent with the theoretical tradition shaping attachment theory (derived from psychoanalytic theory) that early parent-child relationships would be a consistent, formative influence on sociopersonality development. Thus, the development of a reliable methodology and the discovery that individual differences in relationship quality could be stable over time contributed to the enthusiasm initially generated for attachment theory and research.

Since that time, however, there have been many studies of the stability of attachment security, none of them confirming the initial expectation that attachments are highly consistent over time. Table 2.1 summarizes studies examining the stability of early attachment classifications. Studies were included in this table when the Strange Situation was used on each occasion because these studies provide the most valid window into the consistency of attachment relationships over time (studies using different attachment measures on each occasion, by contrast, confound change in attachment with measurement differences, and the Strange Situation is the best-validated attachment assessment). The table shows that the proportion of infants who retain the same attachment classification on each occasion varies widely, from under 50% to nearly 100%, over periods of only 6 to 8 months.

Similar conclusions are yielded from studies using other behavioral measures of attachment over longer intervals. Symons, Clark, Isaksen, and Marshall (1998) reported a correlation of .44 between observer-sorted AQS assessments of 44 children at ages 2 and 5; and Moss, Cyr, Bureau, Tarabulsky, and Dubois-Comtois (2004) reported that 67% of their sample of 120 children retained consistent classifications when assessed in the Cassidy-Marvin procedure at age 3 to 4 and the closely related Main and Cassidy (1988) procedure at age 5 to 6. The first longitudinal studies comparing infant Strange Situation classifications with mid- to late-adolescent Adult Attachment Interview states of mind have yielded mixed results: Two studies (Hamilton, 2000; Waters, Merrick, Treboux, Crowell,

*Notes:* Age is in months. Overall stability of attachment classification is expressed as the proportion of the sample maintaining the same classification at each age.

<sup>a</sup> Pennsylvania State samples included exclusively firstborn sons. Pittsburgh sample was recruited for a study of postpartum depression; depression was unrelated to attachment classification or its stability over time.

<sup>b</sup> Sample was equally divided between full-term and low-birthweight preterm infants. Term status was unrelated to attachment classification or to its stability. Strange Situation assessments with mothers and fathers were separated by approximately 1 month.

<sup>c</sup> Stability estimates from these studies are based on overlapping subsamples.

& Albersheim, 2000) found that nearly two-thirds of the sample obtained the same attachment classification in infancy and adolescence, whereas three studies (Lewis, Feiring, & Rosenthal, 2000; Weinfield, Sroufe, & Egeland, 2000; Zimmermann & Grossmann, 1997) found no continuity. Other evidence also indicates that consistency in attachment classification over time should not

necessarily be anticipated. Dozier and colleagues (2001) found that by only a few months after their foster care placements, infants' attachment security had already begun to be predictable by knowledge of the foster mothers' attachment states of mind at a level comparable to that found in biological mother-child dyads. There is, in short, no normative stability to attachment

relationships from the early years.<sup>5</sup> Attachment relationships sometimes stay the same, but sometimes they change (Thompson, 2000).

This conclusion does not threaten the validity of the Strange Situation because of the extensive external validity for the procedure. However, because it conflicts with certain theoretical expectations, it requires explanation. Are the changes that occur in attachment security random or systematic, perhaps even lawful? Serious attention to this issue is important not just for theoretical reasons. Understanding the causes of continuity and change in attachment security could be relevant to identifying protective factors for the maintenance of security in the lives of some children and catalysts to security in the lives of others whose early experiences have been relationally insecure.

One suggestion offered by these studies is that secure attachments tend to be more stable than insecure ones (see Thompson, 1998). Bowlby (1969/1982) explained this in terms of the self-perpetuating mutual satisfactions that the caregiver and infant derive from a secure relationship. However, the handful of stability studies enlisting the D classification suggest that infant disorganization/disorientation may also be more stable than the organized, insecure classifications, perhaps because of the extremity and consistency of the antecedent caregiving conditions giving rise to disorganized attachment (van Ijzendoorn et al., 1979). Therefore, there can be catalysts to relational consistency of both positive and negative kinds, although this clearly merits greater research attention.

Attachment researchers have hypothesized that attachment relationships are more likely to change when stresses alter familiar patterns of parent-child interaction, and there is some evidence in support of this view. Vaughn, Egeland, Sroufe, and Waters (1979) found that the mothers of infants who shifted from securely attached at 12 months to insecurely attached at 18 months reported significantly higher amounts of life stress compared with the mothers of infants who maintained secure attachment at each age. These findings are consistent with the association between stressful events and height-

ened attachment insecurity in the socioeconomically stressed samples earlier described. In longer-term studies, the frequency of negative life events between attachment assessments is associated with changes in the security of attachment from infancy to adulthood, especially shifts toward insecure adult attachment representations (Hamilton, 2000; Lewis et al., 2000; Waters, Weinfield, & Hamilton, 2000; Weinfield et al., 2000; see also Beckwith, Cohen, & Hamilton, 1999). These events include parental divorce or serious illness, parental loss, child maltreatment, and other intervening events of significance and severity, although some of them (particularly divorce) are experienced by a high proportion of children in countries like the United States.

Stresses may not be the only influences provoking changes in attachment. Thompson, Lamb, and Estes (1982) found with a middle-class sample that comparatively nonstressful changes in parent-infant interaction, such as those resulting from the mother's return to work and the onset of nonmaternal care, were associated with changes in attachment security. These life events were associated with changes from insecurity to security and the reverse. Thus, change and stress can alter familiar patterns of parent-child interaction and, as a consequence, the security of attachment, with stress promoting a change toward insecurity. This may help to explain why the proportion of stable attachment relationships in middle-class samples is not strikingly higher than those for lower-income samples (Table 2.1), and why studies with samples that were specifically selected to exclude such influences reported higher consistency in attachment relationships over time (e.g., Main & Weston, 1981). Owen, Easterbrooks, Chase-Lansdale, and Goldberg (1984) did not find an association between changes in attachment and shifts in maternal employment, however, although the latter were associated with changes in the security of infant-*father* attachments.

A somewhat more refined hypothesis is that changes in the quality or sensitivity of caregiving—which may result from changing or stressful life conditions—are associated with change in attachment security. Frodi, Grolnick, and Bridges (1985) found no associations between the stability of attachment and intervening life events or child care patterns, but reported associations with the sensitivity of maternal care. Infants who were either consistently secure or became secure from 12 to 20 months had mothers who were more sensitive and less controlling at 12 months. A similar conclusion derives from the NICHD Study of Early Child Care, which found that changes in

<sup>5</sup> Although Fraley (2002) concluded from a meta-analysis review of many of these studies that there is moderate stability of attachment security across the first 19 years of life, his analysis focused exclusively on the secure-insecure distinction and thus ignored important changes that occur between the insecure classifications, which tend to be more unstable over time than the secure group.

maternal sensitivity were significantly associated with changes in attachment security from 15 months (assessed via the Strange Situation) to 36 months (assessed via the Cassidy-Marvin procedure; NICHD Early Child Care Research Network, 2001). Only 46% of the sample maintained the same attachment classification over time, with low or decreasing maternal sensitivity in home observations from 24 to 36 months predicting which infants would change from secure to insecure, and higher sensitivity over this period predicting which infants would change from insecure to secure (but see Belsky, Campbell, Cohn, and Moore, 1996, for a failure to find similar differences). Thus, changes in the security of attachment may be associated with changes in the sensitivity of parental care, which is consistent with attachment theory.

Changes in the sensitivity of care can derive from many influences. In a study using the AQS, Teti, Sakin, Kucera, Corns, and Das Eiden (1996) found that the attachment security of firstborn preschoolers decreased following the birth of a new sibling. The children whose security scores dropped most dramatically had mothers with significantly higher scores on depression, anxiety, and/or hostility compared with the mothers of children who maintained high security scores. In this study, furthermore, firstborns' security scores were also predicted by measures of the mothers' marital harmony and affective involvement with the firstborn. Thus, the impact of the secondborn's birth on the security of mother-firstborn attachment was moderated by the mother's capacities to cope successfully with the new birth, which was itself predicted not only by her personality style but also by the support she received from her partner. It seems likely that similar processes of coping and adjustment would mediate the impact of family events on the sensitivity of parental care and the consistency of child-parent attachments over time. When caregivers can cope adaptively with changing life circumstances and negative events, sometimes with the assistance of others, they are more likely to maintain familiar patterns of interaction and consistent attachment relationships over time.

Taken together, these studies collectively portray the continuity of attachment security as a relational process that is influenced both by the quality of care in infancy and the subsequent quality of care after infancy. Such a view is consistent with Bowlby's claim that attachment patterns are a product both of personal history and current circumstances. It suggests that rather than early experience launching children on highly predictable developmental pathways, or psychological growth deriving

from current experience alone (Fraley, 2002), relational history and current experience each exert important influences on a child's psychosocial functioning.

But further exploration of the determinants of stability and change in attachment security is essential for several reasons. First, far greater understanding of the conditions that are associated with relational changes, and why they are influential, is needed. The pattern of findings thus far suggests that different kinds of influences are associated with changes from security to insecurity compared to the reverse, but these are confounded with the broader socioeconomic circumstances of the family and thus require further study. Second, the association between negative life events and change in attachment is moderate but not strong, suggesting that other influences are also relevant and perhaps preeminent in altering prior relational patterns (Thompson, 2000; Waters, Weinfield, & Hamilton, 2000). These could include the coping capacities of the parent (as noted earlier) or the child, as suggested by the emotional security hypothesis of Davies and Cummings (1994). Other potential influences include the availability of other attachment partners who provide greater relational stability to the child, the child's personal construals of the caregiver's behavior that could moderate the impact of stressful events on the child's expectations for care, and temperamental qualities that may alter a child's vulnerability or resiliency to the personal impact of negative life events. Each of these hypotheses merits further empirical exploration, and few have yet been studied. Third, our understanding is especially impoverished with respect to the influences that can cause formerly insecure children to become secure, despite the relevance of this to preventive and interventive efforts. Although parent-child therapeutic interventions informed by attachment theory have been shown to benefit young children growing up in at-risk circumstances (e.g., Cicchetti, Toth, & Rogosch, 1999), little is known about the ordinary conditions that can provoke transitions to secure attachment in nontherapeutic contexts. Further study of this issue can have potential importance for fostering more positive early parent-child relationships and to the study of early childhood mental health.

### **Early Attachment and Subsequent Psychological Development**

If the consistency of attachment relationships is due to an interaction of early sensitive care and subsequent ex-

perience, then this should also be true of the sequelae of attachment security: The extent to which attachment predicts later sociability, behavior problems, or other outcomes should depend on both early security and the child's subsequent experiences, particularly of sensitive care. Belsky and Pasco Fearon (2002a) confirmed this expectation from attachment theory using data from the NICHD Study of Early Child Care. Analyzing Strange Situation classifications at 15 months and subsequent measures of maternal sensitivity at 24 months, they reported that the children who obtained the highest scores on a broad range of social and cognitive measures at 36 months were those who were securely attached and who subsequently experienced sensitive care. Those performing most poorly at 36 months were insecurely attached in infancy and experienced later insensitive care. Interestingly, of the two intermediate groups, children who were initially insecurely attached but subsequently experienced sensitive care scored higher on all outcome measures than children who were initially secure but later experienced insensitive care. Similar findings have been reported by other attachment researchers (e.g., Easterbrooks & Goldberg, 1990; Egeland, Kalkoske, Gottesman, & Erickson, 1990; Erikson, Sroufe, & Egeland, 1985; Sroufe, Egeland, & Kreutzer, 1990). Belsky and Pasco Fearon (2002a) also found that maternal-report measures of life stress, depression, social support, and family resources at 24 months helped to explain why some securely attached infants subsequently experienced insensitive care, and why some initially insecure infants later experienced sensitive maternal care. In each case, maternal insensitivity was positively associated with the number of negative life events and lack of support that mothers experienced when children were age 2. In a corollary report from the same NICHD study, Belsky and Pasco Fearon (2002b) reported that a cumulative measure of contextual risk during the child's first 3 years moderated some of the associations between early attachment and later behavior.

In another reanalysis of the NICHD Study of Early Child Care, Raikes and Thompson (2005d) expanded on these findings. They examined the association between multiple early assessments of attachment security (at 15, 24, and 36 months) and later measures of parent-child relationship quality with children's social-cognitive functioning at 54 months and first grade. They found that *both* concurrent parenting quality and early attachment security were associated with social-cognitive outcomes, and that children with insecure attachment histories

were more sensitive to the effects of parenting quality later in life than children with secure attachment histories. Moreover, attachment security at 24 and 36 months (when children's mental representations are maturing) but not at 15 months was predictive of later social cognition, and security at multiple ages was more predictive than a secure attachment at only one assessment. It was, in short, cumulative relational experience that predicted children's social-cognitive functioning at school entry, which included assessments of children's attributions for peer behavior, their ability to generate appropriate responses to social problems, and self-perceived loneliness.

These findings, taken together, indicate that early security interacts with the quality of subsequent experience (particularly maternal care and broader life stresses) in predicting developmental outcomes. Indeed, these findings suggest that later caregiving may be at least as important as early security in predicting later behavior. Unfortunately, most of the research on the outcomes of early attachment is insensitive to these developmentally interactive influences. Although virtually all attachment theorists agree that the consequences of a secure or insecure attachment arise from an interaction between early security and the continuing quality of parental care, most studies are designed in a simple pre-post manner in which security in an antecedent assessment is associated with a later behavioral outcome. This makes it impossible to determine whether early security is linked to later behavior because caregivers have remained consistently supportive (or unsupportive) over time, or even whether the child's attachment has remained consistently secure or insecure. If either is true, then predictive relations between attachment and later behavior may be better attributed to the continuing influences of parental sensitivity or attachment security. Moreover, few studies are designed to enable an assessment of possible moderators of the association between early security and its hypothesized outcomes, which include not only the sensitivity of parental care and family stress but also other features of parental behavior that can facilitate or impede later developmental outcomes. Thus, research on the predictive relations between attachment and later behavior is often agnostic concerning its causes (Thompson, 1999).

This is unfortunate because attachment theory is ready to move beyond simple pre-post research to a more incisive exploration of the conditions underlying continuity and change in psychological growth. It is as

important today to understand *why* early security is (or is not) related to later psychological functioning as it is to establish a predictive relation. In this regard, theory development must proceed in tandem with more sophisticated research designs to enable the examination of more complex, interactive predictive models than the simple expectation that early security predicts later psychosocial functioning.

Guided by a general expectation that a secure attachment predicts better later functioning, as noted earlier, researchers have studied a wide range of hypothesized outcomes. It is important, however, to distinguish different outcome domains in assessing the importance of attachment security for psychological development. This is because a secure attachment might be expected to have stronger, more enduring, and more direct associations with sequelae that are more specifically related to issues of relational trust and security than to outcomes that are not.

The most direct result of a secure attachment would be for the *parent-child relationship*: An early secure attachment should predict more positive subsequent parent-child interaction. This expectation is confirmed in short-term follow-up studies during the 2nd year in which securely attached children showed greater enthusiasm, compliance, and positive affect (and less frustration and aggression) during shared tasks with their mothers (e.g., Frankel & Bates, 1990; Matas, Arend, & Sroufe, 1978; Slade, 1987). Secure infants tend to maintain more harmonious relations with their mothers in the 2nd year. However, in each of these studies, the mothers of securely attached infants were themselves more sensitive and helpful toward offspring in follow-up assessments, and thus supported the positive behavior of their children. It is more appropriate, therefore, to conclude that securely attached *dyads* tend to maintain interactive harmony in the 2nd year. This continuity in parent-child harmony provides significant benefits for child socialization and personality development for securely attached children (Waters et al., 1991). However, the beneficial effects of a secure attachment in infancy may wane over time. Researchers have not found longer-term associations between security in infancy and parent-child interaction at ages 3 (Youngblade & Belsky, 1992) and 5 (van Ijzendoorn, van der Veer, & van Vliet-Visser, 1987), even though long-term associations have sometimes been demonstrated, as noted earlier, between attachment measures at different ages. This is consistent with the findings of studies concerning the stability of attachment classifications, which indicate, as noted ear-

lier, that relationships may remain consistent or change after infancy. Consequently, although attachment security in infancy may inaugurate short-term consistency in the harmony of parent-child relations, the evidence concerning long-term continuity is mixed, with continuity likely depending on important mediating conditions in the ecology of family life.

What about the benefits of attachment security for children's experience of *other close relationships*? A meta-analysis by Schneider, Atkinson, and Tardif (2001) found a modest association between parent-child attachment and children's peer relationships (combined effect size .20) and confirmed that this association is stronger for studies of children's close friendships (effect size .24) than for relationships with other peers (effect size .14), which is consistent with other reviews of this literature (Thompson, 1998, 1999). Strange Situation, AQS, and representational attachment assessments for older children were used in the studies reviewed in this meta-analysis, and findings for each were consistent with these conclusions. Schneider and colleagues also concluded that this association is stronger for peer relations in middle childhood and adolescence than in early childhood and suggested that this derives from the consolidation and sophistication of representational processes related to friendship in older children. However, this conclusion integrates studies involving long-term prediction from infant attachment with studies in which attachment and peer relations were each assessed in childhood or adolescence, and thus the meaning of this association is not entirely clear from this meta-analysis.

Other studies support the conclusion that attachment security is more strongly associated with children's functioning in close relationships. In the Minnesota Study of Risk and Adaptation (see Sroufe, Egeland, Carlson, & Collins, 2005), for example, infants who were securely attached were later less dependent on their preschool teachers and functioned better in the preschool setting (Sroufe, 1983). Bost, Vaughn, Washington, Cielinski, and Bradbard (1998) found that secure preschoolers (assessed via observer AQS scores) had more extensive and supportive social networks and were also higher on sociometric assessments of peer competence (see Booth, Rubin, & Rose-Krasnor, 1998, and DeMulder, Denham, Schmidt, & Mitchell, 2000, for similar results). Anan and Barnett (1999) also found (in a sample of lower-income African American 6.5-year-olds) that secure attachment (assessed 2 years earlier) was associated with children's perceptions of greater social support, and social support mediated the associa-

tion between secure attachment and lower scores on externalizing and internalizing problems. To be sure, there is evidence that securely attached infants are also more sociable with unfamiliar adults during the 2nd or 3rd year (e.g., Main & Weston, 1981; Thompson & Lamb, 1983), which may derive from the generalization of the social skills that secure infants acquire with their mothers. However, mothers were present during stranger sociability assessments in these studies, and each study in which concurrent maternal behavior was evaluated yielded differences indicating that the mothers of secure children were more supportive and child centered with their offspring. Thus, differences in stranger sociability may be a dyadic phenomenon. Differences in more intimate relationships appear, by contrast, to be a function of the capacity of securely attached children to create more positive relationships.

Attachment researchers have also studied the associations between relational security and *personality development*. The Minnesota Study of Risk and Adaptation, a uniquely comprehensive, prospective longitudinal study of children and families in poverty, has focused extensively on the association between attachment and personality within the organizational perspective of attachment theory and Sroufe's portrayal of the "continuity of adaptation" of age-related developmental challenges. In this study, children were recruited with their families in infancy and followed through age 28, with personality characteristics assessed regularly through behavioral observations, interviews, observer ratings, semiprojective instruments, and self-reports. Sroufe and his colleagues found significant continuities between early attachment security (assessed in the Strange Situation at 12 and 18 months) and personality dimensions throughout childhood and adolescence, including associations between secure attachment and measures of emotional health, self-esteem, agency and self-confidence, positive affect, ego resiliency, and social competence in interactions with peers, teachers, camp counselors, romantic partners, and others (see Sroufe et al., 2005, for a comprehensive report, which also includes a list of citations to specific research reports and a comprehensive list of measures). Moreover, consistent with the emphasis on both developmental history and current experience, Sroufe and his colleagues found that the prediction of these and other personality features was enhanced when (a) early attachment measures were supplemented by other indicators of the quality of early care, (b) there was consideration of continuity in the quality of care between infancy and later ages, and (c)

early measures were supplemented by more contemporaneous assessments of relational functioning and/or personality, especially when long-term prediction was involved (e.g., Carlson, Sroufe, & Egeland, 2004). Taken together, this study yielded impressive evidence of the predictable organization of personality and behavioral functioning from childhood to early adulthood as a function of the interactive effects of early caregiving, subsequent experiences, and relational influences. Although some of the findings of this project have not been replicated by others (e.g., Easterbrooks & Goldberg, 1990; Frankel & Bates, 1990), the study offers an important portrayal of the place of attachment security in the multifactorial construction of personality development (Thompson, in press).

Security of attachment as a protective or risk factor to the development of *psychopathology* has also been the focus of research inquiry. In the Minnesota study, insecure-resistant attachment in infancy predicted anxiety disorders in adolescence, but there were few other associations between the organized insecure classifications and later psychopathology (Sroufe et al., 2005). In another at-risk sample, Lyons-Ruth, Easterbrooks, and Cibelli (1997) reported that avoidant attachment in the Strange Situation was associated with teacher-report internalizing symptomatology indexed by the Child Behavior Checklist (CBCL) at age 7, although there was no association with teacher-reported anxiety or behavior problems at age 5 (Lyons-Ruth, Alpern, & Repacholi, 1993). A number of studies have failed to discern a reliable association between early organized insecurity in the Strange Situation and the development of behavioral problems, especially in middle-class samples (e.g., Bates & Bayles, 1988; Erickson et al., 1985; Fagot & Kavanagh, 1990). However, analyses from the NICHD Study of Early Child Care found that insecurity at 24 months (on the AQS) predicted maternal and caregiver CBCL ratings at age 3 of internalizing and externalizing behavior problems, and insecurity at 36 months (using the Cassidy-Marvin procedure) predicted internalizing problems on the same assessments (McCartney et al., 2004). Thus, research evidence concerning the association between organized insecure attachment and the development of behavior problems in childhood is quite mixed. There is some evidence that this association is stronger in lower-income families, which are subject to other risk factors for child problems, than in middle-class homes, but the research evidence is inconclusive.

Further attention to the clinical implications of attachment security has accompanied the creation of the

disorganized/disoriented (group D) classification. Children in this group may be at risk for the development of later clinical problems, especially when they are in stressed or lower-income families. In the Minnesota study, infants who were classified D in the Strange Situation later obtained significantly higher scores on a global index of psychopathology and, in particular, of dissociative symptomatology in adolescence (Sroufe et al., 2005; see also Carlson, 1998). Lyons-Ruth and her colleagues (1995, 1997) reported that disorganized attachment in the Strange Situation was associated with teacher-reported externalizing symptoms on the CBCL at age 7, and with teacher-reported hostility at age 5 (see also Shaw, Owens, Vondra, Keenan, & Winslow, 1996, for similar findings using the Strange Situation with a low-income sample, and Moss, Parent, et al., 1996, and Moss, Bureau, et al., 2004, for comparable findings using the Cassidy-Marvin procedure with older children from middle-class families).<sup>6</sup> Shaw, Keenan, Vondra, Delliquadri, and Giovanelli (1997) and Moss, Bureau, and colleagues (2004) also reported higher scores for D children on internalizing symptomatology, and Moss, Cyr, and Dubois-Comtois (2004) have found contemporaneous associations between disorganized attachment and behavior problems in school-age children, with the different D subgroups predicting externalizing and internalizing problems. However, in a somewhat discordant report, McCartney and colleagues (2004), analyzing data from the NICHD Study of Early Child Care, found no reliable associations between disorganized attachment in the Strange Situation (at 15 months) or the Cassidy-Marvin procedure (at 36 months) and mother- or caregiver-reported behavior problems at age 3.

These mixed findings suggest that further examination of the association between insecure attachment and the development of behavior problems is warranted. In doing so, two interpretive cautions should be noted. First, since the origins of infant attachment disorganization are based in the same risk factors that also contribute to later psychopathology (such as maternal psychosocial problems and depression, family stress, and other factors), it

is unsurprising that in studies that have included these additional risks in predictive models, both disorganized attachment and other family risks combine to predict later child psychopathology (e.g., Carlson, 1998; Lyons-Ruth et al., 1993; Shaw et al., 1997). This is one of the reasons that the association between attachment insecurity and later behavior problems tends to be stronger in socioeconomically distressed families, but it also suggests that the sequelae of insecurity derive, in part, from continuity in the risk factors that initially contributed to attachment insecurity earlier in the child's life. Second, it should be clear that insecure attachment—even disorganized attachment—is not an index of psychopathology but only a risk factor. These findings show that although insecurity increases the chances of later behavior problems, the prediction of child psychopathology should be viewed in the context of multifactorial models involving early caregiving influences, continuing family adversity, ineffective parenting, and atypical child characteristics (Greenberg, 1999).

Indeed, the same conclusion is true of the other sequelae of the security of attachment. Because each of these hypothesized outcomes is multidetermined, attachment security is likely to explain a significant but small proportion of variance in each, with the amount of variance declining over time as other developmental influences emerge. This is one reason why future studies that include multiple predictors of later outcomes will be more informative in situating the security of attachment in the constellation of other influences that predict later parent-child relationships, social competence, personality, and risk for psychopathology. Furthermore, the large majority of research studies on the outcomes of attachment security focus on child-mother attachment relationships, even though attachment theorists recognize that children develop meaningful relationships with fathers and other attachment partners. It seems likely that studies incorporating the influence of multiple attachment relationships will have greater predictive power than those focusing on the child-mother relationships alone, but few studies have considered the roles of fathers and other caregivers.

What can we conclude, therefore, about the association between early attachment and later psychological development? Early security clearly makes a difference for the child's future in concert with other family influences. It inaugurates a more harmonious mother-child relationship that provides continuing benefits for the young child's receptivity to mothers' socialization incentives. It is associated with more positive personality

<sup>6</sup>These findings are consistent with a meta-analytic review by van Ijzendoorn and De Wolff (1997) who reported that there is a moderately strong association between disorganized/disoriented attachment and externalizing behavior (combined effect size .29), but the extraordinary heterogeneity of the samples and the assessments of disorganization for the 12 studies they summarized makes the meaning of this conclusion uncertain.

characteristics and greater social competence, especially in other close relationships with peers and adults. Attachment security is also a protective factor in the development of psychological well-being, with insecure attachment—especially disorganized insecurity—a risk factor for the development of behavioral problems. A secure attachment alone is not necessarily a strong predictor of long-term outcomes but, in concert with continuing supportive care, it meaningfully improves the odds for positive psychological growth. What is less clear is why these outcomes emerge. Attachment security is likely to be associated with more positive social skills, self-regulatory capacities, modes of social and emotional understanding, motivational processes, social expectations, causal attributions, and self-referential beliefs that contribute to the benefits of a secure attachment and the challenges of an insecure one. Attachment security is also likely to be associated with continuing parental sensitivity that provides ongoing support for healthy psychological growth. But thus far, researchers have yet to incisively explore the psychological processes underlying the association between early attachment security and its later psychological outcomes. This constitutes a central agenda for future attachment research.

A recent study by Denham, Blair, Schmidt, and DeMulder (2002) provides an example of the kind of research that would advance this understanding. In this study, multiple measures of attachment security (including observer AQS) were assessed when children were age 3, along with multiple measures of emotional (in)competence, including assessments of emotion understanding, regulation, and anger expression. Children were later studied in their kindergarten classrooms to assess peer competence through sociometric ratings and teacher-rated social competence measures. Latent variable path-analytic procedures were used to confirm two avenues from preschool attachment security to kindergarten social competence: (1) a direct pathway and (2) an indirect path through emotional competence (see also Denham et al., 2001). As we shall see, there is considerable research elucidating how securely attached children develop skills of emotion understanding through the more open conversation shared with their mothers, and this research suggests that skills in emotional competence may be one means by which the social skills of secure children are enhanced. To Denham and colleagues, the mediating influence of emotional competence illustrates one of several facets of the internal working models generated by the security of attachment.

## Internal Working Models

One of Bowlby's most heuristically powerful formulations is the view that attachment security influences psychological growth through children's developing mental representations, or *internal working models* (IWMs), of the social world. Internal working models are based on young children's expectations for the behavior of their attachment figures that develop into broader representations of themselves, their attachment figures, interpretations of their relational experiences, and decision rules about how to interact with others. These working models also become interpretive filters through which children (and adults) reconstruct their understanding of new experiences and relationships in ways that are consistent with past experiences and expectations, sometimes enlisting unconscious defensive processes in doing so. As a consequence, children choose new partners and behave with them in ways that are consistent with, and thus help to confirm, the expectations created from earlier attachment relationships. In this manner, IWMs constitute the bridge between the infant's experience of sensitive or insensitive care and the development of beliefs and expectations that affect subsequent experience in close relationships (Bretherton & Munholland, 1999). Furthermore, young children are believed to internalize conceptions of themselves from early relational experience that are incorporated into developing IWMs and that also constitute a perceptual lens for experiences that affect self-concept and other developing self-referential beliefs. In this manner, secure or insecure attachments shape the organization of personality through the influence of mental working models arising from attachment security.

This is a valuable way of thinking about socioemotional development that is representational, integrative, affectively oriented, and relationally based. Its breadth, however, poses some conceptual challenges for attachment theory. Grossmann (1999) has pointed out that at least two formulations of IWMs can be found in Bowlby's theory. One conceptualizes IWMs in a manner resembling the dynamic unconscious by which relational experience is interpreted through the perceptual-affective schemas of infancy; these prelinguistic models have enduring influence but remain largely inaccessible to conscious reflection. The other conceptualizes IWMs as resembling other, conscious representational models like scripts and schemas that evolve developmentally and can be consciously accessed. These are different formulations and have different implications for theory and assessment. Perhaps as a consequence, basic questions concerning how

IWMs develop, how their development is affected by other facets of conceptual growth, and changes in IWMs over time remain unclear in attachment theory (Thompson & Raikes, 2003). Another problem is the explanatory breadth that IWMs can assume. As Hinde (1988) noted, "in the very power of such a model lies a trap: it can too easily explain anything" (p. 378), a concern shared by other developmental scientists (Belsky & Cassidy, 1994; Rutter & O'Connor, 1999). Over the years, as attachment security has been studied in relation to a widening array of developmental outcomes, the concept of internal working models has been enlisted to account for unexpected as well as hypothesized associations, giving credence to Belsky and Cassidy's (1994) concern that IWMs would constitute a "catch-all, post hoc explanation" for such research findings. The inclusiveness of the IWM construct has expanded with every new empirical finding that is "explained" with reference to it.

This has also presented a considerable challenge for efforts to assess children's mental working models derived from attachment relationships. Attachment researchers have created a variety of assessments of children's mental representations of relational experience, many of them based on semiprojective narrative approaches that involve children's responses to doll-play materials, story-completion probes, evocative pictures, and other materials (see Solomon & George, 1999, and Stevenson-Hinde & Verschuere, 2002, for reviews of these methods). These procedures rely on the assumption that in responding to materials that are designed to evoke attachment-related issues, children will project onto the materials their own feelings and beliefs associated with their attachment experiences. Surprisingly, no procedures have been developed to directly assess children's expectations for the behavior of their attachment figures in familiar situations or their scripts for social interaction with their attachment figures.

Considerable thoughtful creativity has been devoted to semiprojective measurement development, but Solomon and George (1999) have chastised the "frontier mentality" of researchers who have produced these representational assessments with inadequate attention to their validation, especially by comparison to the careful validation of behavioral measures of attachment security. This may be due to the challenges inherent in such validation efforts. The coherence, emotional themes, and resolution of young children's narrative responses to semiprojective assessments are likely affected not only by the representations of relationships that researchers

hope to assess but also by other influences on narrative content and quality that derive from children's linguistic skills and verbal fluency, parent-child discourse, social desirability influences, culture, and ethnicity. There are also developmental considerations related to validation because the coherence of young children's story-completion discourse probably means something different compared to coherence in an adolescent's or adult's response to Adult Attachment Interview (AAI) probes. Attachment researchers have generally sought to validate representational measures of attachment security by establishing predictive or contemporaneous associations with behavioral attachment measures, even though security assessed by narrative coherence and emotional openness is not the same thing as security assessed by secure base behavior. But the important task of elucidating the meaning of differences in narrative responses to semiprojective probes and their association with parent-child interaction at home remains to be accomplished (Raikes & Thompson, 2005b; Waters & Cummings, 2000).

There have been at least two recent efforts to contribute greater theoretical clarity to the IWM construct in ways that have implications for assessment. Bretherton (1990, 1991; Bretherton & Munholland, 1999) has described mental working models in terms of the formulations of script theory and constructive memory and emphasized the openness of communication between parent and child as a significant developmental influence on the construction of working models in early childhood. More generally, she describes IWMs as a system of hierarchically organized representational systems that involve different levels of generalizability and are relevant to various broader belief systems, suggesting that elements of IWMs can be studied in the context of other conceptual achievements of the childhood years.

Building on this view, Thompson (1998, 2000) has proposed a developmental account that associates the growth of IWMs with other developing mental processes that encode, represent, interpret, and remember social experiences.<sup>7</sup> Drawing on literatures concerning the de-

<sup>7</sup>In a related view, Spangler and Delius (2003) have proposed that IWMs should be portrayed as a "theory of attachment" (or, perhaps, a "theory of relationships") involving coherently integrated knowledge of relational processes and causal influences that generate specific predictions and expectations for relational experience. Such a view, drawn from theory-theory of young children's intuitive beliefs about mind, physics, and biological kinds (Wellman, 2002), also offers considerable potential utility in clarifying the IWM construct.

development of implicit memory, event representation, autobiographical memory, theory of mind, and other features of social understanding, he portrays the growth of IWMs as building on and integrating these allied conceptual achievements that concern, like IWMs do, understanding of people and social events, self-understanding, and interpretations of relational experience. In this developmental view, IWMs change considerably with age, especially during periods of significant representational advance (such as the transition to symbolic representational capacities in early childhood, and the emergence of abstract thought in adolescence) when earlier representational systems become reorganized (see also Ainsworth, 1989; Crittenden, 2000). Thompson also argues that IWMs may have greatest influence on other aspects of sociopersonality growth during the developmental periods when these capabilities are maturing most significantly. The working models associated with a secure attachment may influence emotion understanding most strongly in early childhood, for example, when children's conceptions of others' feelings begin to become consolidated. Finally, in this view, IWMs are shaped not only by the child's direct experience of close relationships but also by the secondary representations of experience mediated by language through parent-child conversation. Consistent with literatures reviewed elsewhere in this chapter, he argues, language provides young children with considerable insight into others' feelings, thoughts, knowledge, and motives and are likely to significantly influence developing IWMs as they shape children's emergent conceptions of emotion, intention, and mind (see Thompson et al., 2003).

These newer portrayals of the development of mental working models emphasize the associations between IWMs and other conceptual systems and suggest that rather than trying to study working models directly through semiprojective procedures and other avenues, attachment researchers might equally fruitfully glean an understanding of their developmental influence by studying the representational correlates of differences in attachment security. By understanding how secure and insecure attachments are associated with differences in emotion understanding, self-awareness, and other characteristics, it might be possible to identify the influence of working models. There is now emerging an empirical literature documenting how the security of attachment is associated with representations of self, others, and relationships.

Belsky, Spritz, and Crnic (1996) hypothesized that differential processing of schema-consistent information, owing to the influence of IWMs, would cause securely attached children to remember positive events more accurately than insecure children. In a study in which 3-year-olds' delayed recognition memory for positive and negative events during a previously viewed puppet show was assessed, this expectation was confirmed. A recent study using data from the NICHD Study of Early Child Care also showed attachment-related differences in attentional processes, with disorganized children showing especially poor attentional performance (Pasco Fearon & Belsky, 2004). The conclusion that children with different attachment histories differentially attend to and remember emotionally related events merits further investigation because of its relevance to understanding the influence of the mental representations associated with attachment history and its broader implications for understanding attachment functioning.

Attachment security should be associated with children's conceptions of relationships, and one study has confirmed this to be true of peer relationships. Cassidy, Kirsh, Scolton, and Parke (1996) examined the associations between attachment security and children's sensitivity to the feelings of peers and attributions concerning peer motivations in response to hypothetical stories involving negative actions with ambiguous intent. Although attachment security from infant Strange Situation assessments did not confirm the expectation that securely attached 4-year-olds would be more likely to attribute benign motives to story characters, this expectation was confirmed when attachment security and peer measures were obtained contemporaneously in kindergarteners and first graders. Moreover, these representations of peer relationships in the older children were found to mediate the association between attachment security and peer sociometric status. Consistent with the findings of Denham, Blair, and colleagues (2002) described earlier, representations of the feelings and intentions of other children helped to account for the greater social competence of secure children. As noted earlier, furthermore, Raikes and Thompson (2005d) found that attachment history (especially in concert with subsequent supportive parenting) predicted children's attributions for peer behavior and social problem solving at 54 months and first grade, especially when children were securely attached on multiple early assessments.

Several studies have found that securely attached children are more competent in emotion understanding

in contemporaneous associations using the AQS (Laible & Thompson, 1998; Ontai & Thompson, 2002) and in predictive associations from infant Strange Situation classifications (Steele, Steele, Croft, & Fonagy, 1999) or early childhood AQS (Raikes & Thompson, 2005a; see also de Rosnay & Harris, 2002). These studies also indicate that securely attached children are especially proficient at understanding negative emotions and mixed feelings, which are each conceptually complex. Why do secure children better understand emotions? There is some indication that secure children acquire this understanding because of how they talk about emotion with their mothers. Ontai and Thompson (2002) found that attachment security interacted with elaborative maternal discourse in predicting emotion understanding: More secure 5-year-olds whose mothers had earlier used a more descriptively rich, elaborative style of conversation about emotion with them (in storybook reading and discussions of past events) were more advanced in positive emotion understanding (see also Laible, 2004b, for similar findings). Because the mothers of securely attached children have been found to be generally more elaborative in their style of conversation with offspring (Farrant & Reese, 2000; Laible, 2004b; Laible & Thompson, 2000; see Reese, 2002, for a review), these findings offer support for the view from attachment theory that secure dyads share a more “open, fluid communication” style that enables discussion of feelings (particularly mixed or negative emotions) and the child’s greater comprehension of them (Bretherton, 1990). One of the benefits of more open shared communication between mother and child—in which mothers provide more detailed information concerning emotions and other psychological experiences—is that young children can share troubled or confusing feelings with their caregivers and obtain an understanding response. This research thus suggests important associations between mother-child discourse style, the development of IWMs and of emotion understanding, and attachment security, consistent with the earlier review of research concerning the growth of emotion understanding in preschoolers. Indeed, Raikes and Thompson (2005a) found that the quality of mother-child conversations about emotion mediated the association between attachment security and emotion understanding in 3-year-olds. The influence of maternal discourse also suggests one way that the intergenerational transmission of attachment security and related representations might occur.

Similar influences may also account for the association between attachment and conscience development. A secure attachment is associated with conscience development (Laible & Thompson, 2000) but, as discussed later, attachment security is especially influential for children who are temperamentally relatively fearless, for whom the emotional incentives of the mother-child relationship motivate moral compliance (Kochanska, 1991, 1995). Attachment security is accompanied by mother-child discourse style in shaping early conscience development, with mothers who more richly and elaboratively discuss the feelings of other people contributing most to young children’s internalization of moral values (Laible & Thompson, 2000). As noted in a later section, this conclusion is consistent with Hoffman’s (1983, 2000) classic formulations concerning the nature of parental communication contributing to moral internalization. Further evidence of how attachment interacts with other parental influences derives from the findings of Kochanska and colleagues (2004) of how attachment security interacts with parental discipline practices on the growth of conscience. In their longitudinal analysis, they found that for securely attached children, the parent’s use of responsiveness and gentle discipline predicted later conscience, but for insecure children there was no such association. These findings suggest that the security of attachment moderates the influence of other relational influences on early socialization. With respect to conscience, for example, the adult’s disciplinary practices may have differential emotional impact depending on the broader relationship shared by parent and child.

Attachment theory argues that the IWMs deriving from a secure or insecure attachment influence self-concept, particularly conceptions of the self as loved and loveable. In a study of contemporaneous associations between attachment and multiple measures of self-understanding, Cassidy (1988) found that securely attached 6-year-olds described themselves in generally positive terms but were capable of admitting that they were imperfect. Insecurely attached children either revealed a more negative self-image or resisted admitting flaws. Clark and Symons (2000) found stronger contemporaneous associations between attachment security and two assessments of self-concept at age 5 than predictive associations with attachment at age 2, but the associations depended on the measure of self-concept. Goodvin, Meyer, Thompson, and Hayes (2005) also found that securely attached preschoolers viewed themselves more

positively and self-concept was more stable over time than for insecure children, while maternal emotional difficulties (depression and parenting stress) predicted children's negative self-perceptions. In problem-solving tasks, insecurely attached preschoolers expressed greater frustration and inability and asked for help sooner and in unnecessary circumstances (Colman & Thompson, 2002). These findings suggest that attachment security and developing self-concept are associated, and warrant further exploration of the mediating processes by which this occurs.

Finally, attachment theory does not make strong predictions concerning the benefits of a secure attachment for understanding others' thoughts and beliefs and, perhaps as a consequence, there is mixed evidence for the association between attachment security and theory of mind. Meins et al. (2002) found no association between early attachment and children's later performance on theory of mind tasks, but Symons and Clark (2000) found a contemporaneous association between attachment and theory of mind in 5-year-olds. In light of the variety of assessments of theory of mind in preschoolers and the direct and indirect avenues by which attachment relationships might be influential in its development, further reflection is warranted on whether and why an association between these constructs might exist.

Taken together, the research on the representational correlates of attachment security contributes to an appreciation of why the mental models associated with secure or insecure attachments are so conceptually exciting for developmental analysis. The conclusions of these studies suggest:

- Mental representations of peer intentions, emotional inferences, and other psychological processes mediate between attachment security and its behavioral outcomes, such as social competence.
- Differences in processes of parent-child discourse may interact with the broader security of the parent-child relationship to shape young children's developing emotion understanding and, quite likely, conscience development, and possibly contribute to the intergenerational transmission of expectations and beliefs associated with the security of attachment.
- Attachment security and its allied representations may moderate the influence of other parental practices, such as discipline approaches, on children's

conscience development and possibly other behavioral outcomes.

- A child's relational history may also sensitize or blunt attention to other features of social experience in ways suggested by the findings of Belsky and his colleagues.
- For many domains of psychological development, such as theory of mind, greater reflection on the role of attachment security is needed.

Further research on the representational correlates of the security of attachment may contribute to understanding how multiple attachment relationships become enfolded into the development of secure or insecure persons by adolescence or early adulthood. It is noteworthy that most of the research reviewed here has not sought to directly assess internal working models, but rather has sought to comprehend their functioning through more specific analyses of the associations between attachment and conceptions of peer relationships, emotion understanding, self-concept, and other psychological processes associated with the mental models derived from attachment relationships. In so doing, we derive a portrayal of working models as rapidly developing processes that mediate between attachment security and its behavioral outcomes, interacting with other relational influences between parents and offspring, and sensitizing awareness of social processes.

## Summary

Despite its controversial status in developmental psychology (Thompson, 2005), attachment theory remains uniquely generative because of how it integrates ideas concerning the effects of early relational experience on socioemotional and personality development, constructivist views on the growth of social relatedness, the development of representations concerning relationships and self, and the relevance of these for the growth of psychological well-being and psychopathology. Its future potential for remaining a central view of early personality development depends on the capacities of attachment theorists and researchers to update Bowlby's provocative formulations with the thinking of contemporary developmental science and the yield of their own empirical studies. The findings of the studies reviewed in this section suggest that there remains considerable

potential for the generation of new ideas within the attachment framework.

## CONSCIENCE

Conscience development is concerned with how children construct and act consistently with generalizable, internal standards of conduct. It is closely tied to moral judgment, but the growth of conscience also encompasses the affective, temperamental, and relational influences that, together with moral judgment, shape moral conduct. The study of conscience thus provides a window into how emotional, cognitive, and relational influences intersect to guide young children's developing views of themselves in relation to others and the broader values of the social world (Kochanska & Thompson, 1997; Thompson, Meyer, & McGinley, 2006).

Not surprisingly, contemporary research on conscience has emerged in the shadow of moral development theory. Traditional approaches to moral development, such as learning theory and the cognitive-developmental views of Piaget and Kohlberg, have portrayed morality in early childhood as distinct from that of older children and adolescents because of the younger child's egocentric, preconventional moral orientation. By contrast with older children who are concerned with maintaining harmonious social relations, and adolescents who are viewed as ethical, humanistic moralists, young children are portrayed as authoritarian, utilitarian moralists who are guided by rewards, punishment, and obedience. But new research, together with new understandings of young children's conceptual skills and relational experiences, have contributed to a new view of early conscience and of the importance of early childhood to the development of mature morality. It is now becoming clear that conscience in early childhood shares much in common with the morality of later years because of preschoolers' sensitivity to the feelings of others and the relational incentives for cooperation. Parental influences encompass far more than sanctions and reinforcements and include maintaining a relationship of mutual responsiveness and trust, enlisting conversational catalysts for moral understanding, and proactive efforts that foster cooperation and compliance in young children. Early childhood is increasingly viewed as providing a foundation for the morality of values, humanistic regard, and relationships of later years.

## Intuitive Morality of Early Childhood

In early childhood, the conceptual foundations of moral development become established. Young children are not egocentric but rather, as earlier noted, are intensely interested in the desires, intentions, feelings, and thoughts of other people. Their sensitivity to others' reactions contributes to their anticipation of and responsiveness to disapproval and, later, to a dawning understanding of normative standards of appearance and behavior late in the 2nd year. As noted earlier, by 18 to 19 months of age, young children begin to respond with heightened interest and concern to objects that are damaged or flawed (Kagan, 1981, in press; S. Lamb, 1993). Kagan (1981) has interpreted this phenomenon as an emergent moral sense, based on caregivers' reactions to damaged objects and the young child's emergent sensitivity to standards. Consistent with this view, Kochanska, Casey, and Fukumoto (1995) found that older children (26- to 41-month-olds) who responded with greater concern to flawed objects also showed greater distress to rigged mishaps for which they believed they were responsible. These studies suggest that young children internalize normative standards for appearance and integrity based, in part, on their observations of how adults respond to violations of these standards in everyday experience (such as cleaning or discarding soiled toys). This is at the same time that toddlers begin to respond with embarrassment and concern to a spot of rouge on their noses, reflecting their awareness of normative standards for personal appearance (Lewis, 2000; Lewis & Brooks-Gunn, 1979).

Young children also appropriate behavioral standards and distinguish between different domains of behavioral obligation (see Turiel, Chapter 13, this *Handbook*, this volume). Much as adults do, 3- and 4-year-olds distinguish between moral and social-conventional standards, viewing moral violations as more serious and less revocable owing, in part, to their harm to others (Smetana, 1981, 1997; Smetana & Braeges, 1990). In complex social situations, such as gender exclusion in peer play, preschoolers prioritize equal treatment over convention in their consideration for fairness by age 5 (Killen et al., 2001; Theimer et al., 2001). By age 4, furthermore, individual differences in emotion understanding and knowledge of mental states (i.e., theory of mind) predict differences in children's moral judgments in friendship relations (Dunn, Cutting, & Demetriou, 2000; see also Dunn, Brown, & Maguire, 1995). Thus, young children

develop an intuitive morality that arises from the socialization efforts of caregivers in tandem with their own sensitivity to the feelings and thoughts of others and their developing grasp of normative standards of appearance and behavior.

Young children's focus on normative standards is unsurprising in light of their search for other constancies in everyday experience. This is one reason why they acquire such an early grasp of obligation in moral, conventional, and prudential concerns. As Harris and Nunez (1996) have shown, even 3-year-olds are highly skilled in understanding how a prescriptive rule applies to different circumstances (e.g., "Mom says if Cathy rides her bike she should put her helmet on"), even though they are not as skilled at applying a similar descriptive, but not prescriptive, maxim (e.g., "When Cathy rides her bike, she always wears her helmet"). In a provocative analysis, Wellman and Miller (2003) have proposed that just as 3-year-olds have difficulty conceptualizing beliefs that are discordant with reality, so also they have difficulty understanding obligation that is discordant with behavior, so they are prone to assert that rules cannot be broken and obligations must necessarily be fulfilled. Behavioral obligations describe normative reality in the eyes of young children, according to Wellman and Miller, and violations are special sources of concern. This concern with what is obligatory and normative, which is similar to the moral absolutism observed in young children long ago by Piaget (1965), is consistent with young children's interest in objects that are flawed and mirror appearances that are rouge marked, and suggests that an important conceptual foundation for early conscience development is young children's attunement to the normative standards and behavioral expectations that are part of their developing representations of what they might typically expect in everyday experience.

Young children's developing representations of normative and behavioral standards are conceptually salient because they are likely to be embedded in broader prototypical knowledge structures by which children represent everyday experiences (Hudson, 1993; Nelson, 1978). Many of the moral, conventional, and prudential standards conveyed to young children are related to routine events and are repeatedly confirmed in these contexts, whether consisting of prohibitions about making "messes" and breaking things, self-control with respect to waiting, sharing, aggression, and eating, withdrawing from touching dangerous objects, self-care, or participation in family routines (Gralinski & Kopp,

1993; Smetana et al., 2000). Caregivers distinguish between different obligatory domains in their discussion of expectations with young children, justifying moral rules for their interpersonal consequences, for example, and prudential rules by safety concerns (Smetana, 1997; Smetana et al., 2000). Thus, preschoolers' understanding of *how things are done* includes standards for *how one should act* in these and other everyday situations, and this may help to explain young children's inflexibility with the application of behavioral expectations just as they are rigid in their beliefs about how common routines are conducted. Expectations for how a person acts may become regarded as normative and obligatory just as are expectations for how others will act in these prototypical situations.

Ironically, the normative absolutism of the young child's thinking about obligation does not necessarily translate into behavioral compliance, as every parent knows. This arises, in part, because many moral situations involve frustrating present desires in favor of broader (often future) goals, which is a conceptual challenge for young children (Lagattuta, 2005). It is also challenging to comprehend the feelings and interests of multiple participants in interpersonal conflict, especially when self-interest is involved. As Arsenio and his colleagues have shown, for example, young children perceive victimizers as feeling positively about their misconduct, partly because children focus on the satisfaction of the victimizer's desires rather than the victim's distress (Arsenio & Lover, 1999). These studies highlight that even with their sensitivity to others' feelings, comprehending simultaneously the emotional perspectives of multiple people is still difficult for young children. Thus, the young intuitive moralist's deontic understanding does not readily translate into moral compliance. The result is everyday experience with the disapproval of caregivers and the feelings of guilt that may result.

### Moral Emotion

Moral emotion also emerges early, and contributes to the incentives for moral compliance because of its relevance to the self and relationships. As noted elsewhere, the development of self-understanding occurs in concert with the emergence of self-referent emotions that are elicited in everyday situations in which adults make salient attributions of responsibility for achievement or wrongdoing. With respect to guilt and shame, parental

responses to a young child's misbehavior typically make explicit the behavioral values the child has violated, and it is remarkable how early children begin to respond with these emotions (Barrett, 1998; Lewis, 2000; Thompson et al., 2005). Kochanska, Gross, Lin, and Nichols (2002) observed children's affective and behavioral responses at 22, 33, and 45 months to experimental situations involving rigged mishaps for which children believed they were responsible. Young children exhibited concern and distress at each age, and individual differences in these responses were stable over time and were modestly predictive of a battery of conscience assessments at 56 months. Moreover, children who displayed more of these behaviors at each age were found to be temperamentally more fearful, and their mothers used less power assertion in discipline encounters. These developmental findings are consistent with maternal reports concerning the development of guilt in offspring, which also report significant growth in the affective and behavioral manifestations of guilt over this period (Kochanska, DeVet, Goldman, Murray, & Putnam, 1994; Stipek, Gralinski, & Kopp, 1990; Zahn-Waxler & Robinson, 1995; see Eisenberg, Fabes, & Spinrad, Chapter 11, this *Handbook*, this volume). At the same time that young children are becoming aware of normative and behavioral expectations, they are also becoming prone to self-referent moral emotions that can significantly motivate compliance.

Temperamental individuality is an important mediator of children's experience of the affective discomfort and anxiety associated with wrongdoing. In a theoretical analysis, Kochanska (1993) proposed that conscience development may assume two developmental pathways: (1) through the motivation to avoid the emotional discomfort associated with wrongdoing, and (2) through the motivation to maintain good relations with caregivers by exercising behavioral self-control. She proposed that a child's temperamental profile is influential in determining which developmental pathway predominantly contributes to the growth of conscience. This view was subsequently elaborated in two studies showing that for temperamentally fearful young children, conscience was predicted by maternal control strategies that deemphasized power and instead enlisted nonassertive guidance and "gentle discipline." These children are naturally prone to fear and anxiety after wrongdoing, Kochanska reasoned, and thus nonpunitive discipline that enlists the child's preexisting worry without creating overwhelming distress is likely to con-

tribute best to moral internalization. By contrast, for children who were temperamentally relatively fearless, conscience was instead best predicted by the security of attachment and maternal warm responsiveness. For these children, the relational incentives of the mother-child relationship better motivated moral internalization and helped to consolidate a positive, mutually responsive parent-child relationship (Kochanska, 1991, 1995; see Kochanska, 1997a, and Kochanska et al., 2002, however, for somewhat different findings). These findings suggest that temperament may influence conscience development because it mediates children's emotional experience of parenting practices in response to wrongdoing.

Temperament may be related to conscience development in other ways. Young children who are high on effortful (or inhibitory) control are more capable of exercising self-restraint to comply or desist, and research by Kochanska and her colleagues suggests that these children are also higher on measures of conscience in both contemporaneous and longitudinal assessments (e.g., Kochanska, 1993; Kochanska, Murray, & Coy, 1997). Kochanska and her colleagues (1994) also reported that preschool girls who were higher on temperamental reactivity obtained higher scores on a maternal report measure of the child's guilt, consistent with the view that reactive children would be more sensitive to disapproval and criticism.

The temperament research underscores that there are alternative avenues to conscience development because young children are not morally cooperative for the same reasons. For some, cooperation springs from broader capacities for self-control; for others, maintaining good relations with caregivers (and the threats to relational harmony arising from misbehavior) is central; for still others, moral cooperation derives from efforts to avoid the fear and anxiety that arises from disapproval. This suggests that the moral socialization efforts of parents must be adapted to the child's temperamental profile and other characteristics. Furthermore, this literature suggests that not only moral resources but also moral vulnerabilities inhere in these temperamental profiles. Temperamentally fearful children may be vulnerable to becoming guilt-prone and morally inflexible as a result; temperamentally fearless children may misbehave when they can escape detection or avoid worry about the caregiver's loss of love. Because moral emotions are such powerful motivators of moral compliance, the influences of temperament on the emotional tendencies and

self-regulatory capacities that underlie moral conduct are potentially important for healthy and unhealthy forms of moral motivation.

There is yet another emotional resource for conscience development that emphasizes the prosocial over the prohibitive side of morality. Empathy begins to emerge during the 2nd year and continues to unfold with growth in emotion understanding in early childhood (Zahn-Waxler, 2000; Zahn-Waxler & Radke-Yarrow, 1990; Zahn-Waxler & Robinson, 1995). To be sure, the sight and sound of another person's distress, fear, or anger is a motivationally complex and stressful event for young children. It may lead to sympathetic feelings and prosocial initiatives, but young children may also ignore, laugh at, or aggress toward another in distress, or seek comfort for themselves because of threats to their own emotional security and limited social understanding. This is one reason why it is important to index empathy in young children as an affective response rather than as an instrumental (i.e., prosocial) behavior. However, when adults can assist the child in understanding the emotions they are witnessing in another, especially by clarifying causality and responsibility, raw empathic arousal can become enlisted into prosocial initiatives toward another person, and into guilt when the child is the perpetrator of another's distress (Zahn-Waxler & Radke-Yarrow, 1990; Zahn-Waxler & Robinson, 1995). Moreover, as children mature throughout the preschool years, their vicarious emotional responding becomes increasingly predictive of prosocial behavior (Eisenberg & Fabes, 1998; see also Eisenberg & Fabes 1995; Miller, Eisenberg, Fabes, & Shell, 1996). Viewed in this light, empathy alone may not reliably elicit moral responding in young children, but instead is a setting condition from which prosocial initiatives may arise. Equally important, empathy is one of the emotional catalysts for young children developing a moral awareness in which the feelings and needs of other people are central.

### Relational Influences

Fortunately, young children are not alone in their efforts to comply and cooperate. Parents and other caregivers contribute in many ways to the development of conscience. Beginning in infancy, when animated facial and vocal expressions of emotion are used by parents to warn or deter a locomoting child from a dangerous or disapproved activity, social referencing is enlisted to instill certain behaviors with emotional meaning and an-

ticipated disapproval (Campos et al., 1999; Emde & Buchsbaum, 1990). Later, as the distal warning becomes remembered, behavioral compliance arises from the toddler "referencing the absent parent" in memory (Emde, Biringen, Clyman, & Oppenheim, 1991; Emde & Buchsbaum, 1990). Parents intervene to remove the child from disapproved conduct and sanction disobedience, but they also proactively avoid discipline encounters by distracting attention, providing anticipatory guidance or alternative activities, or other diversionary tactics (Holden & West, 1989). There is also considerable direct instruction of young children about moral, conventional, and prudential rules of conduct by parents who strive to enlist children's cooperation (Smetana et al., 2000). Beyond these, at least three other facets of the parent-child relationship contribute significantly to conscience development in the preschool years: (1) the overall warmth and cooperativeness of the parent-child relationship, (2) child management strategies used by parents in discipline encounters, and (3) broader conversational discourse between parents and offspring that incorporates morally relevant themes.

The warmth and cooperativeness of the parent-child relationship is important, especially early in life, because conscience development is part of a child's broader induction into a relational system of reciprocity characterized by mutual obligations (Kochanska, 1997b; Waters et al., 1991). The human consequences of personal conduct become experienced directly for the first time in a parent-child relationship, and thus the quality of that relationship, especially its mutual responsiveness, helps to orient a young child's moral sensitivity to humanistic concerns and heighten the child's receptiveness to the parent's socialization initiatives. In several studies in which the mutual responsiveness of parents with young children was assessed during extended home observations, Kochanska and her colleagues found that dyadic differences in this relational quality predicted measures of the child's conscience development both contemporaneously and longitudinally (e.g., Kochanska, 1997b; Kochanska, Forman, & Coy, 1999; Kochanska & Murray, 2000; see also Laible & Thompson, 2000). Related research has helped to explain why. Mothers in mutually responsive relationships use less power assertion with offspring and they are more empathic, as are their children in response to maternal simulations of distress (Kochanska, 1997b; Kochanska et al., 1999). In a behavior genetic study, Deater-Deckard and O'Connor (2000)

concluded that dyadic mutually responsive orientation exemplifies an evocative gene-environment correlation in the parent-child relationship, which is consistent with the temperament research reviewed earlier.

Another index of relational quality is the security of attachment, and, as earlier noted, there is research evidence that a secure attachment is positively associated with cooperation and conscience development (e.g., Kochanska, 1995; Laible & Thompson, 2000). Interestingly, neither research group has reported a significant association between measures of attachment security and mutually responsive orientation between parent and child, despite their apparent conceptual overlap. Taken together, these studies underscore the importance of a harmonious relationship of positive mutuality between parent and child as a foundation for the growth of conscience and for cooperative conduct in young children.

A second feature of the parent-child relationship that contributes to conscience development is how the parent responds when young children misbehave. The discipline encounter has been the focus of extensive study for many years, and research findings with toddlers and preschoolers are consistent with those of older children in concluding that interventions that are coercive and power assertive elicit not only children's situational compliance but also young children's frustration and occasionally defiance. However, discipline that emphasizes reasoning and provides justification for compliance is more likely to foster internalized values in young children, even though children may also assert their autonomy through bargaining and negotiation (Crockenberg & Litman, 1990; Kuczynski, Kochanska, Radke-Yarrow, & Girnius-Brown, 1987; Laible & Thompson, 2002). This is likely to be one reason why, over the course of the preschool years, parents increasingly rely on verbal strategies over physical interventions for enlisting children's compliance (Dunn & Munn, 1987; Kuczynski et al., 1987).

Parental explanations, justifications, and reasoning may be especially important for young children who, in the context of heated emotions over misbehavior, may not immediately comprehend what is wrong or who is culpable. In their intervention, most parents provide a cognitive structure that explicitly links their response to the standards the parent has previously conveyed ("You know better than to hit your sister!"), invokes salient attributions of responsibility ("Why did you hit her?"), identifies consequences for another ("Look, she's crying!"), and often directly induces the self-

referent evaluation and affect ("Bad boy! You should be ashamed of yourself!"). In doing so, the parent not only explicitly denotes causal associations between the child's behavior, consequences for another, the parent's response, and the experience of moral affect but also may provide an interpretation of the event that is different from the child's own. To the extent to which this is clearly communicated and understood by young children, this experience can be conceptually provocative to young children who are otherwise striving to understand others' beliefs, feelings, motives, and their associations with the child's own. Furthermore, parental explanations and reasoning in the discipline encounter also introduce young offspring to cultural and moral interpretations of the child's behavior. As Miller and her colleagues have shown, for example, mothers in the United States tend to attribute child misconduct to spunk or mischievousness, but Chinese and Chinese-American mothers emphasize much more the shame inherent in misbehavior, each consistent with their cultural values (Miller, Fung, & Mintz, 1996; Miller, Wiley, Fung, & Liang, 1997).

This straightforward and rationalist account of the effects of discipline in early conscience is complicated, however, in several ways (Grusec & Goodnow, 1994; Grusec, Goodnow, & Kuczynski, 2000). First, multiple parental goals are likely to compete in how parents respond to any discipline encounter. In many circumstances, a priority on moral tutelage must vie with other goals, including effecting immediate child compliance, enabling children to responsibly choose among behavioral alternatives, enhancing parent-child communication and understanding, allowing children to assert themselves, and other worthwhile aims (Hastings & Grusec, 1998; Holden & Miller, 1999). The reasons for the child's misbehavior, the child's characteristics (such as temperament), and situational constraints (e.g., public versus private setting) are among the important influences on the goals that parents choose to pursue during conflict with the child, and this helps to explain why parents are not necessarily consistent in their parenting practices across different situations (Holden & Miller, 1999). The clarity of the parent's moral message is thus likely to be obscured by the alternative socialization goals that are also being pursued, or by the parent's effort to integrate inconsistent goals (e.g., values transmission while enabling child autonomy).

Second, not only what the parent says but the broader relational context influences conscience development. A

clear explanation warranting compliance is likely to have different meaning to a child who shares a warm and supportive relationship with the caregiver compared to a child who has experienced considerable prior conflict or distrust in that person. The view that children in warm, secure relationships may be more responsive to parental discipline practices than children in insecure relationships was recently tested by Kochanska et al. (2004), who assessed attachment security at 14 months, parental disciplinary practices at 14 to 45 months, and conscience at 56 months. For securely attached children, there was a significant positive longitudinal association between parental gentle discipline/ responsiveness and later conscience; for insecure children, there was no such association. The expectation that specific parental practices have differential consequences based on the broader tenor of the parent-child relationship is consistent with other studies of the effects of parent-child conversational discourse on conscience development (Thompson et al., 2003; see following), and suggests that adult explanations may “sound differently” to children who share different kinds of relationships with them.

Third, young children are participants in the process of values appropriation. They interpret what they are told in the discipline encounter in light of their own perceptions of fairness, the emotional effects of the parent's behavior (e.g., threats to security or a sense of autonomy), and the relevance and consistency of the parental message with what else they know (Grusec & Goodnow, 1994; Kuczynski et al., 1997). The importance of children's constructions of parental values is consistent with the literature on temperament and conscience discussed earlier and with the studies highlighting the mediating influence of the parent-child relationship on discipline effects. Furthermore, parental attitudes and discipline practices vary in relation to the outcome expectancies of parents—parents intervene based, in part, on how they anticipate the child will react to their intended intervention (Holden, Miller, & Harris, 1999; Holden, Thompson, Zambarano, & Marshall, 1997). Thus, a child's construal of the discipline encounter is important not only for its effects on conscience development but also for how it influences the child's behavioral response which, in turn, affects future parental conduct. Studies such as these are important for reaffirming the importance of bidirectional and transactional models of early moral socialization, by contrast with traditional portrayals of values internalization.

Fourth, although conflict is conceptually provocative and contributes to values clarification, conflict between a young child and a parent is also threatening to young children, and the emotion generated by the discipline encounter may undermine the child's comprehension and processing of the parent's moral message. This is consistent with Hoffman's (1983, 2000) classic formulation of the discipline encounter, but it emphasizes how much the difference in power between participants in conflict can make a full and accurate comprehension of the message from an authority difficult. As noted by Thompson (1998), from a depth of processing memory model it is likely that a young child's coherent processing and understanding of the parent's message will be undermined by the heightened arousal created by the discipline encounter, even when parents are careful to use discipline approaches that do not unduly heighten the child's discomfort. This is especially likely if the young child's cognitive resources are also being mobilized for negotiation or bargaining (Crockenberg & Litman, 1990; Kuczynski et al., 1987).

This is one reason that students of conscience development have focused on a third feature of the parent-child relationship that is associated with conscience development: conversations that occur outside the discipline encounter. These conversations may be planned or spontaneous and their topics may concern (a) events in the past, such as the child's prior misbehavior or admirable conduct; (b) a shared experience in the future, such as going to a public setting where good behavior is necessary; (c) immediate events, such as a sibling's temper tantrum; (d) storybook reading; (e) pretend play; or (f) other shared experiences. In these contexts, even when parents are not explicitly intending these conversations to be a means of transmitting moral lessons, the judgments, values, inferences, assumptions, and other interpretations that parents naturally incorporate into these conversations make them potentially potent forums for early moral understanding and conscience development. Equally important, the young child's cognitive resources are more likely to be focused on understanding and responding to the parent's message with less competing emotional arousal than in the discipline encounter.

Variations in the content and style of parental discourse in conversation influence early conscience development. Laible and Thompson (2000) recorded conversations between parents and their 4-year-olds about past incidents in which the child had either

misbehaved or behaved appropriately. Mothers who more frequently referred to the feelings of other people had children who were more advanced on measures of conscience, but maternal references to rules and the consequences of breaking them from the same conversations were unrelated to conscience. These findings were replicated in a prospective longitudinal study in which maternal references to feelings (but not references to rules and moral evaluations) during conflict with the child at 30 months predicted the child's conscience development 6 months later (Laible & Thompson, 2002). In another study, 2- to 3-year-old children whose mothers used reasoning and humanistic concerns in resolving conflict with them were more advanced in measures of moral understanding in follow-up assessments in kindergarten and first grade (Dunn et al., 1995). These findings suggest that one of the most important features of parent-child conversations on morally relevant themes is how they sensitize young children to the human dimensions of misbehavior and good conduct, helping children to comprehend the effects of their actions on how people feel. In a sense, these conversations put a human face on morality.

Just as in the discipline encounter, the warmth, emotional tone, and constructiveness of the parent's demeanor can be as important as what is said to the child. When they were in conflict with their young offspring, mothers who took the initiative to resolve conflict, using justifications to explain and clarify their expectations, and who managed to avoid aggravating and exacerbating tension (such as through threats or teasing) had young children who were more advanced on measures of conscience development at age 3 (Laible, 2004a; Laible & Thompson, 2002; see also Dunn et al., 1995 described earlier). By contrast, mothers who were conversationally "power assertive" when recounting the child's misbehavior in the recent past—conveying a critical or negative attitude, feelings of disappointment or anger, or involving reproach or punishment—had preschool children who obtained lower scores on measures of "moral cognition" assessed via children's story-completion responses to moral dilemmas (Kochanska, Aksan, & Nichols, 2003). As Hoffman (1983, 2000) has long argued, power assertion in the discipline encounter heightens children's anxiety and defensiveness and undermines retention of the parent's moral message, and it is likely that the same occurs in conversations about moral issues outside of discipline. Conversely, just as the well-documented effects of in-

ductive discipline on moral internalization occur when the adult combines warmth with a rational explanation that reduces threat to the child, similar influences occur in conversations outside of the discipline encounter as well. These conclusions also suggest that conscience development in young children is influenced by parent-child discourse in a manner similar to how older children are affected (Thompson et al., 2003).

Finally, just as the broader affective quality of the parent-child relationship is an important mediator of the effects of discipline in young children (Kochanska et al., 2004), the same is true of the effects of parent-child conversational discourse. Mothers' references to people's feelings interacts with the shared warmth of the parent-child relationship in its association with conscience development (Laible & Thompson, 2000; Thompson et al., 2003). Thus, broader relational quality combines with specific features of parent-child discourse to shape young children's conscience development.

## Summary

The dissonance between the portrayal of conscience development emerging from these studies and traditional portrayals of the self-interested, preconventional, ego-centric young child is an incentive to expanding understanding of the intuitive morality of early childhood and its developmental influences. These studies make it apparent that young children are acquiring moral orientations that are simpler, but fundamentally similar to, those of older children and adolescents, and therefore the experiences and influences of early childhood may provide an essential foundation for moral development at later ages. Viewed in this light, young children's conceptual growth, developing emotional understanding, and relational experiences may provide essential cornerstones for the later emergence of the internal, humanistic, self-committed morality of older children. Young children clearly are not "premoral" in any serious sense.

The study of conscience development has also offered developmentalists new questions and interesting methodologies with which to explore them. Beyond longitudinal studies that integrate the morality of early childhood with the better-studied moral reasoning of middle childhood, greater exploration of how young children conceptualize moral obligations would contribute to understanding how they perceive themselves as moral actors and (in Kochanska's evocative phrase) "moral selves." The relational catalysts to conscience

development also merit further exploration, especially in efforts to integrate understanding of parental practices in conversation, discipline, and other interactive situations that contribute to the development of moral awareness in young children. Given the growing evidence that conscience emerges not primarily from the prohibitive morality of parental discipline but from the incentives provided by a harmonious, mutually cooperative parent-child relationship, a portrayal of early moral growth that underscores children's appropriation of values from shared activity in the family may be more appropriate than the traditional internalization formulation. By underscoring the multifaceted shared contexts in which early conscience develops, such an approach highlights how parents and children mutually create the moral environment they share as a family.

## SELF

The development of self-awareness provides a window into the psychological growth of the child. Over the course of a few years, young children acquire capacities to engage with others intersubjectively, visually recognize their mirror images, attribute behavioral and psychological qualities to themselves, create autobiographical accounts, and situate themselves temporally as individuals with continuity into the past and future. With each developmental advance the child becomes a more complex, multidimensional *self* while also becoming more insightfully self-aware. Advances in self-awareness also transform young children's social interactions. They make children more psychologically self-conscious social actors who also possess greater insight into others. Like emotional development, the growth of self in early childhood involves the progressive elaboration of biologically basic capacities in ways that integrate the influences of conceptual growth, relational processes, and the child's own constructions of experience. These features of the development of self have stimulated considerable recent research into this topic, although important questions remain to be addressed.

### Developmentally Emergent Dimensions of Self

It is common to describe the 2nd year as when *the self* emerges, but enduring aspects of self-awareness have developmentally earlier origins. Both Gibson (1995) and Neisser (1995) argue that the earliest forms of prerepre-

sentational self-awareness arise from the integrated perceptual experiences deriving from movement and activity beginning soon after birth. The synchronous multimodal perceptual experience arising from self-produced activity fundamentally distinguishes the perceiver from objects (and people) acted on or that move around the infant. Neisser's portrayal of this "ecological self" addresses the traditional assumption that infants are born adualistic (i.e., incapable of differentiating the external from the internal world) by noting that perceptual experience itself distinguishes subjective from surround—in Gibson's (1995) evocative words, "to perceive the world is to coperceive oneself" (p. 6). Indeed, in this Gibsonian view, subsequent developmental changes in the perception of affordances in the environment also entail developmental changes in self-awareness (e.g., awareness of emergent capabilities) such as in how flat, extended surfaces afford walking to a 15-month-old toddler but not a 6-month-old. Moreover, these integrated perceptual experiences provide avenues for other, more complex forms of self-awareness to develop. By 5 months, the integration of kinesthetic and visual experience during movement enables a primitive kind of featural self-recognition: Infants can distinguish videos of their own leg movements from those of another infant (Bahrick & Watson, 1985; Rochat & Morgan, 1995). The initial organization and integration of experience around an implicit frame of reference thus constitutes one of the earliest forms of self-awareness.

Another is the experience of agency. As earlier noted, very young infants respond to contingency and by 2 to 3 months they respond with positive affect to contingent responding but become affectively negative if the contingency is interrupted (Lewis et al., 1990; Rovee-Collier, 1989; Watson, 1985). Initiating actions that have a predictable impact on objects and people, and the positive affect that results from the awareness of control, are together likely to be highly salient experiences contributing to self-awareness early in infancy. Early social interaction taps into the young infant's contingency awareness, which contributes to the delight of face-to-face play, and variability in caregiver responsiveness, such as the subdued responding of depressed mothers, consequently has a significant impact on infant affect and sociability. Taken together, therefore, the earliest forms of prerepresentational self-awareness are perceptual, affective, and agentic in quality, contributing to the emergence of initial *existential self-awareness*, and the foundation of James's (1890) "I-self."

By the final months of the 1st year, infants are not only agentic but also volitional. In their goal-directed efforts, as Piaget noted, infants can substitute an alternative means for one that has been frustrated and act strategically to accomplish their intentions. This inaugurates, according to Tomasello (1995b, 1999; Tomasello & Rakoczy, 2003), a conceptual advance in which infants begin to perceive others also as intentional actors. As earlier discussed, this is manifested in a variety of behaviors that reflect the infant's awareness that other people have subjectivity that can be understood and intentions that can be influenced, including joint attention, social referencing, imitative learning, and the emergence of intentional communicative efforts (Carpenter, Nagell, & Tomasello, 1998). Moreover, by the end of the 1st year, the infant's experience of goal directedness often conflicts with others' goals and intentions (of which every parent of a locomotor infant is aware), contributing to the self-awareness that derives from conflicts between his or her own goals and those of another. As a result, social interaction involves the infant's goal directedness combined with a dawning awareness that subjective, intentional states are at the root of others' behavior. According to Tomasello (1995b), it is not only the development of a new intersubjective capacity that inaugurates an advance in self-awareness but also the infant's growing realization that the self can be the object of another's attention, intention, and emotional response. Just as infants enlist another's emotional evaluation of objects and events in social referencing, they also become sensitive to the adult's emotional demeanor when attention is focused on themselves, and variability in the caregiver's warmth, emotional tone, and sensitivity become increasingly important at this time. This awareness sets the stage for the growth of self-referent emotions, like embarrassment, and self-referential evaluative emotions, like pride, guilt, and shame, later in the 2nd year. The end of the 1st year witnesses, therefore, the emergence of the *intersubjective self*.

When do infants begin to exhibit *featural self-recognition*—the ability to recognize their physical features? This is commonly taken as the central index of self-awareness, but as noted earlier, recognition that one's features and actions are familiar can mean different things at different ages. Legerstee, Anderson, and Schaffer (1998) found that 8-month-old infants could discriminate static and dynamic video images of their faces from those of peers (5-month-olds could discrimi-

nate only dynamic images), and infants of both ages could also discriminate the sound of their nondistressed vocalizations from those of other infants. Prior experience with vocal play and mirror images could contribute to these discriminations, with the strong integration of visual-kinesthetic and auditory-kinesthetic perceptual experience during these activities marking them as self-initiated (see Bahrick, Moss, & Fadil, 1996, for findings with younger infants). But these results do not necessarily imply that infants are recognizing themselves in these facial and vocal displays. By 18 months, however, after their noses have been surreptitiously marked with a spot of rouge, toddlers reliably show mark-directed behavior when placed before a mirror (Lewis & Brooks-Gunn, 1979). Featural self-recognition is based on the contingency between movement and motion in the mirror, but this behavior also reflects additional psychological achievements: Young children exhibit self-referent emotions like embarrassment at this age (Lewis, 2000), becoming aware of standards for appearance and behavior that also evoke special attention to soiled toys or faces (Kagan, 1981; S. Lamb, 1993). Consequently, toddlers' responses to the classic rouge task entails more complex influences than mere featural self-recognition, and its psychological meaning incorporates greater self-awareness and the application of standards for normative appearance (i.e., my nose is not ordinarily red). Mirror self-recognition at 18 months builds on the achievements of intersubjective self-awareness at age 1 to consolidate the beginning of objective self-awareness in young children, or James's (1890) "me-self."

In light of the development of the "me-self," it is unsurprising that late in the 2nd year and early in the third, toddlers exhibit emerging indications of other representational forms of self-awareness. These include increased verbal self-referential behavior (e.g., "me big!"; Bates, 1990) and verbal labeling of internal experiences (such as emotions; Bretherton et al., 1986), assertions of competence and responsibility as autonomous agents (such as in self-monitoring, refusing assistance, and insisting on "do it myself"; Bullock & Lutkenhaus, 1988, 1990; Stipek, Gralinski, & Kopp, 1990), growing sensitivity to evaluative standards and the emergence of conscience (Thompson, Meyer, & McGinley, 2006), assertions of ownership (Fasig, 2000), the emergence of self-control (Kopp & Wyer, 1994), categorizing the self by gender and in other ways, and young children's growing interest in how their behavior is regarded by others (Emde & Buchsbaum, 1990; Stipek, Recchia, & Mc-

Clintic, 1992). The more complex self-representations of early childhood are reflected also in the emergence of self-referential emotions during the 2nd and 3rd years. By the end of the 2nd year and increasingly in the third, the simple joy of success becomes accompanied by looking and smiling to an adult and calling attention to the feat; the simple sadness of failure becomes accompanied either by avoidance of eye contact with the adult and turning away or by reparative activity and confession; and in response to conspicuous attention toddlers increasingly respond with smiling, gaze aversion, and self-touching (Barrett, 1998; Barrett, Zahn-Waxler, & Cole, 1993; Kochanska et al., 2002; Lewis, 2000; Stipek, 1995; Stipek et al., 1992).

Taken together, young children are beginning to regard themselves in more multidimensional and evaluative ways early in the 3rd year as they increasingly perceive themselves as objects of the attention and thought of others. This is part of the legacy of the intersubjectivity that emerges by the first birthday, and the greater sensitivity to the evaluations of others arising from developing psychological understanding and intersubjective awareness as featural self-recognition is attained. Moreover, during the 2nd year, developing capacities for receptive language clarify not only the child's status as the object of others' evaluations but also lexicalizes these evaluations as they are conveyed through language. Young children not only appropriate others' evaluations of themselves but also the evaluative standards they use as part of children's effort to comprehend constancies and expectations for everyday experience. These processes contribute to the emergence of the *conceptual self* (the "cognitive self" of Howe & Courage, 1993, 1997) that will continue to evolve in sophistication and scope in the years that follow.

Somewhat later, in the 4th and 5th years, young children begin to perceive themselves in more explicitly characterological terms at about the same time that they begin to perceive others in terms of psychological traits (Marsh, Ellis, & Craven, 2002; Measelle, Ablow, Cowan, & Cowan, 1998). To be sure, young children often rely on concrete, observable features and action tendencies in their spontaneous self-descriptions but they can also use psychological trait terms provided by other people appropriately as personality self-descriptions (e.g., "I am naughty sometimes, but good with adults"; Eder, 1989, 1990). Although young children's use of trait terms like *good* and *naughty* lacks the rich meaning inherent in how older people use these con-

cepts, these self-descriptions are like personality traits in that they show stability over time, are similar to how others (such as their mothers and teachers) describe them, and show convergent validity when correlated with external measures of the same characteristics (Eder & Mangelsdorf, 1997; Goodvin et al., 2005; Marsh et al., 2002; Measelle et al., 1998). Even a preschooler's use of a concrete feature, such as describing his- or herself as a girl or boy, is accompanied by a basic understanding of the psychological attributes and stereotypes associated with being male or female (Ruble & Martin, Chapter 14, this *Handbook*, this volume). To be sure, young children's personality self-descriptions show greater stability and convergent validity with increasing age, consistent with growth in children's understanding of personality characteristics more generally (Marsh, Craven, & Debus, 1998). Moreover, young children tend to be unduly optimistic about the modifiability of individual traits, particularly the stability of positive qualities and the changeability of negative ones. Current research confirms, however, the emergence of the conceptual self in early childhood and of psychological self-descriptors in the child's self-concept.

Another important advance in self-awareness occurs when young children can perceive themselves in a temporal context. Comprehending how past experiences can influence the present self, and the ability to anticipate the self in future contexts, are significant advances in self-awareness because of their relevance to strategic planning, delay of gratification, moral compliance, performance evaluation, autobiographical memory, and self-understanding. These advances depend on a capacity to perceive an identity between the present self and the self that existed in the past and that will exist in the future. The realization that it is the same "I" in each temporal context distinguishes this kind of self-awareness from earlier-developing capacities to evoke expectations from past events, recall specific past experiences, or anticipate future events (Moore & Lemmon, 2001). Povinelli (1995, 2001) has shown that temporal self-awareness begins to emerge at about 4 years of age. In experimental procedures that are analogous to the mirror self-recognition tasks, young children were videotaped playing with an experimenter who surreptitiously (but on film) placed a large sticker on the child's head. When they later watched themselves on the videotapes, most 4-year-olds located and removed the sticker that was still on their heads. By contrast, younger 3-year-olds recognized themselves in the videos but most

did not touch the stickers on their heads, apparently unable to associate the event on film with their current condition (Povinelli, Landau, & Perilloux, 1996; Povinelli & Simon, 1998; see also Povinelli, Landry, Theall, Clark, & Castille, 1999 for similar results using different procedures).

The growth of the *temporal self* by age 4, as indexed by the delayed self-recognition task, is believed to be associated with at least two interrelated conceptual achievements: (1) a dawning awareness of the representational nature of knowledge (also relevant to theory of mind development) and (2) the ability to reason in a causal temporal-spatial manner (Povinelli, 2001; Welch-Ross, 2001). Together they contribute to the child's realization that knowledge is subjective and personal, knowledge will vary even though the self remains constant, and current experience and knowledge are affected by past influences on the self. There has not, however, been definitive empirical examination of these ideas. Performance on the delayed self-recognition task is positively correlated with delay of gratification in preschoolers (Lemmon & Moore, 2001) and with some aspects of autobiographical memory, although not with performance on theory of mind tasks (Welch-Ross, 2001; Zelazo, Sommerville, & Nichols, 1999). Much more research clearly is needed.

### Self-Regulation

Accompanying these multifaceted changes in self-awareness is growth in the young child's capacities for self-management. According to Kopp's (1982; Kopp & Wyer, 1994) well-known formulation, the preschool years witness significant advances in behavioral self-control because of growth in children's capacities for remembering, representing, and generalizing behavioral standards, conceiving the self as an autonomous and responsible agent, altering behavior in response to remembered standards, and (somewhat later) engaging in a more continuous and self-generated monitoring of compliance with these standards. Kopp regards the 2nd and 3rd years as central to the development of self-control. The more mature and autonomous skills of self-regulation are an achievement of the 4th year.

This formulation has been expanded in recent years with new appreciation of the temperamental, neurobiological, and caregiving contributions to the growth of self-regulation (see Eisenberg, 2002, for a review related to emotion regulation). Temperament theorists, most notably Rothbart (1989), have long recognized that

temperamental qualities index the self-regulatory and reactive qualities of behavioral style (see Rothbart & Bates, Chapter 3, this *Handbook*, this volume). Differences in temperamental effortful control best reflect this feature of individuality, which have been found to emerge early in childhood and to be associated with better emotion regulation, conscience development, and other adaptive qualities (Kochanska, 1993; Kochanska, Murray, & Coy, 1997; Kochanska, Murray, & Harlan, 2000). Although neurobiological studies of the development of self-regulation are still limited with children, it is apparent that the growth of self-control is associated with maturation of multiple regions of the prefrontal cortex that are associated with emotional, attentional, cognitive, and behavioral self-control (Johnson, 1997). Finally, an extensive body of empirical literature documents the association between self-regulatory competence in early childhood and sensitive, supportive maternal care and the association between parental overcontrol, punitiveness, and negative affect and children's behavioral dysregulation (see Eisenberg, 2002; Fox & Calkins, 2003).

These advances help to account for expanding research interest in the development of self-regulation, but this remains an extraordinarily difficult area of study. Research into emotion regulation illustrates why (see Cole, Martin, & Dennis, 2004, and commentaries that follow; also Eisenberg & Spinrad, 2004). Emotional regulatory processes can be automatic or effortful, but distinguishing these is important to understanding their developmental course. The processes of and influences on emotion regulation are often indistinguishable from those affecting emotional arousal, leading to uncertainty over whether regulatory processes can be independently identified and studied. Moreover, emotion regulation can arise from external sources (such as the efforts of caregivers) as well as self-initiated efforts, and, although each manages emotion, extrinsic and intrinsic regulatory efforts entail different influences and developmental course (Thompson & Meyer, in press). This means that a child can display moderate levels of emotional arousal appropriate to the situation, but this can arise because of (a) the child's temperamental effortful control; (b) the coaching, support, and incentives of caregivers; (c) the fact that this child was not highly aroused in the circumstances (owing to temperament, prior experience, or other factors); and/or (d) the child's enlistment of emotional self-regulatory strategies. Distinguishing these influences on emotionality is a conceptual and empirical challenge. Finally, individual

differences in emotion regulation must be studied functionally to comprehend their relevance to broader differences in emotional or social competence (Thompson, 1994). Young children may develop strategies of emotion regulation that are adaptive in some social contexts but maladaptive in others, and individual differences in attentional, behavioral, cognitive, and emotional self-regulation may have common bases but also different developmental pathways.

Taken together, these challenges do not mitigate the value of studying the development of self-regulation and the origins and consequences of individual differences in self-control. But they do indicate that considerably greater conceptual and empirical clarification of the nature of self-regulation—and its attentional, emotional, cognitive, and behavioral components—is needed to guide future inquiry.

### Development of Autobiographical Memory

Autobiographical memory can be defined as explicit memory of past events that is organized around the significance of these events for the self. The growth of autobiographical memory during the preschool years reflects advances in self-awareness but also other developing capacities, including the developing representation of events in memory, social influences on the reconstruction and recall of past experiences, conceptual skills related to the representation of knowledge, and the influence of language in the construction of memory and its reporting (Reese, 2002). Because of its complexity, there has been considerable debate among developmental scientists concerning the nature of autobiographical memory and its developmental influences, accompanied by significantly expanded research attention to this phenomenon.

One influential view has been offered by Howe and Courage (1993, 1997), who have proposed that autobiographical memory emerges late in the 2nd year after the development of the “cognitive self,” a knowledge structure that organizes memories of personal experiences. The development of the cognitive self is, according to these theorists, revealed at 18 months by the visual self-recognition of toddlers in the mirror-rouge task and by other indicators of self-awareness at this time. Howe and Courage argue that evidence for autobiographical memory during this period can be found in research showing that personal events can be recalled by infants and young children several weeks or months after their occurrence, and the recall of these children, although re-

liant on carefully designed nonverbal responses or the interrogatory assistance of questioners, is generally coherent and accurate (Howe & Courage, 1997; see generally Bauer 2002a, 2002b). In their view, once toddlers have become capable of representing themselves physically and conceptually by the end of the 2nd year, personal memories become mnemonically tagged as autobiographical.

Most other developmentalists portray the emergence of autobiographical memory at a later age, however, owing in part to a stronger distinction between episodic and autobiographical memory (see Fivush, 2001). In their view, autobiographical memory is distinctive because it incorporates an awareness of the personal, present significance of the past event. To Welch-Ross (1995, 2001), the social metacognitive skills essential to the development of autobiographical memory concern knowledge representation—understanding how knowledge is connected to unique experiences in the personal past—together with a personal, subjective stance to remembered events, and the ability to reason about causal connections between events across time. Perner (2001; Perner & Ruffman, 1995) likewise implicates metacognitive skills, especially the capacity to comprehend autobiographical memories as personal “reexperiences” of, and thus deriving from, past events directly experienced. Nelson and Fivush (2004; see also Nelson, 1993b, 1996; Fivush, 2001) portray autobiographical memory as a distinct memory system that builds on the development of a sense of self, theory of mind, knowledge representations, and an awareness of the temporal connections between past and present events. They also emphasize the influence of narrative discourse between the child and a caregiver during reminiscence as the means by which many of these conceptual foundations of autobiographical memory are fostered in early childhood.

The conclusion of these theorists that autobiographical memory emerges at age 3.5 or 4 is easy to reconcile with research findings that most adults do not remember personal events from earlier than about age 3.5 (the end of “childhood amnesia”) and to integrate with other developing conceptual achievements of early childhood, including theory of mind, self-understanding, and comprehension of psychological causality. In one empirical test of alternative theoretical views, Harley and Reese (1999) assessed 19-month-olds’ self-recognition in the mirror-rouge task along with maternal reminiscing style in conversation with the child. They found that each variable uniquely predicted children’s later memory skill: children who developed featural self-recognition

earlier and the offspring of mothers with an elaborative reminiscing style were each more proficient in recalling personal experiences. However, subsequent analyses revealed that by age 2, the effects of early self-recognition ability on subsequent autobiographical recall were mediated by maternal reminiscing style (Reese, 2002). Thus, it seems that the emergence of the cognitive self in early childhood is an important contributor to the development of autobiographical memory, but especially in juxtaposition with social influences on the construction of memory.

Regardless of their theoretical bent concerning age of onset, many developmental theorists agree that the growth of autobiographical memory entails social influences as well as conceptual achievements. Nelson and Fivush (2004) argue, in particular, that the content and structure of narrative discourse with an adult about shared experiences provides essential catalysts to the representation of autobiographical events and the development of self. These conceptual catalysts through narrative include: (a) helping young children understand the personal significance of remembered events, sometimes with reference to prior experiences; (b) enabling young children to conceptualize their experience in a temporal-causal framework in which past events relate to present experience; (c) contributing to children's comprehension of the distinctiveness of their subjective remembrance, partly as it compares (and conflicts) with the adult's own recollection; and (d) helping to structure and reorganize the child's direct representation of the experience into a form that is more memorable and can be shared. By scaffolding a young child's memory through narrative, adults foster the temporal understanding, sense of self, subjective orientation, and other metacognitive skills relevant to autobiographical memory (Nelson & Fivush, 2004). Similar views have been offered by Miller (1994, Miller et al., 1997; Wiley, Rose, Burger, & Miller, 1998), who has emphasized how cultural and subcultural beliefs about the self become appropriated by young children through the content of narrative discourse—or "personal storytelling"—with family members.

Autobiographical memory is thus not an individual recollection but rather a shared construction. This is especially true early in childhood when direct representations of experience are likely to be somewhat disorganized and incomplete, and when the adult narrative can provide the structure and interpretive framework that establishes the significance of personal events to the child and makes them more memorable. Consider,

for example, the following brief conversation between a 21-month-old and his mother about conflict over breakfast cereal earlier in the morning (from Dunn & Brown, 1991, p. 97):

**Child:** Eat my Weetabix. Eat my Weetabix. Crying.

**Mother:** Crying, weren't you? We had quite a battle. "One more mouthful, Michael." And what did you do? You spat it out!

**Child:** (pretends to cry)

In the mother's elaborated representation of their shared experience, she provides her son with a temporal sequence of events leading to his emotional reaction (which was the source of his conversational prompt), emphasizing the significance of the event for him, and at the same time conveying a representation of the event that was likely to be quite different from his own. In doing so, she not only enlisted his direct representation into a narrative structure for verbal sharing but also sequenced essential features of their shared experience in a manner that made the episode more memorable. She also contributed to his developing self-awareness by clarifying that although they shared this experience, their viewpoints were different and thus the understanding they derived from it was different (and thus that knowledge is subjective). The mother provided, in short, a memorable narrative structure and lessons in understanding and self. Although it is uncertain how much this shared retelling would, at 21 months, contribute to the development of an autobiographical memory, the mother's scaffolding of her son's representations of events over time would be likely to contribute to memories that are autobiographical in nature.

Consistent with this view, longitudinal research shows that mothers with a more elaborative narrative style (i.e., richly descriptive and evaluative, providing background and contextual information and eliciting information from the child) have children who themselves are later found to engage in more detailed, richer reminiscing and provide more extensive autobiographical accounts compared to the offspring of mothers with a less elaborative narrative style (Farrant & Reese, 2000; Haden, Haine, & Fivush, 1997; Harley & Reese, 1999; Reese, Haden, & Fivush, 1993; see Reese, 2002 for a review). Individual differences in maternal narrative style are consistent across the preschool years (Farrant & Reese, 2000; Reese et al., 1993) and across siblings (Haden, 1998), although child characteristics (such as age and gender) also influence maternal elaborativeness

(Reese, 2002). One study found that in a socioeconomically disadvantaged sample, mothers who were trained to use an elaborative style in conversation with their 3.5-year-olds were found to use more contextual questions and open-ended prompts a year later. By age 5.5, their children themselves were more elaborative in their narrative style (Peterson, Jesso, & McCabe, 1999). Taken together, these findings suggest that the detail and richness of young children's autobiographical memories are significantly influenced by the quality of reminiscing they share with their caregivers, and that conceptions of self may also be conceptually elaborated in these conversational contexts. This conclusion is consistent with those of earlier discussions in this chapter concerning the influence of conversational catalysts on the development of emotion understanding, theory of mind, and other aspects of psychological understanding.

In the context of shared reminiscing, young children are likely to appropriate not only organized personal memories and a narrative style but also much more. Reconsider the earlier conversation between Michael and his mother over Weetabix and notice the other lessons provided by the adult in her representation of the morning's confrontation. The mother instructed her son about emotion and morality: In her portrayal, crying is associated with misbehavior and defiance (not with having to eat horrible breakfast cereal, which may have been her son's initial representation). She provided lessons about the self: Good boys cooperate, but Michael was uncooperative and that is why he cried. There were also lessons about relationships, which, according to his mother, are harmonious when sons are cooperative with their mothers' requests but are disrupted by filial defiance (rather than by maternal insistence). In short, the mother interpreted the morning's events in her framework of assumptions, causal attributions, beliefs, and values. These beliefs constitute part of the context of mother-child reminiscing and, although it is unclear how many of these lessons are likely to be internalized at age 2, they are likely to have a significant influence on young children's developing conceptions of emotion, morality, self, and relationships as such conversations become part of the landscape of parent-child interaction during the preschool years (Thompson et al., 2003).

Adults incorporate certain values into their shared conversations with young children because they are cultural members who nonconsciously embrace cultural beliefs about the self, relationships, and morality. In an observational study, Miller and her colleagues showed, for example, how the "personal storytelling" of Chinese

and American mothers portrayed the child's experience consistently with the broader values of their cultures. Chinese and Chinese-American mothers used storytelling with their children to convey moralistic themes, with an emphasis on the shame inherent in misconduct, while American mothers used storytelling for its entertainment value, emphasizing instead the child's spunk or mischievousness over misconduct (Miller, Potts, Fung, Hoogstra, & Mintz, 1990; Miller et al., 1996, 1997). Wang, Leichtman, and Davies (2000) noted that American mothers co-constructed reminiscences with their preschool offspring that emphasized the child's personal predilections and opinions, while Chinese mothers focused on moral rules and behavioral standards (see also Mullen & Yi, 1995). The influence of these conversational foci is reflected in the self-descriptions and autobiographical accounts of Asian and American young children. American children have been found to be more self-focused, use more internal state language and evaluations, and provide more detail about specific past events, by contrast with the greater emphasis on social roles and relationships and daily routines of Asian children (Han, Leichtman, & Wang, 1998; Wang, 2004). These findings suggest that the shared construction of autobiographical narrative, and the self-understanding that relates to it, is one way that cultural values concerning the self, relationships, and morality are conveyed intergenerationally (Fivush, 2004).

Young children do not merely appropriate the representations of personal experience interpreted by their caregivers: They are active construers of their own direct experiences. Although the language and the narrative structure offered by the adult are extremely important influences in shaping children's personal representations through conversation (partly owing to how language articulates and clarifies internal psychological realities), as children develop competencies in representing, interpreting, and remembering personal experience they are likely to object to parental constructions of their experience that are dissonant with their own. Levine, Stein, and Liwag (1999) showed that parents and young children commonly disagree about the child's feelings and experiences during shared events, often when adults make assumptions about the child's goals that are incorrect, and that disagreements occur most frequently for negative emotions. Disagreements between parents and offspring also commonly arise when adults omit from their narrative crucial aspects of the experience that figure prominently in children's own recollections. Little is known, however, about how

children respond to such discrepancies in parent-child conversation, and this is a topic meriting further inquiry because of its relevance to children's comprehension of the personal, subjective nature of knowledge as well as to attachment theorists' views about the origins of the relational origins of defensive exclusion.

### Summary

The conclusion that the early development of self derives from an interaction of the child's construals of personal experience and the adult's scaffolding of personal understanding confers on this topic unique research opportunities and challenges. Contrary to other forms of psychological understanding, children have special expertise concerning their characteristics, experiences, and self-knowledge that will increasingly vie with the adult's interpretations as children mature and acquire more robust, internally consistent self-referent beliefs. Yet, because of their psychological sophistication, caregivers are also uniquely insightful about the feelings, motivations, and individuality of the children they care for. Moreover, they begin to shape young children's self-awareness from an early age, beginning with the emotional signals they convey concerning the child's activities, to their appraisals of the child's successes and failures, to the construction of autobiographical memory in conversations about everyday events. Yet, there are elements of the child's experiences—and construals of that experience—that are always private and inaccessible to the adult, in part because they cannot easily be conveyed. Somehow, in the context of the shared activity of a young child, who is both expert and novice in self-understanding, and an adult, who has limited but sophisticated insight into the child's characteristics, self-understanding is jointly constructed. Understanding this developmental process is an important and valuable challenge for future research.

### CONCLUSION

Often the most innovative thinking in developmental science is integrative. A field that commonly parcels the developmental process into separable domains or periods benefits from efforts to integrate insight from studies of cognitive and social functioning, or across stages of growth, or between typically and atypically develop-

ing populations. This is certainly true of the study of early sociopersonality development. The most notable reflection of this integrative potential is in the study of early social cognition, where the developmentally downward extension of theory of mind research touches on the long-standing interests of social developmentalists in the expectations and self-awareness deriving from social interaction in infancy. Research on conscience development likewise integrates understanding of emotion, temperament, cognition, and parenting in new ways of conceptualizing the interaction of child and adult in the appropriation of moral standards. Attachment theory and research benefits from the integration of research on event representation, autobiographical memory, and parent-child narrative in theoretical conceptions of the internal working models associated with security. The broader science of developing relationships is also increasingly integrating biological perspectives into understanding of the nature and consequences of early family relationships.

In these and other domains of early sociopersonality growth, development arises from the interaction of a young child, equipped with a powerfully inductive mind, and people with whom the child is in continuous relationship. Relational partners are conceptual catalysts because of the ubiquity of their shared experiences with the young child; their intimate knowledge of the child's characteristics, individuality, and developmental needs; and the opportunities they enlist to stimulate behavioral and conceptual growth (often without awareness of doing so) in interactive activities. Throughout this review of research on early social understanding, conscience, and development of self, the importance of parents, peers, siblings, and other relational partners is continuously apparent.

For this reason, the developmental model that seems most useful in comprehending early sociopersonality development is not socialization (which emphasizes the child as the recipient of understanding) or constructivism (which emphasizes the independently inductive mind), but rather a model of the appropriation of understanding through shared activity (Rogoff, 1990). This neo-Vygotskian formulation emphasizes the shared creation of knowledge through the interaction of the child with a partner in the everyday activities highlighted in this review, such as social interaction, relief of distress, conflict of wills, and shared conversation. Such a theoretical orientation enables an integration of the profound insights into the developing mind provided by

cognitive-developmental scholars with the exquisite studies of early social interaction offered by students of sociopersonality development and has the potential of generating new insights into early development. The value of such an orientation has been highlighted throughout this review, from research describing the association of maternal “mind-mindedness” with the development of psychological understanding, to research on attachment security as a mediator of the influence of parental discipline practices on moral internalization, to studies of the influence of parent-child conversation on the development of autobiographical memory. In each case, conceptual growth arises from the generative influence of social experience on a young mind that is powerfully prepared to glean new understanding from that experience.

Bridging the conceptual perspectives of cognitive and sociopersonality research is a significant advance for future research, just as are efforts to bridge biological and social perspectives to relationships, and to bridge understanding of typical and atypical developmental processes. Each is important because in the end, the continuing vitality of research in this area derives from our success in reassembling the developing child: one who thinks, feels, and relates, who is both biological and social, who maintains continuity across time while dramatic developmental changes occur, and who is in relationship with multiple partners in diverse social ecologies. Our capacities as research scientists to see the developing child as a coherent, integrated being underlies our capacities to imagine the developmental process for all of its complexity, scope, and vitality.

Recent years have witnessed major advances in our understanding of temperament in childhood. Early views on temperament as unchanging and stable have been replaced by more dynamic views of developmental change in temperament. An early emphasis on temperament in infancy has been extended to the study of childhood and adolescence, and research on temperament has burgeoned (Rothbart & Derryberry, 2002). In addition, rapid advances have been made in our understanding of temperament-environment interactions. In this chapter, we explore both historical influences and more recent advances in our understanding of individual differences

in temperament, differences observed by parents and physicians long before their systematic study by students of human development.

## A DEFINITION OF TEMPERAMENT

Gordon Allport (1961) defined temperament as “the characteristic phenomena of an individual’s emotional nature, including his susceptibility to emotional stimulation, his customary strength and speed of response,

the quality of his prevailing mood, these phenomena being regarded as dependent upon constitutional make-up and, therefore, largely hereditary in origin" (p. 34). Allport's definition focused on individual differences in emotional reactivity. Thomas and Chess (1977), however, took a broader approach to temperament, including individual differences in attention and activity level.

Taking into account both of these approaches, we have defined temperament as constitutionally based individual differences in reactivity and self-regulation, in the domains of affect, activity, and attention (Rothbart & Bates, 1998; Rothbart & Derryberry, 1981). By the term *constitutional*, we refer to the biological bases of temperament, influenced over time by heredity, maturation, and experience. *Reactivity* and *self-regulation* are umbrella terms that broadly organize the temperament domain. By *reactivity*, we refer to responsiveness to change in the external and internal environment. Reactivity includes a broad range of reactions (e.g., the emotions of fear, cardiac reactivity) and more general tendencies (e.g., negative emotionality), thus it is not limited to general reactivity. Parameters of reactivity are measured by the latency, duration, and intensity parameters of motor, affective, and attentional reactions (e.g., fear, anger, positive affect, or orienting; Rothbart & Derryberry, 1981). Emotional reactivity also includes action tendencies. Thus, fear predisposes freezing, attack, and/or inhibition, and positive affectivity predisposes approach. The expression or inhibition of these behavioral tendencies can feed back to influence the ongoing emotional reaction. By *self-regulation*, we refer to processes such as effortful control and orienting that function to modulate reactivity. We believe (as does Kagan, 1998) that other important dimensions of temperament are likely to be identified in the future.

Temperament describes tendencies or dispositions that are not continually expressed but require appropriate eliciting conditions. Fearful children, for example, are not continually distressed and inhibited, but under conditions of novelty, sudden change in stimulation, or signals of punishment, they may be particularly prone to a fearful reaction. Easily frustrated children are not continually irritable or angry, but when their goals are blocked or there is a failure of their expectations, they will be particularly prone to frustration.

### Temperament and Personality

Temperament represents the affective, activational, and attentional core of personality, whereas personality in-

cludes much more than temperament, particularly the content of thought, skills, habits, values, defenses, morals, beliefs, and social cognition. Social cognition includes the perception of the self, others, and the relation of self to objects, events, and others. Over time, social cognition becomes increasingly important in eliciting and moderating temperamental processes. This happens, for example, when anger comes to be elicited by judgments that others have broken the rules when we have been following them. These perceptions can be influenced by temperament (Derryberry & Reed, 1994), but they involve separable thought processes as well. Personality traits have been defined as patterns of thoughts, emotion, and behavior that show consistency across situations and stability over time, and that "affect the individual's getting along with other people and with himself" (Hilgard, 1962, p. 447). Temperament traits similarly show consistency across situations and stability over time, but they are limited to basic processes of reactivity and self-regulation, and do not include the specific content of thought or the use of conceptually based defenses (e.g., paranoia).

In our view, *temperament* is the appropriate term for describing individual differences in reactivity and self-regulation in nonhuman animals and young infants. Although some researchers refer to individual differences in animals as their "personality" (e.g., Gosling & John, 1999), we find it helpful to consider the aspects of individuality we share with other animals separately from those involving the content of thought that are more distinctly human. Animal models of temperament allow investigations of affective and cognitive neuroscience that are not possible in humans, and aid in the study of the neural underpinnings of temperament. Strelau (1983) takes a similar position to ours, arguing that temperament results from biological evolution, and is "peculiar to both humans and animals, which cannot be said of personality" (p. 258). In addition, "The individual has a temperament from the moment of birth, since it is determined by inborn physiological mechanisms which, in turn, may be modified under environmental influences" (p. 258).

We begin this chapter with a brief history of temperament research, considering its recent history, its ancient roots, and its study in adulthood. In the second section, we examine the structure of temperament as it has emerged from research on child development and from some of the major theoretical models of the neurosciences. We also consider results of the search for a taxonomic structure of adult personality traits, and re-

late temperament structure to the resulting Big Three and Big Five factors of personality.

In the third section, we discuss methods and measures for the study of temperament, considering both the benefits and liabilities of some of the major empirical approaches. Because the use of parent-report in temperament research has been questioned (Kagan, 1994, 1998; Kagan & Fox, Chapter 4, this *Handbook*, this volume), we critically consider contributions of parent-report. In the fourth section, we focus on temperament and development, considering issues of continuity and change. In the fifth section, we discuss relations between temperament and behavioral adjustment. The final section presents our conclusions and indicates future directions for the study of temperament and development. Overall, we organize research findings on temperament in a developmental framework. The literature review is not comprehensive, but we hope it captures some of the major issues and approaches to the study of temperament in childhood. We now begin with a historical review of temperament in childhood and adulthood.

## HISTORY OF TEMPERAMENT: RESEARCH ON CHILDHOOD

Several lines of inquiry have contributed to contemporary temperament research on children. One is the research of the normative child psychologists in the 1920s and 1930s, who observed large numbers of children to establish the normal sequences of motor and mental development and studied small samples of children intensively over time. In doing so, they noted striking temperamental variability among the children they observed (Gesell, 1928, as cited in Kessen, 1965; Shirley, 1933). Shirley's intensive study of the motor development of a group of infants during the first 2 years led to her observation of the infant's "core of personality." Shirley (1933) noted that developmentally, "Both constancy and change characterize the personality of the baby. Traits are constant enough to make it plausible that a nucleus of personality exists at birth and that this nucleus persists and grows and determines to a certain degree the relative importance of (other) traits" (p. 56). She devoted a full volume to these traits, even though her original intention had been to study only motor and intellectual development. Fifteen years later, Neilson (1948) located 15 of Shirley's 25 babies, asking judges to match Shirley's infant personality sketches to descriptions of the children as adolescents, based on as-

sessments by clinicians blind to their identity. These matches were more successful than would have been expected by chance.

Gesell (1928, as cited in Kessen, 1965) identified the critical importance of the child's temperament in what he called the developmental "web of life." His views of alternative developmental pathways, so important to recent thinking, are illustrated in the case of C. D.:

This girl exhibited a striking degree of amenability, sociality, and good nature as early as the age of 9 months. . . . She is now 5 years of age, and in spite of a varied experience in boarding homes and institutions she has not lost these engaging characteristics. They are part and parcel of her make-up quite as much as the lowered tempo and the lowered trend of her general development. It can be predicted with much certainty that she will retain her present emotional equipment when she is an adolescent and an adult. But more than this cannot be predicted in the field of personality. For whether she becomes a delinquent, and she is potentially one, will depend upon her subsequent training, conditioning, and supervision. She is potentially also a willing, helpful, productive worker. Environment retains a critical role even though heredity sets metes and bounds. (Gesell, 1928, pp. 372–373)

Three important concepts from Gesell and Shirley are further elaborated in this chapter. First, temperament traits are constitutionally based characteristics that provide the core of personality and influence directions for development. Second, although some stability of temperament is expected across age, developmental outcomes will also depend on the child's experience in the social context. Finally, as in the case of C. D., a given set of temperamental characteristics allows for multiple possible outcomes. Different trajectories and outcomes may occur for children with similar temperamental traits, and children differing in temperament may come to similar developmental outcomes via different pathways (Kochanska, 1995).

## Clinical Research

A second major line of research on temperament in childhood came from biologically oriented clinicians. Bergman and Escalona (1949) identified children who were particularly reactive to low intensities of stimulation in one or more sensory modalities. In Escalona's (1968) groundbreaking book, *The Roots of Individuality*, she proposed the concept of "effective experience," the idea that events in children's lives are experienced only

as they are filtered through the individual child's nervous system. A given event will thus differ in its effects for children who differ in temperament. An adult's vigorous play, for example, may lead to pleasure in one child and distress in another. Escalona noted that objective coding of environmental events alone will not capture essential information about the individual child's reaction to them. Infants observed by Escalona (1968) were followed in developmental studies of vulnerability, resiliency and coping by Murphy and Moriarty (1976). In other studies, Fries and Woolf (1954) identified and studied congenital activity type, Korner (1964) studied neonatal individuality and developed an extensive assessment schedule for the newborn, and Birns (1965) and her associates developed and implemented some of the earliest standardized assessments of temperament.

Among clinical investigators, Thomas, Chess, Birch, Hertzog, and Korn (1963) published the first of their volumes on the extremely influential New York Longitudinal Study (NYLS). Inspired by differences among their own children, Chess and Thomas studied individual differences in what they called the "primary reaction patterns," collecting interviews from parents of infants on repeated occasions. Beginning when their initial sample of 22 infants was 3 to 6 months of age, parents were extensively interviewed about their infants' behavior in varying contexts. Each infant reaction and its context was then typed on a separate sheet of paper, and Birch inductively sorted the descriptions into categories that came to represent the nine NYLS temperament dimensions (Chess & Thomas, personal communication, October, 1992; Thomas et al., 1963): (1) Activity Level, (2) Approach/Withdrawal, (3) Adaptability, (4) Mood, (5) Threshold, (6) Intensity, (7) Distractibility, (8) Rhythmicity, and (9) Attention Span/Persistence. Later, Michael Rutter suggested the term *temperament* to describe their area of study, and this term was adopted by the NYLS group (Chess & Thomas, personal communication, October, 1992).

### Acceptance of Temperament Research

Reports from the NYLS arrived at an opportune time, when researchers in social development were becoming increasingly aware of the contributions of individual children to their own development. One influence was the burgeoning of infancy research, with researchers studying the initial state of the individual and its subsequent adaptations (Osofsky, 1979). Because the initial state

varied from child to child (Korner, 1964), early differences could be seen as providing the raw material for later development. Ideas originally put forward by Robert Sears and associates (e.g., Sears, Maccoby, & Levin, 1957) were also reemerging regarding bidirectionality in the effects of socialization, from child to caregiver and caregiver to child (Bell, 1968). Finally, cognitive approaches stressed children's influences on their own development via their perceptual and cognitive mental representations of events (Kohlberg, 1969). Research on temperament would now introduce the idea that, in addition to individual differences in thought patterns, individual differences in children's *emotional* processing could bias their affective representations of experience, with important implications for their development.

### HISTORY OF TEMPERAMENT IN ADULTHOOD

Adult studies of temperament have a much longer history than developmental work, much of it focused on biological aspects of personality. Temperament ideas go back to Greco-Roman physicians over 2,000 years ago, and to even earlier traditions in China and India (Diamond, 1974; Needham, 1973). In this thinking, psychological characteristics were consistently linked to the physiology of the individual as it was understood at the time. Thus, ancient Greco-Roman physicians identified the well-known fourfold typology and linked it to the bodily humors: the sanguine individual, positive and outgoing (with a predominance of blood); the melancholic person, prone to fear and sadness (with a predominance of black bile); the choleric person, irritable and prone to aggression (with a predominance of yellow bile); and the phlegmatic person, slow to excitation (with a predominance of phlegm; Diamond, 1974). The fourfold typology was used throughout the Middle Ages and in the writings of Kant. By the time of Wundt (1903), however, a shift was made away from positing temperamental "types" to studying dimensions of variability in temperament, a shift that has only recently been reversed in Kagan's (1994, 1998) and others' (Caspi, Sugden, et al., 2003) use of temperament typologies.

### Jung's Theory

Psychological types were put forward by Jung (1923), but they differed in important ways from current typologies. In Jung's view, introverted and extraverted tenden-

cies were universal and reflected in thinking, feeling, sensation, and intuition. Jung argued that introverted *and* extraverted tendencies are present in all persons, but that, for a given person, one attitude becomes more elaborated and conscious, while the other is less elaborated, more primitive, and, for the most part, unconscious. Differences among children in extraversion and introversion, he wrote, can be seen early in life:

The earliest mark of extraversion in a child is his quick adaptation to the environment, and the extraordinary attention he gives to objects, especially to his effect upon them. Shyness in regard to objects is very slight; the child moves and lives among them with trust. He makes quick perceptions, but in a haphazard way. Apparently he develops more quickly than an introverted child, since he is less cautious, and as a rule, has no fear. Apparently, too, he feels no barrier between himself and objects, and hence he can play with them freely and learn through them. He gladly pushes his undertakings to an extreme, and risks himself in the attempt. Everything unknown seems alluring. (Jung, 1928, as cited in Fordham, 1953, p. 303)

Objects as described by psychoanalysts include both physical and social entities, so the more introverted child would be expected to dislike new social situations and to approach strangers with caution and fear. Jung suggests that the introvert would also be inclined toward pessimism about the future, and the extravert would show more ready approach and action on objects (impulsivity), greater sociability, and more optimism about the future (Jung, 1923).

### Eastern and Western Schools of Temperament and Personality

In addition to Jung's theoretical model of introversion-extraversion, similar dimensions emerged from early factor-analytic studies of temperament in adults. In Great Britain, Webb (1915) analyzed self-report items referring to emotionality, activity, qualities of the self, and intelligence and thus identified two broad factors. One, labeled "w," was defined as "consistency of action resulting from deliberate volition or will" (Webb, 1915, p. 34). This factor bears similarities to temperamental Effortful Control in childhood (Kochanska, Murray, & Harlan, 2000; Rothbart, Ahadi, Hershey, & Fisher, 2001), and to the higher-order personality factors more recently labeled Control, Constraint, or Conscientiousness (Digman & Inouye, 1986). A second factor assessed distress proneness or negative emotionality, sometimes

labeled emotional stability-instability; Eysenck (1967) would later call it Neuroticism. By 1937, Burt had also identified the factor of Extraversion-Introversion, and later factor-analytic research on questionnaire assessed personality has repeatedly identified three factors: Extraversion, Neuroticism, and Conscientiousness. These three factors, sometimes called the Big Three, along with factors of Agreeableness and Openness to experience, have been extracted from factor analyses of trait descriptive words and personality items, and constitute what have been called the Big Five personality factors (Costa & McCrae, 1988; Goldberg, 1990).

Soviet and Eastern European research on temperament began with Pavlov's (1955/1935) observations of individual differences among dogs in conditioning experiments, and led to an active research tradition described by Strelau (1983). Pavlov linked temperamental differences among the animals, which he also generalized to humans, to qualities of the central nervous system, including strength of neural activation. Strength of activation was related to the "law of strength" in classical conditioning, whereby increasing the intensity of a conditioned stimulus led to the increased intensity of the animal's response. For some animals, however, increasing stimulus intensity led to failure to respond. Pavlov described these animals as having a weak nervous system; animals with a strong nervous system maintained the law of strength even at high levels of stimulus intensity. Additional Pavlovian temperament constructs included strength of inhibition, balance between activation and inhibition, and mobility—flexibility of nervous system adjustment to changing conditions. Soviet researchers began their work in the laboratory, but a lack of generality of their measures across stimulus and response modalities, a phenomenon they called partiality, led to a general shift in their focus from the laboratory to the use of questionnaire methods (Strelau, 1983).

Although British and Soviet schools took different historical directions in the study of temperament, with British researchers moving from questionnaires to the laboratory, and Eastern European researchers from the laboratory to questionnaires, both schools remain actively involved in the study of temperament, and both link individual differences in temperament to hypothetical nervous system function. We now review studies of the structure of temperament as it has emerged from research on infancy and childhood and describe neural models conceptually related to this structure.

THE STRUCTURE OF TEMPERAMENT

In this section, we consider research on temperament that has led to revision of the original list of nine NYLS dimensions (Tables 3.1 and 3.2). Much of this research employed factor analysis of large sets of items within the temperament domain. Factor analysis allows researchers to see simultaneously the relations and nonrelations among large sets of behavior descriptions. A major limitation of the factor analytic method is that the dimensions yielded by the analysis depend on the descriptors included in the initial data matrix. Several broad dimensions of temperament have consistently emerged from different sets of data.

Infant Studies

In a review of the structure of temperament as indicated by infant studies (Rothbart & Bates, 1998; Rothbart & Mauro, 1990), six dimensions were identified that provided a shorter list of temperament variables for future researchers (Table 3.1). Individual differences in positive emotionality were differentiated from negative emotionality, and two kinds of negative emotion were identified: fear and anger/irritable distress.

Infant scales with different names often measure similar constructs. Goldsmith and Rieser-Danner (1986) had both mothers and day-care teachers of 4- to 8-month-old infants fill out the Revised Infant Temperament Questionnaire (RITQ; W. Carey & McDevitt, 1978), the Infant Characteristics Questionnaire (ICQ; Bates, Freeland, & Lounsbury, 1979), and the Infant Behavior Questionnaire (IBQ; Rothbart, 1981). Distress to novelty was assessed by all three of these instruments: IBQ Fear, ICQ Unadaptable, and RITQ Approach-Withdrawal scales. Intercorrelations across these scales were high. For mothers, they ranged from .60 to .69, with the

average  $r = .64$ ; for day-care teachers, the intercorrelations ranged from .51 to .73, with the average  $r = .63$  (Goldsmith & Rieser-Danner, 1986).

The second shared dimension was Irritable Distress, assessed by IBQ Distress to Limitations, RITQ Negative Mood (which includes positive affect at one pole), and ICQ Fussy/Difficult scales. Intercorrelations among these scales for mothers ranged from .44 to .63, with an average of .54; for day-care teachers, the correlations ranged from .66 to .74, with an average of .71. The third shared temperament dimension was Activity Level, assessed only on the RITQ and IBQ scales, where the correlation for both mothers and day-care teachers was .65.

Gartstein and Rothbart (2003) have recently studied the factor structure of expanded scales measuring parent-reported infant temperament, as adapted from dimensions identified in research on temperament in childhood (Table 3.2). Factor analysis of a large data set describing 3- to 12-month-old children yielded three broad dimensions: *Surgency/Extraversion*, defined primarily from scales of Approach, Vocal Reactivity, High Intensity Pleasure (stimulation seeking), Smiling and Laughter, Activity Level and Perceptual Sensitivity; *Negative Affectivity*, with loadings from Sadness, Frustration, Fear, and loading negatively, Falling Reactivity; and *Orienting/Regulation*, with loadings from Low Intensity Pleasure, Cuddliness, Duration of Orienting, and Soothability and a secondary loading for Smiling and Laughter. As early as infancy, there is thus evidence for three broad temperament dimensions.

A number of important conclusions have emerged from factor analytic studies on the structure of infant temperament as reviewed by Rothbart and Mauro (1990) and Rothbart and Bates (1998). First, the structure appears to correspond more to dimensions of reactivity in the basic emotions and attention/regulation than to a general style. Second, bipolar constructs such as ap-

TABLE 3.1 Dimensions of Temperament in Infancy

Broad Factors	Narrow Dimensions	
Negative emotionality	Fear	Sadness
	Frustration/irritability	Falling reactivity
Surgency/extraversion	Approach	Smiling and laughter
	Vocal reactivity	Activity level
	High intensity pleasure	Perceptual sensitivity
Orienting/regulation	Low intensity pleasure	Cuddliness
	Duration of orienting	Soothability
Rhythmicity		

TABLE 3.2 Dimensions of Temperament in Childhood

Broad Factors	Narrow Dimensions	
Negative emotionality	Fear Shyness Frustration/irritability	Resistance to control Sadness Soothability Discomfort
Surgency/extraversion	Activity level	Positive anticipation
High intensity pleasure	Sociability	
Effortful control/self-regulation	Inhibitory control Attentional focusing Persistence	Low intensity pleasure Perceptual sensitivity
Agreeableness/adaptability	Manageability	Affiliation

proach versus withdrawal and good versus bad mood have not emerged from these analyses; instead, unipolar constructs of infant temperament have gained support. Third, these dimensions also correspond to individual differences emerging from studies of nonhuman animals (Gosling & John, 1999), allowing links between temperament constructs in humans and the psychobiology of individual differences.

### Childhood Studies

Factor analyses of questionnaire items based on the NYLS for older children have similarly revealed a shorter list of broad temperament factors (Table 3.2). Analysis of mother reports for 3- to 8-year-olds on the Thomas and Chess (1977) Childhood Temperament Questionnaire in the Australian Temperament Project (ATP) yielded factors of *Inflexibility* (irritability and uncooperativeness), *Persistence*, *Sociability*, and *Rhythmicity* (Sanson, Smart, Prior, Oberklaid, & Pedlow, 1994); second-order factors extracted from the ATP data were labeled *Negative Emotionality*, *Self-Regulation*, and *Sociability*.

The Children's Behavior Questionnaire (CBQ; Rothbart et al., 2001) has also consistently yielded three broad factors, found in U.S. replications and in research performed in the People's Republic of China and Japan (Ahadi, Rothbart, & Ye, 1993; Kochanska, DeVet, Goldman, Murray, & Putnam, 1993; Rothbart et al., 2001). The first, called *Surgency/Extraversion*, is defined primarily by the scales of Approach, High Intensity Pleasure (sensation-seeking), Activity Level, and a negative contribution from Shyness. The second, called *Negative Affectivity*, is defined by the scales of Discomfort, Fear, Anger/Frustration, Sadness, and loading negatively, Soothability. The third factor, labeled *Effortful Control*, is defined by the scales of Inhibitory Control, Atten-

tional Focusing, Low Intensity Pleasure, and Perceptual Sensitivity. These three factors map well on the second-order factors identified by Sanson et al. (1994): Surgency/Extraversion on Sociability; Negative Affectivity on Negative Emotionality, and Effortful Control on Self-Regulation.

The first three factors emerging from a recent factor analysis of NYLS-inspired Middle Childhood Temperament Questionnaire items (Hegvik, McDevitt, & Carey, 1982) for 8- to 12-year-olds (McClowry, Hegvik, & Teglasi, 1993) also show similarity to these factors: *Approach/Withdrawal*, *Negative Reactivity*, and *Task Persistence*. McClowry et al.'s (1993) two smaller factors, *Activity* and *Responsiveness*, also parallel smaller factors in the ATP (Sanson et al., 1994).

Presley and Martin's (1994) analysis of teacher reports of 3- to 7-year-olds on the Temperament Assessment Battery for Children yielded five factors demonstrating some overlap with those described above. These include *Social Inhibition*, *Negative Emotionality*, *Agreeableness/Adaptability*, *Activity Level*, and *Task Persistence*. In their review of factor analytic studies on infant and child temperament, Martin, Wisenbaker, and Huttunen (1994) note the robustness of the general temperament factors of Negative Emotionality, Task persistence, Adaptability, and Social Inhibition. They see Activity Level as more problematic because it is related to both negative and positive affect early in life.

The factors emerging from research on temperament in childhood show strong conceptual similarities with the Big Three factors and three of the Big Five or FFM factors that have been extracted from analyses of self- and peer descriptions of personality in adults (Goldberg, 1993) and children (Ahadi & Rothbart, 1994; Caspi, Chapter 6, this *Handbook*, this volume; Digman & Inouye, 1986). The *Negative Affectivity* factor from childhood measures is conceptually similar to the broad

adult dimension of *Neuroticism* or *Negative Emotionality*. The *Surgency and Sociability* factors are similar to the broad adult dimension of *Extraversion* or *Positive Emotionality*. The *Persistence*, *Self-Regulation*, or *Effortful Control* factors map upon the adult dimension of *Control/Constraint* (see Ahadi & Rothbart, 1994), and Martin et al.'s (1994) *Agreeableness/Adaptability* factor onto the adult dimension of *Agreeableness*.

In our research on adults, we have found strong one-to-one correlations between factor scores derived from factor analysis of temperament scales and Big Five measures (Rothbart, Ahadi, & Evans, 2000), between Negative Emotionality and Neuroticism, Positive Emotionality and Extraversion, and Effortful Control and Conscientiousness. In addition, Perceptual Sensitivity was related to Openness, and temperamental Affiliation to Agreeableness. Neuroticism, however, often contains negative judgments about the self that may be strongly related to an individual's experiences with others; these may or may not have a strong temperamental base, and research on temperament and personality in childhood becomes very important.

In research with the Combined Temperament and Personality Scales (CTPQ) describing 565 children between the ages of 3 and 12, we have extracted factors that included Positive Emotion, Gregariousness, Warmth, and Soothability (*Sociable Extraversion*); Anxiety, Self-consciousness, Dependency, and Depression/Sadness (*Internalizing Negative Emotionality*); Inhibitory Control, Order, Diligence, Self-discipline, Attentional focusing, and low Distractibility (*Conscientiousness*); Aesthetics/Creative Ideas, Intellect, and Perceptual Sensitivity (*Openness*); and Excitement seeking, Assertiveness, Self-centered, Noncompliance/Aggression, Manipulative, Activity, and Anger/Hostility and Impulsivity (*Unsocialized Stimulation Seeking*; Rothbart & Victor, 2004). This research differentiates fearful and angry negative affect, and links aspects of extraversion with both unsocialized stimulation seeking and sociable extraversion. Longitudinal research will be important in identifying the experiential and self-regulatory temperament influences on these two outcomes.

Shiner (1998) has also recently contributed an important review of the structure of personality in middle childhood. Her preliminary taxonomy includes these dimensions: sociability, social inhibition, prosocial disposition, dominance, aggressiveness, negative emotionality, mastery motivation, inhibitory control, per-

sistence/attention, and activity level. Shiner indicates the importance of placing these dimensions in a developmental context. We can, for example, study irritability in infants, but aggression cannot be observed until later in the development. The hierarchical structure of Shiner's (1998) additional dimensions will also be of interest. Does dominance, for example, relate more to extraversion/surgency, or to agreeableness/affiliation? Does anger proneness relate more to negative emotionality or agreeableness/affiliation (Shiner, 1998)? In Rothbart and Victor's (2004) research, it loads on the Unsocialized Stimulation Seeking factor.

### Summary

As noted earlier, work to date on temperament structure in infancy and in childhood suggests revisions of the original NYLS nine dimensions to include (with broad, aggregated constructs in parentheses): Positive Affect and Activity Level (*Surgency/Extraversion*), Fearful Distress, Irritable Distress (*General Negative Emotionality*), Effortful Control/Task Persistence, and Agreeableness/Adaptability. In our next section, we make tentative links between these constructs and models developed in the neurosciences.

## NEURAL MODELS OF TEMPERAMENT

We now describe neural models developed to enhance our understanding of temperament. Cloninger (1986), Gray (1991), LeDoux (1989), Panksepp (1998), and Zuckerman (1984) have all made contributions to the development of neural models for temperament (see review by Rothbart, Derryberry, & Posner, 1994). We begin by describing models for positive emotionality and approach (*Surgency/Extraversion*), and fear. Irritability/anger is also discussed, and it is seen, along with fear, discomfort, and sadness, to represent part of a general construct of susceptibility to negative affect or negative emotionality. The emotion-based dimensions are related to differences observed in nonhuman animals (Gosling & John, 1999; Panksepp, 1998), and to factor structures extracted from studies of personality in adults and temperament in childhood. The fourth dimension, Effortful Control, will be further discussed in connection with neural models for individual differences in executive attention (Posner & Fan, in press).

### Emotion as an Information-Processing System

Emotions can be seen as broadly integrative systems that order feeling, thought, and action (LeDoux, 1989). They also represent the output of information processing networks assessing the meaning or affective significance of events for the individual (LeDoux, 1989). Whereas object recognition systems and spatial processing systems address the questions, "What is it?" and "Where is it?" neural emotion processing networks address the questions, "Is it good for me?" "Is it bad for me?" and "What shall I do about it?" When there are individual differences in temperamental emotionality, there are thus differences in object perception as well.

In neural processing of emotion, thalamic connections route information about object qualities of a stimulus through sensory pathways (LeDoux, 1989). Simultaneously, information is routed to the limbic system and the amygdala, where memories of the affective meaning of the stimulus further influence the process. Later object processing can update the emotional analysis, but in the meantime, back projections from the amygdala can influence subsequent sensory processing. Output of the amygdala to organized autonomic reactions via the hypothalamus and to motor activation via the corpus striatum reflects the motivational aspect of the emotions (LeDoux, 1989).

### Attention as a Control System

Neuroimaging studies demonstrate connections between emotional processing networks and the executive attention system that allow the selection of emotional information for conscious processing so that we may or may not be aware of our emotional evaluations (Bush, Luu, & Posner, 2000; Posner & Rothbart, 1991). Attentional systems can select for conscious processing aspects of emotional analyses, and emotion can also influence the focusing and shifting of attention (Derryberry & Reed, 1996, 2002; Gray, 1991). An important aspect of social adaptation involves the appropriateness of a child's social interaction and the related acceptance of the child by others (Parker & Asher, 1987). Information about the state of others will thus be an important contributor to appropriate social action, and failure of this information to access action and consciousness can be a critical element in the development of disordered functioning. When attention is focused on threatening stimuli or on

the self, access to information about others is likely to be less accessible. These are important examples of information-processing aspects of temperament that have major implications for social development, and we discuss them again in the section on temperament and the development of personality.

### Positive Emotionality/Approach and Extraversion

We now briefly review neural models developed to describe a physical substrate for approach and fearful inhibition. Based on animal research, Gray (1991) described the behavioral activation system (BAS), involving sensitivity to rewards, and the behavioral inhibition system (BIS), involving sensitivity to punishment, nonreward, novelty, and innate fear stimuli (see applications to children by Blair, 2003). These two systems are seen as mutually inhibitory, with their balance determining degrees of extraversion-introversion. Gray also posited a fight-flight system that moderates unconditioned punishment (Gray, 1991). According to Gray's BAS model, reward-related projections from the amygdala to the nucleus accumbens activate a motor program that increases proximity to the desired stimulus and facilitates goal-oriented behavior (Gray & McNaughton, 1996).

In a broader behavioral facilitation system (BFS), Depue and Collins (1999) proposed a circuit involving the nucleus accumbens, ventral pallidum, and dopaminergic neurons that codes the intensity of the rewarding stimuli, with related circuits involving the medial orbital cortex, amygdala, and hippocampus integrating the "salient incentive context." Individual differences in the functioning of this network are thought to arise from variation in the dopaminergic projections that encode the intensity of incentive motivation. With development, dopaminergic facilitation can enhance responsivity to positive incentive stimuli (Depue & Collins, 1999) and provide a neural basis for a positive feedback system. This system can lead initially approaching children to become even more approaching, and temperamental differences in extraversion to become greater with time.

Depue and Iacono (1989) used the BFS to account for initiation of locomotor activity, incentive-reward motivation, exploration of environmental novelty (if stronger than opposing fear reactions), and irritable aggression. Panksepp (1982, 1986b, 1998) concluded that "the general function of DA [dopamine] activity in appetitive

behavior is to promote the expression of motivational excitement and anticipatory eagerness—the heightened energization of animals searching for and expecting rewards” (1986a, p. 91). Cloninger (1986, 1987) also specified a novelty-seeking dimension related to DA functioning, as did Zuckerman (1984) in his dimension of sensation seeking (see review by Rothbart, 1989a).

A broad approach dimension has also been linked to positive affect. Tellegen’s (1985) research on personality yielded a broad factor of Positive Emotionality, including pleasure and positive anticipation, and Watson and Clark (1997) have argued that positive affect is the core of individual differences in Extraversion. The children’s temperament factor of Surgency/Extraversion (Rothbart et al., 2001) fits well with these models. In research on infants (Rothbart, 1988; Rothbart, Derryberry, & Hershey, 2000), expressions of smiling and laughter were related to their rapid latency to approach objects, and predicted their anticipatory eagerness about upcoming positive events at the age of 7 years.

In recent functional Magnetic Resonance Imagery (fMRI) research with adults, Canli et al. (2001) found that persons higher in extraversion showed greater brain response to positive than negative stimuli in widespread frontal, temporal, and limbic activation of both hemispheres. Those higher in neuroticism reacted more to negative than to positive stimuli, showing more circumscribed activation (fronto-temporal on the left side) and deactivation in a right frontal area. In a follow-up study focusing on the amygdala, extraversion was correlated with left amygdala activation to happy, but not to fearful, faces (Canli, Sivers, Whitfield, Gotlib, & Gabrieli, 2002). Neuroticism was not correlated with activation to any of the emotional faces, except for significant amygdala activation for the fearful expression.

### Fear and Behavioral Inhibition

Fear is an emotional response activated in the presence of threat or signals of upcoming danger, and its function appears to be a defensive one. Fear activation is accompanied by inhibition of ongoing motor programs and preparation of response systems controlling coping options such as fleeing, fighting, or hiding (see review by Rothbart, Derryberry et al., 1994). In Gray’s (1991) behavioral inhibition system model (BIS), the fear-related BIS is based on circuits including the orbital frontal cortex, medial septal area, and the hippocam-

pus. However, the amygdala has been more often identified as the critical structure in the processing of conditioned fear (LeDoux, 1989). Emotional networks involving the amygdala also appear to respond more strongly to novel than to familiar stimuli (Nishijo, Ono, & Nishino, 1988). Amygdala lesions in rodents disrupt autonomic and cortisol reactions, behavioral freezing, and fear vocalizations; similar findings have been reported in primates (Lawrence & Calder, 2004). In humans, functional neuroimaging studies by Calder, Lawrence, and Young (2001) and others support involvement of the amygdala in both acquiring and expressing fear, although not in the voluntary production of facial expressions of fear (Anderson & Phelps, 2002). The amygdala also is involved in the recognition of fear in the human face (Calder et al., 2001), and there is evidence in humans that amygdala damage is related to reduced fear experience (Adolphs et al., 1999; Sprengelmeyer et al., 1999).

Projections from the amygdala implement autonomic and behavioral components of fear, including startle, motor inhibition, facial expression, and cardiovascular and respiratory changes (Davis, Hitchcock, & Rosen, 1987). Individual variability in the structure and functioning of any of these subsystems may be related to variations in behavioral expressions of fear, and multiple components of other affective motivational systems, such as approach/positive affect and anger/irritable distress, would also be expected.

The amygdala also appears to affect information processing in the cortex. For example, the basolateral nucleus of the amygdala projects to frontal and cingulate regions involved in the executive attention system (Posner & Petersen, 1990), as well as to ventral occipital and temporal pathways involved in processing object information. These connections are consistent with findings that anxious individuals show enhanced attention to threatening sources of information (e.g., Derryberry & Reed, 1994). A more detailed analysis of structures related to behavioral inhibition can be found in Kagan and Fox’s chapter, Chapter 4, this *Handbook*, this volume.

A psychobiological analysis of fear suggests there may be less disagreement about temperament variables than had been previously thought. Fear as we have described it includes arousal, felt emotion, motor response preparation for flight and/or attack (with responses often inhibited), and attention toward the fear-inducing stimulus and/or possible escape routes (Davis et al., 1987). When temperament researchers study aspects of

this construct, they sometimes stress (a) the motivational aspects of the individual's response (e.g., Thomas & Chess's, 1977, Approach/Withdrawal; Kagan's, 1994, behavioral inhibition), (b) the distress proneness aspects (Buss & Plomin's, 1975, Emotionality; Goldsmith & Campos', 1982, Fear), (c) its duration and susceptibility to interventions (Rothbart's, 1981, Soothability), (d) its relation to arousal (Strelau's, 1983, reactivity), or (e) multiple components of response (Rothbart & Derryberry's, 1981, Fear). If we take the broader view of fear suggested by neuroscience work, agreement is more evident, and intercorrelations among scales measuring the differently named constructs as discussed earlier further support this contention (Goldsmith, Rieser-Danner, & Briggs, 1991).

We have now touched on possible neural substrates for approach/positive affect systems related to reward seeking, and for fear, linked to the inhibition of approach and of sensation seeking that might lead to punishment ("harm avoidance"). An important aspect of these constructs for students of social development is that they describe individual differences in susceptibility to reward and punishment, suggesting that some children will be more activated by reward and some children will find stopping an activity easier when there is a high likelihood of punishment (Rothbart, Ahadi, & Hershey, 1994). When a situation involves both potential rewards and punishments, such as interactions with a stranger, the balance between approach and fear tendencies based on temperament and previous experience will be critical to behavioral outcomes.

This model has direct applications to child socialization. If we consider a toddler performing an enjoyable act, such as shredding the pages of a book, the child's initial activities will be influenced by the approach or extraversion system. Now the parent gives a sharp, punishing command for the child to stop. Will the child's activity be inhibited? Patterson (1980) found that parents of nonproblem children were effective in stopping their children's aversive behavior on three out of four occasions when they punished. When parents of problem children used punishment, however, children were likely to actually continue the punished behavior (Patterson, 1980; Snyder, 1977). Although parenting skills are also involved, children's temperament is likely to make a basic contribution to this situation.

Individual differences in risky behaviors and accident-proneness (Matheny, 1991; Schwebel, 2004),

mastery motivation (Rothbart & Hwang, 2005), and affective representations of the environment (Derryberry & Reed, 1994) are all likely to be influenced by temperamental approach and inhibition tendencies in interaction with past experience. The coping strategies children use will also be influenced by their tendencies to approach or inhibit action. Quay (1993) has employed Gray's constructs of the BAS and BIS to analyze the development of undersocialized aggressive conduct disorder. In the next section, we describe temperament systems related to distress, overstimulation, irritability and anger, and possible controls offered by affiliative tendencies.

### **Optimal Levels of Stimulation and Distress to Overstimulation**

We have now described individual differences in systems of fear and approach/extraversion. However, processes related to arousability have also been proposed to underlie approach and withdrawal. One model incorporates the idea of "optimal level" of stimulation. This approach derives temperament from general arousability or "strength of nervous system," put forward in the Soviet and Eastern European schools—Eysenck's (1967) model—and ideas developed by Bell (1974). In the theory of Berlyne (1971), arousal potential (created by stimulus intensity, novelty, and surprise) activates two motivational systems: one related to pleasure and approach (elicited at lower levels of arousal potential), the other to distress and withdrawal (elicited at higher levels of arousal potential). The two systems oppose each other. Individual differences in the strength of each of these two systems support a level of optimal arousal—the point where approach and pleasure are at their highest, but withdrawal processes do not yet dominate.

Schneirla (1959) put forward similar ideas, describing Approach and Withdrawal systems across species related to the intensity of stimuli. Eysenck (1967) argued that introverts are more arousable and sensitive to stimulation at low intensity levels than extraverts, linking this arousal to the Ascending Reticular Activation System. Introverts were seen to experience both pleasure and discomfort at lower levels of stimulus intensity; this lower optimal level of arousal would lead them to seek lower stimulus levels. In Strelau's (1983) model, more strongly reactive individuals engage in self-regulatory activities to maintain their optimal levels of

stimulation. Soviet researchers' concept of nervous system strength of activation or endurance under high-intensity stimulation, and Strelau's reactivity construct are dimensions involving both sensitivity and susceptibility to distress that might be present in early life. More recently, Aron and Aron (1997) have also linked sensory sensitivity and reactivity to distress.

Developmental research on temperament shows mixed support for a positive relation between sensitivity and susceptibility to distress. Miller and Bates (1986) found significant positive correlations between temperature sensitivity and susceptibility to the negative emotions. In Keogh's (Keogh, Pullis, & Caldwell, 1982) Teacher Temperament Questionnaire, the third factor, labeled Reactivity, included both negative affect and sensitivity items. In research with the CBQ, positive correlations between perceptual sensitivity and discomfort are regularly obtained (Goldsmith, Buss, & Lemery, 1997; King & Wachs, 1995; Rothbart, Posner, & Hershey, 1995), but in the CTPQ, perceptual sensitivity was moderately related to openness and social extraversion (including *positive* affect), and slightly negatively related to the internalizing negative affects. Andersson, Bohlin, and Hagekull (1999) found that parent reported reactivity to sensory stimulation at 10 months was related to greater stranger wariness at 10 months and social inhibition at 25 months. Martin et al. (1994) have also reviewed three factor analytic studies finding sensitivity items to load with items assessing negative emotionality. Laboratory research assessing children's sensory thresholds along with their thresholds for pleasure and discomfort would be helpful in further testing this theoretical relationship.

### Anger/Irritability

In Gray's (1991) model, the fight-flight system is constituted by circuits connecting the amygdala, ventromedial nucleus of the hypothalamus, central gray region of the midbrain, and somatic and motor effector nuclei of the lower brain stem processing information involving unconditioned punishment and nonreward. When there is detection of painful or frustrating input, the brain stem effectors produce aggressive or defensive behavior. Individual differences in reactivity of this fight-flight system are also thought to underlie aggressive aspects of Eysenck's general Psychoticism dimension,

and Panksepp (1982) describes similar neural circuitry in connection with a "rage" system (see review by Rothbart, Derryberry, et al., 1994).

Important distinctions have more recently been made, however, among varieties of aggression and anger, and their underlying neural systems. Aggression as a self-defense reaction seems to be based on the functioning of the same amygdala circuits as involved in the production of fear (Blanchard & Takahashi, 1988). Aggression linked to protection of resources, competition, and offensive aggression, however, involves a different system based on the monoamine dopamine (DA; Lawrence & Calder, 2004). The DA system has been linked to both the production of offensive aggression (Smeets & González, 2000), and to the recognition of anger in the human face (Lawrence, Calder, McGowan, & Grasby, 2002). In Lawrence et al.'s study, DA blockade impaired the recognition of anger, while sparing recognition of other emotions and of facial identity.

We have noted earlier that Depue and Iacono (1989) suggest the dopaminergic system may facilitate irritable aggression aimed at removing a frustrating obstacle, consistent with findings that DA agonists (e.g., amphetamine) can enhance aggressive behaviors. Their view suggests links between approach and frustration/anger, and children's activity level and anger have been consistently positively related in parent-reported temperament (Rothbart & Derryberry, 2002). In addition, infant activity level predicts not only positive emotionality at age 7, but also higher anger/frustration and low soothability-falling reactivity (Rothbart, Derryberry, & Hershey, 2000). Together with findings relating 7-year surgency to aggression (Rothbart et al., 2000), this suggests that strong approach tendencies may be linked to negative and positive emotions (Derryberry & Reed, 1994; Rothbart et al., 2000). Children who showed a short latency to grasp objects at 6.5, 10, and 13.5 months showed high levels of positive anticipation and impulsivity at age 7, as well as high anger-frustration and aggression, again suggesting that strong approach tendencies can contribute to both later anger-related negative emotions and to positive emotions.

### Negative Emotionality or General Distress Proneness

Negative Emotionality or distress proneness is often viewed as a general dimension subsuming emotions of

fear, anticipatory anxiety, sadness, frustration/anger, guilt, and discomfort. For example, the Five-Factor model of adult personality includes negative emotions as components of the Neuroticism superfactor. Neuroticism/Negative Emotionality has been found to be orthogonal to Extraversion/Positive Emotionality (Eysenck & Eysenck, 1985; Tellegen, 1985; Watson & Clark, 1992). As evident in our previous discussion, however, the positive relationship between anger/frustration and strong approach tendencies suggests that a more differentiated model is needed.

As noted earlier, separable neural systems have been found to be related to different forms of negative affect. There are nevertheless several possibilities for identifying higher order negative emotion reactions. One is the link between systems supporting fear and defensive aggression (Blanchard & Takahashi, 1988). Defensive aggression in animal models seems to be based on the same amygdalar circuits as fear, and in humans, anger in response to threat may also be linked to fear.

Negative affect systems are also regulated by more general neurochemical systems including dopaminergic and serotonergic projections arising from the midbrain, and by circulating gonadal and corticosteroid hormones (Rothbart, Derryberry, et al., 1994; Zuckerman, 1995). Neurochemical influences may thus also provide coherence of emotional states in an individual, and support more general factors of temperament such as negative emotionality. For example, serotonergic projections from the midbrain raphe nuclei appear to moderate limbic circuits related to anxiety and aggression (Spoont, 1992). Low serotonergic activity may thus increase an individual's vulnerability to both fear and frustration, contributing to a general factor of negative affectivity, including depression. Gonadal hormones are related to both positive affect and aggressiveness (Zuckerman, 1991), possibly influencing individual differences in positive and angry states. Neural structures can thus support variability at broad and specific levels, although more research in the area is definitely needed.

### **Affiliativeness/Agreeableness**

We share with other animals, including mammals, birds, and fish, systems of affiliation that support pair bonds and the care of the young (Insel, 2003). Panksepp (1986c) indicates that affiliative and prosocial behav-

iors may depend in part on opiate projections from higher limbic regions (e.g., amygdala, cingulate cortex) to the ventromedial hypothalamus, with brain opiates promoting social comfort and bonding, and opiate withdrawal promoting irritability and aggressiveness. Because ventromedial hypothalamic lesions dramatically increase aggression, Panksepp (1986a) also suggests that this brain region normally inhibits aggressive behaviors controlled by the midbrain's central gray area. Hypothalamic projections can allow for friendly, trusting, and helpful behaviors between members of a species by suppressing aggressive tendencies. Mechanisms underlying prosocial and aggressive behaviors would in this way be reciprocally related, in keeping with the bipolar Agreeableness-Hostility dimension found in Five Factor Models of personality. Panksepp (1993) has also reviewed research suggesting links between social bonding and the hypothalamic neuropeptide oxytocin (OXY), involved in maternal behavior, feelings of social acceptance and social bonding, and reduction of separation distress. OXY is also released during sexual activity by both females and males.

Agreeableness, including at the high end, the prosocial emotions and behaviors and affiliative tendencies, and at the low end, aggression and manipulativeness, has been increasingly studied in childhood (Graziano, 1994; Graziano & Eisenberg, 1997; Graziano & Tobin, 2002). Like other originally bipolar dimensions, prosocial and antagonistic dispositions have also been studied separately (Bohart & Stipek, 2001), and Graziano and Eisenberg (1997) suggest that the two dispositions may be separable, even though negatively related. On a related issue, Shiner and Caspi (2003) point out that antisocial and prosocial behavior have different etiologies (Krueger, Hicks, & McGue, 2001). Any temperamental predisposition to prosocial behavior needs to be seen as an open system, interacting with social experience for its outcomes. In research described earlier linking temperament to personality in early and middle childhood, two forms of extraversion/surgency have been identified; one linked to prosocial behavior and the other to antisocial behavior and aggression (Victor, Rothbart, & Baker, 2006), again suggesting the importance of socialization to pro- or antisocial behavior, and reminiscent of Gesell's (1928, as cited in Kessen, 1965) comment earlier in our chapter that C.D. could become either a delinquent or a willing and responsible worker, depending on her training.

## Attentional Networks

Functional neuroimaging has allowed many cognitive tasks to be analyzed by the brain areas they activate, and studies of attention have been among the most often examined (Corbetta, Kincade, & Shulman, 2002; Driver, Eimer, & Macaluso, in press; Posner & Fan, in press). Imaging data support the presence of three networks related to different aspects of attention, carrying out the functions of alerting, orienting, and executive attention (Posner & Fan, in press). We discuss orienting and executive attention in this section, although alerting is also likely to prove of interest to future temperament studies.

Orienting involves aligning attention to a source of signals. It may be overt (as in eye movements) or covert (occurring without any movement; Posner, 1980). Orienting can be manipulated by presenting a cue indicating where in space an event will occur, thereby directing attention to the cued location (Posner, 1980). Orienting to visual events has been associated with posterior brain areas, including the superior parietal lobe and temporal parietal junction and the frontal eye fields (Corbetta et al., 2002). Lesions of the parietal lobe and superior temporal lobe have been consistently related to difficulties in orienting (Karnath, Ferber, & Himmelbach, 2001).

Orienting early in life is a reactive aspect of attention, and children differ both in their latency to orient and their duration of orienting (see review by Ruff & Rothbart, 1996). In the IBQ, individual differences in duration of orienting in infancy are positively related to smiling and laughter and vocal activity, suggesting that orienting may be part of an early positive reactivity or interest system (Rothbart, 1988; Rothbart, Derryberry, et al., 2000).

The second major control system over reactive approach and action (the first is fearful inhibition as discussed earlier) is that of effortful control, supported by development of the executive attention network (Posner & Rothbart, 2000). Executive attention and effortful control are related to volition and awareness of input (Posner & Rothbart, 1991). There are limits on how much we can simultaneously attend to in directed thought or action. Areas of the midfrontal lobe, including the anterior cingulate gyrus, appear to underlie a general executive attentional network (Vogt, Finch, & Olson, 1992), in combination with lateral prefrontal areas. The anterior cingulate represents the outflow of

the limbic system, and is thus closely tied to emotion. It also has close connections to adjacent motor systems. Activity of the anterior cingulate is modified by dopamine input from the underlying basal ganglia. The anterior cingulate structure consists of alternating bands of cells with close connections to the dorso-lateral frontal cortex and to the posterior parietal lobe (Goldman-Rakic, 1988), suggesting a highly integrative role. The anterior cingulate thus appears to provide an important connection between widely different aspects of attention (e.g., attention to semantic or emotional content, or visual location).

Persistence, a dimension of personality conceptually related to effortful control in temperament, has been related to brain activation (Gusnard et al., 2003). The effects of persistence act strongly on midline and lateral prefrontal areas that are quite different than those found active for positive and negative affect, suggesting regulatory aspects of persistence. An increasingly accepted view (Posner & Rothbart, 2000) is that effortful control, represented in midline frontal areas, acts to regulate brain areas like the amygdala that are more clearly related to reactive aspects of negative affect.

In additional research, children who showed rapid approach as infants tended to be low in attentional control and inhibitory control at age 7, consistent with findings of a negative relation between Surgency/Extraversion and Effortful Control (Rothbart, Derryberry, et al., 1994), and suggesting that strong approach tendencies may constrain the development of voluntary self-control. If approach tendencies are viewed as the “accelerator” toward action, and inhibitory tendencies as the “brakes,” stronger accelerative tendencies may weaken the braking influence of inhibitory control (Rothbart & Derryberry, 2002).

Executive control of attention is often studied by tasks that involve conflict, such as varieties of the Stroop task, where subjects are asked to respond with the color of ink (e.g., red) while ignoring the color word name (e.g., blue; Bush et al., 2000). Resolving conflict in the Stroop task activates midline frontal areas (anterior cingulate) and lateral prefrontal cortex (Botvinick, Braver, Barch, Carter, & Cohen, 2001; Fan, Flombaum, McCandliss, Thomas, & Posner, 2003). There is also evidence for activation of this network in tasks involving conflict between a central target and surrounding flankers that may be congruent or incongruent with the target (Botvinick et al., 2001; Fan, McCandliss, Sommer, Raz, & Posner, 2002).

### ***Regulatory Functions of Executive Attention***

The anterior cingulate gyrus, one of the main nodes of the executive attention network has been linked to a variety of specific functions (Posner & Fan, in press), including working memory (Duncan & Owen, 2000), emotion (Bush et al., 2000), pain (Rainville, Duncan, Price, Carrier, & Bushnell, 1997), monitoring for conflict (Botvinick et al., 2001), and monitoring for error (Holroyd & Coles, 2002). In emotion studies, the cingulate is often seen as part of a network involving orbital frontal and limbic (amygdala) structures. The frontal areas seem to have the ability to interact with the limbic system (Davidson, Putnam, & Larson, 2000), fitting well with the idea of their supporting self-regulation.

A self-regulatory role for the cingulate has been identified in imaging studies with adults. Cingulate activity was greater when subjects were instructed to control the amount of negative affect felt in viewing a picture (Ochsner, Bunge, Gross, & Gabrieli, 2002). When hypnosis was used to control the perception of pain due to heat, cingulate activity also reflected the perceived degree of pain rather than the physical intensity of the heat stimulus (Rainville et al., 1997). Finally, large lesions of the anterior cingulate either in adults or children result in great difficulty in regulating behavior, particularly in social situations (Anderson, Damasio, Tranel, & Damasio, 2001). Smaller lesions may produce only a temporary inability to deal with conflict in cognitive tasks (Ochsner et al., 2002; Turken & Swick, 1999). These results link the anterior cingulate to regulation of neural activity related to emotion and behavior, and provide evidence for a role of the cingulate as a part of a network involved in regulation, cognition, and affect (Bush et al., 2000; Rueda, Posner, & Rothbart, 2004).

Development of executive attention between 2 and 7 years is indexed by marked changes in the ability to deal with conflict and to detect errors and slow subsequent responses (Mezzacappa, 2004; Rueda, Fan, et al., 2004; see reviews by Rothbart, Posner, & Kieras, in press; Rothbart & Rueda, 2005). Between 30 to 36 months, children are able to perform a variant of the Stroop task, the Spatial Conflict key press task, which in adults is related to activation of the anterior cingulate. In this task, conflict occurs when a stimulus is presented on the side of the screen opposite its corresponding key. The dominant response is to press the key consistent with the object's spatial location; the subdominant response is to press the key that matches the stimulus. At 24 months,

children are unable to properly perform this task, but by 30 months, most children can perform it but are slowed by the conflict, as are adults (Gerardi-Caulton, 2000; Rothbart, Ellis, Rueda, & Posner, 2003). Children performing more efficiently on spatial conflict were rated by their parents as having relatively higher levels of effortful control and lower levels of negative affectivity.

### ***Summary***

Models from neuroscience have been developed related to general dimensions of Approach, Fear/Inhibition or Harm Avoidance, Irritability (Fight-Flight or Rage), and Affiliativeness or Social Reward Dependence, Orienting, and executive attention as a basis of Effortful Control. Optimal level models proposing a link between sensitivity and affect have also found some support in the developmental literature. These dimensions offer a beginning for future work that will more finely differentiate the temperament domain, its development, and relation to the development of personality. In our review, we now move to considering measurement issues in the study of temperament in childhood, providing extensive evaluation of parent reports. It will be helpful for the reader to consider this material in addition to that put forward by Kagan and Fox in Chapter 4, this *Handbook*, this volume. We then discuss recent genetics research and other psychobiological approaches to the study of temperament.

## **MEASUREMENT APPROACHES**

Approaches to measuring temperament in children have included caregiver reports, self-reports for older children, naturalistic observations, and structured laboratory observations (see Table 3.3). Each of these approaches offers relative advantages for temperament study. Caregiver-report questionnaires, for example, can tap the extensive knowledge base of caregivers, who have seen the child in many different situations over a long period of time. Questionnaires are also convenient—they are relatively inexpensive to develop, administer, and analyze, and allow the study of multiple variables (Bates, 1989b, 1994). Alternatively, naturalistic observations can possess high degrees of objectivity and ecological validity, whereas laboratory observations allow the researcher to precisely control the context and specific elicitors of the child's behavior, as well as the time course and intensity of the child's reaction.

**TABLE 3.3 Potential Sources of Measurement Error in Three Child Temperament Assessment Methods**

	A. Rater Characteristics Relatively independent of child behavior	B. Bias in Assessment As a function of child behavior or rater-child interaction	C. Method Factors Relatively independent of both child and rater characteristics
I. Parent questionnaires	<ol style="list-style-type: none"> <li>1. Comprehension of instructions, questions, and rating scales</li> <li>2. Knowledge of child's behavior (and general impression rater has of the child)</li> <li>3. Inaccurate memory: recency effects, selective recall</li> <li>4. State when completing rating task (e.g., anxiety)</li> <li>5. Response sets (e.g., social desirability and acquiescence)</li> <li>6. For ratings, knowledge of implicit reference groups</li> <li>7. Accuracy in detecting and coding rare but important events</li> <li>8. Kind of impression (if any) raters want child/self to make on researcher</li> </ol>	<ol style="list-style-type: none"> <li>1. Observed child behavior occurring in response to parental behavior</li> <li>2. Parents' interpretations of observed behavior as a function of parental characteristics</li> </ol>	<ol style="list-style-type: none"> <li>1. Need to inquire about rarely observed situations</li> <li>2. Adequacy of item selection, wording, and response options</li> </ol>
II. Home observation measures (in vivo coding)	<ol style="list-style-type: none"> <li>1. Limited capacity of coder to process all relevant behavior</li> <li>2. Coding of low-intensity ambiguous behaviors</li> <li>3. State of coder during observation</li> <li>4. Limits of precision of coding</li> <li>5. For ratings, knowledge of implicit reference groups</li> </ol>	<ol style="list-style-type: none"> <li>1. Caregiver-child interaction moderating behavior coded (including I.8)</li> <li>2. For ratings, halo effects</li> </ol>	<ol style="list-style-type: none"> <li>1. Change in child and caregiver behavior due to presence of coder (e.g., decreased conflict)</li> <li>2. Difficulties of sensitively coding the context of behavior</li> <li>3. Limitations to number of instances of behavior (especially rated ones) that can be observed</li> <li>4. Lack of normative data</li> <li>5. Lack of stability in observational time windows; limited sample of behavior</li> </ol>
III. Laboratory measures (Objective measures scored from videotape in episodes designed to elicit temperament-related reactions)	<ol style="list-style-type: none"> <li>1. Scoring of low-intensity ambiguous reactions</li> <li>2. For ratings, knowledge of implicit reference groups</li> <li>3. Limited capacity of coder to process all relevant behavior</li> <li>4. State of coder during observation</li> <li>5. Limits of precision of coding</li> <li>6. Accuracy in detecting and coding of rare but important events</li> </ol>	<ol style="list-style-type: none"> <li>1. Effects of uncontrolled caregiver behavior or other experience prior to or during testing</li> <li>2. Selection of sample, including completion of testing on the basis of child reactions (e.g., distress-prone infants not completing procedures)</li> <li>3. Subtle variations in experimenter reactions to different children (e.g., more soothing behavior toward distress-prone infants)</li> </ol>	<ol style="list-style-type: none"> <li>1. Lack of adequate normative data</li> <li>2. Limitations to number of instances of behavior that can be recorded</li> <li>3. Carryover effects in repeated testing</li> <li>4. Constraints on range of behavioral options</li> <li>5. Novelty of laboratory setting</li> <li>6. Adequate identification of episodes appropriate to evoking temperamental reactions</li> </ol>

Adapted from Bates (1989) as adapted from Rothbart & Goldsmith (1985).

In addition to their respective advantages, each technique also is subject to error. In caregiver report measures, there may be perceptual or response biases in the informant. Naturalistic observations are expensive, and often show relatively low day-to-day reliability so that it

becomes difficult for researchers to collect an adequate sample of relevant behaviors. Laboratory procedures often limit the kinds of behavior that can be elicited, and the repeated testing necessary to measure a complex trait in the laboratory may be unfeasible or involve

carryover effects. More detail on measurement issues can be found in Bates (1987, 1989b, 1994), Goldsmith and Rothbart (1991), Rothbart and Goldsmith (1985), and Slabach, Morrow, and Wachs (1991). In the present chapter, we focus on the issue of the scientific acceptability of caregiver reports. Although the literature often provides admonitions about parent reports, it frequently does not analyze the strengths and limitations of each approach. We have recognized limitations of caregiver report (e.g., Bates, 1980), but nevertheless have found that caregiver reports have broadly established validity (Rothbart & Bates, 1998).

### Meanings of Parent Reports

Parent reports have been extensively used in personality, clinical, and developmental research, including the study of temperament. At the same time, the validity of parent reports about children's temperament has been particularly questioned, especially by Kagan (1998; Kagan & Fox, Chapter 4, this *Handbook*, this volume). We provide an alternative view to the one he has presented.

### Digital versus Analog Validity

Determining the validity of parent reports has often been framed in an absolute or "digital" way, leading to a simple judgment of whether parent reports are valid. Thomas et al. (1963) asked whether a significant correlation existed between parent reports and independent ratings, and finding significant correlations, concluded that parent reports were valid measures of temperament. More typically, when statistically significant correlations between parent ratings and independent ratings have been fairly small in size, the conclusion has been that parent reports are not valid. Any low correlation could be due to problems with observer ratings as well as parent ratings, but this issue is seldom addressed.

Early in the discussion of the meaning of parent reports of temperament, Kagan (1982) advocated a digital view of validity, and has continued to elaborate this view. In his earlier writings, Kagan (1994, 1998) argues that parent reports are not worthy of use in scientific studies of temperament. Kagan and Fox (Chapter 4, this *Handbook*, this volume), concluded that parent-report data should be supplemented by observation. Our own position, reached more or less independently (Bates, 1994; Rothbart, 1995; Rothbart & Hwang, 2002), is also that temperament research benefits from the use of

multiple measures. We would agree with the statement of Vaughn et al. (1992), discussing measures of attachment security, that "it would be most unfortunate if pretensions to methodological rigor forced investigators to ignore sources of relevant developmental information" (p. 470).

### Caregivers' Vantage Point versus Bias and Inaccuracy

One argument for the continued use of parent reports of temperament is that they provide a useful vantage point for observations. Temperament dimensions are by definition general patterns of responses by the child, and parents are in a good position to observe the child's behavior on multiple occasions, including infrequently occurring behavior that nevertheless may be critical to defining a particular temperament dimension. Most families minimize noxious stimulation for their babies, for example, so that it is difficult to observe such situations naturalistically. Parents, in contrast, can describe an infant's response to a variety of naturally occurring stimuli, like being given a shampoo, or hearing the vacuum cleaner start up. Parent observations also meet both concerns about ecological validity and ethical constraints about creating aversive situations to assess temperament in the laboratory.

Kagan (1994, 1998), on the other hand, has argued that parent reports have problems with bias and inaccuracy. Bias and inaccuracy are real concerns, but, in our view, they are not as great a problem as Kagan suggests. Similar concerns have been extensively dealt with in personality research, and the dominant conclusion has been that traits can be reliably assessed by ratings of knowledgeable informants, including the self, friends, and parents (Kenrick & Funder, 1988; Moskowitz & Schwarz, 1982). In addition, validity is a problem for structured and naturalistic observational measures of temperament as well as for parent reports, and we have summarized potential sources of measurement error in three temperament assessment methods in Table 3.3.

Behaviors reliability coded in precisely defined situations have a high degree of objectivity. But this does not mean that the observations also have high validity. Observational research needs to demonstrate the same kinds of validity (content, construct, convergent, discriminant) required of a parent-report measure (Bates, 1989b; Rothbart & Goldsmith, 1985). There are some very promising laboratory assessments of temperament (e.g., Garcia-Coll, Halpern, Vohr, Seifer, & Oh, 1992; Goldsmith & Rothbart, 1991; Kagan, Reznick, & Snidman, 1988; Matheny, Wilson, & Thoben, 1987), but

none has become so established that it can be seen as the gold standard for temperament measurement.

Kagan (1994) has also argued that the language of an individual item on a temperament questionnaire is subject to multiple interpretations. This ambiguity, however, is the main reason why researchers use *scales* of items rather than individual items to measure temperament. Attempts are made to write the best possible items, but the researcher does not expect that by doing this, all sources of error will be eliminated. Basic psychometric theory holds that the reason a set of convergent, but imperfectly correlated items tends to have better test-retest reliability, better stability over time, and better validity is that the error components of individual items tend to cancel each other out when the item scores are added to each other, yielding a closer approximation to a "true" score. This principle is true of aggregation across multiple observations as well as multiple items. Fortunately, one need not be limited to simply adding items and hoping that error is thereby reduced. With analytical tools such as LISREL and EQS, one can also explicitly model linkages between items' and scales' error components, creating latent constructs that more precisely control for measurement error. Other approaches to reducing concerns about validity are to use validity scale filters as in the Minnesota Multiphasic Personality Inventory (MMPI), and to study the ways parents construe child behavior and the items researchers present to them (Bates, 1994).

#### *A Components-of-Variance Approach to Validity*

We prefer to frame the question of validity of parent reports in terms of components of variance, judging a measure's validity on a continuum rather than an absolute judgment. Bates and Bayles (1984) asked how much variance in parent reports could be explained by reports of independent observers in a series of second-order empirical analyses on data from their longitudinal study. They found that: (a) mother ratings of their children on an array of temperament and nontemperament traits showed appropriate convergent and discriminant relations on similar sets of scales from 6 months to 3 years of age; (b) fathers and mothers agreed at generally moderate levels; (c) mothers and observers (in both naturalistic and structured contexts) agreed at generally modest but significant levels; and (d) factors such as anxiety or the tendency to describe oneself in socially desirable ways, which could reflect subjective biases, accounted for only modest portions of the variance.

Measured subjective factors thus did not overshadow measured objective factors as explanations of differences in parents' perceptions of their children. In addition to these components of parents' perceptions, there remained other error components.

Matheny et al. (1987) provided independent support for this model, using an array of laboratory measures. Their aggregated maternal report scores correlated moderately to strongly with laboratory scores of temperament:  $r = .52$  at 12 months,  $.38$  at 18 months, and  $.52$  at 24 months. Their conclusion was that "the objective component of maternal ratings was clearly demonstrable and prominent" (Matheny et al., 1987, p. 324). They also showed that maternal personality characteristics were not only correlated with mothers' perceptions of the child but also correlated with their children's behavior as independently observed in laboratory situations, a finding congruent with genetically based similarities between mother and child.

A pattern of moderate to strong validity correlations for parent report can now be found in a number of places in the literature. One important requirement for ascertaining construct validity is that both measures demonstrate adequate reliability, and often the observational or mechanical measures, not the parent-report measures, are deficient in this regard. To produce adequate reliability, aggregation across multiple measures is often necessary (Rushton, Brainerd, & Pressley, 1983). Eaton (1983) recorded activity level from actometers worn by preschoolers over repeated nursery school free play sessions. Reliability of the actometers was  $.13$  in a single session, but rose to  $.75$  when multiple sessions were aggregated (Eaton, 1994). Aggregated scores also correlated  $.75$  with parent report temperament ratings using the Colorado Childhood Temperament Inventory (CCTI) activity level scale and  $.73$  with composite staff ratings of child activity level.

Asendorpf (1990) used multiple measures on multiple occasions to assess children's behavioral inhibition to strangers (shyness) across a 4-year period beginning at age 3. Measures included a parent-report assessment as well as observations of children's behavior with strange adults and children. Of all the measures taken by Asendorpf, parent report consistently showed the strongest relations with the other measures; for example, parent reported shyness predicted latency to talk to a stranger at 3 years with  $r = .67$ ; the overall average  $r$  between parent-report and other shyness measures across the 4 years ranged from  $.43$  to  $.53$ . Bishop, Spence, and

McDonald (2003) also reported convergence between parent ratings on a new behavioral inhibition questionnaire and both teacher questionnaires and structured observation measures.

Laboratory measures have also been found to be positively related to the Infant Behavior Questionnaire (IBQ) and Toddler Behavior Assessment Questionnaire (TBAQ) (see Goldsmith & Rothbart, 1991) and between temperament measures and model tasks designed to reflect underlying brain function; for example, a positive relation was found between a laboratory spatial conflict task designed to assay executive attention and the CBQ measure of inhibitory control ( $r = .66$ ) for 36-month-old children (Gerardi-Caulton, 2000). Rothbart, Ellis, and Posner (2004) also reported relations between effortful control scales and spatial conflict scores. These findings provide further validation support for parent reports of temperament, but agreement is not always found (see Kagan & Fox, Chapter 4, this *Handbook*, this volume). A comprehensive review of validity studies in the measurement of temperament is needed.

Goldsmith et al. (1991) correlated mother reports with those of day-care teachers in samples of preschoolers, toddlers, and infants. Using a variety of standard temperament scales, they found strong convergence between scales from different questionnaires measuring the same construct, and generally acceptable divergence between scales expected to differ. Correlations between mother and day-care teacher for two older groups were in the typical range for correlations between parents and other observers (.11 to .50 for preschoolers, with the highest correlation on activity level, and .00 to .35 for toddlers, with the highest correlation also for activity), and perhaps a little above this range for infants (.21 to .60, with the highest correlation on one of the measures of approach-sociability). Day-care teachers would presumably be well acquainted with the children, although Goldsmith et al. did not report the degree of acquaintance. However, Goldsmith et al. (1991) emphasize the difference in contexts between mother and teacher observations.

As evidence for potential impact of failure to control context, they cite the Hagekull, Bohlin, and Lindhagen (1984) study. Hagekull et al. (1984) asked parents to directly record infant behavior, such as infants' reactions to loud sounds, over extended periods in specific situations. Parent data converged strongly with independent observers' data: Correlations between parents' and observers' direct observation data for two, 4-hour visits

ranged from .60 (for attentiveness) to .83 (for sensory sensitivity). Contrary to the argument of Seifer, Sameroff, Barrett, and Krafchuk (1994), this suggests that parents are not necessarily deficient or strongly biased in their powers of observation, especially since their training for the task was minimal. Hagekull et al. (1984) also found that for an open time frame, general questionnaire scales completed by the parents converged to a modest to moderately strong degree with scales based on independent direct observation, with correlations ranging from .21 to .63. We attribute the apparent improvements in observer-parent agreement coefficients more to the study's careful effort to observe sufficiently large numbers of key events than to any conceptual or psychometric advantages in the questionnaire they used (the Baby Behavior Questionnaire; BBQ). Although BBQ scales were developed through factor analysis, some of the scales in this instrument have some difficulties in interpretation, related to apparently heterogeneous content.

### *Prenatal Perception Studies*

Researchers have also studied parent expectations of temperament before the child is born, which are often significant predictors of postnatal ratings of temperament (Diener, Goldstein, & Mangelsdorf, 1995; Mebert, 1991), and we discussed these in detail in our 1998 *Handbook* chapter. Diener et al. (1995), for example, looked at mother and father agreement over time. Prenatally, mothers' and fathers' temperament expectations were only modestly to moderately correlated, and the correlation pattern was generally nondifferentiated. Mothers' expectations of unadaptability to novelty, for example, were more highly related to fathers' fussy/difficult expectations than to the father's unadaptability expectations. Postnatally, however, mother-father convergence was considerably stronger, and there was also a strong pattern of discriminant validity. For example, mothers' ratings of unadaptability were correlated with fathers' ratings of unadaptability .67, and with fathers' ratings of difficultness only .28.

Mebert (1991) and Diener et al. (1995) speculated that prenatal expectations reflected a vague internal working model of the infant before birth, which might influence temperament through expectancy confirmation processes (Darley & Fazio, 1980). However, the fact that mother and father perceptions of the infant become so much closer in both a convergent and a discriminant sense from before to after their actual experience

with the baby can be interpreted as evidence for an objective component in the ratings.

### ***Recent Attempts to Make Parent and Observer Perspectives More Similar***

Although some writers have argued that modest parent-observer agreement is simply a product of low validity in the parents' reports, this is not a necessary conclusion. Modest correlations could, for example, reflect observers simply not seeing the behavior parents based their reports on. Naturalistic and structured observation measures are often based on between 30 minutes and 4 hours of observation, and only a few are based on as much as 6 hours total. There is also little evidence that these measures show high test-retest reliability.

Two extensive home observation studies attempted to address such problems (Bornstein, Gaughran, & Segui, 1991; Seifer et al., 1994). In our 1998 handbook chapter, we described these studies in detail, indicating limitation in the designs, and concluding that the ideal large scale study for the limits of the objective component of parent reports of temperament has not yet appeared (Rothbart & Bates, 1998). Studies approaching the ideal would require conceptually well-developed measures with careful attention to both parent-report and observer-report forms. Extra attention would be devoted to validating observer- and parent-report measures, testing for convergence and divergence among measures, as well as studying relations between the measures and alternate ways of observing (e.g., summary ratings versus independently recorded molecular behavior frequencies or naturalistic versus structured observations). One recent example of such a study is that of Forman et al. (2003), who showed that aggregating laboratory measures of temperament across multiple tasks enhanced convergence with mother-report questionnaire measures.

The design would also pay greater attention to assessing contexts of temperament-relevant behavior. Although the concept of temperament implies some degree of cross-situational consistency, there is no reason to suppose that any given trait should be equally well revealed in all contexts, given variability in instigation of the response. The issue of context is crucial to all forms of temperament assessment, and will prove important as early temperament characteristics are linked to developing coping strategies across varying situations.

### ***Shall We Use Parent Reports?***

As we concluded in 1998, evidence to date supports the careful use of parent-report measures of temperament. Two basic reasons to use parent-report measures are (1) that they provide a useful perspective on the temperament of children because parents can see a wide range of child behaviors, and (2) that they have established a fair degree of objective validity. In addition, parent-report measures have contributed to substantial empirical advances, including our understanding of the structure of temperament in relation to the Big Five or Big Three models, as described earlier, and their parallels in psychophysiological systems (Bates, Wachs, & Emde, 1994; Rothbart, Derryberry, et al., 1994). A further reason for using parent reports is that the social relationship aspects of temperament elicited from parents may in themselves be important to understanding development.

Although we draw the conclusion that caregiver reports are useful in research, we share the concerns expressed in the literature about their measurement issues. Caregiver reports must be carefully interpreted as reflecting a combination of subjective and objective factors (Seifer, 2003). Improvements in caregiver-report measures should recognize possible sources of bias, such as parents' tendency to contrast one child with another in rating temperament (Saudino, 2003) on some, but not all, parent report questionnaires (Hwang & Rothbart, 2003). We should also develop subscales to detect specific biases in reporters and improve the generalizability of the observational measures we use to validate caregiver reports (Goldsmith & Hewitt, 2003).

Observational and laboratory measures are appealing and should also be employed in temperament studies; however, they should not at this time be the sole measure of temperament. The primary arguments for this position are that (a) the validity of a number of such measures of temperament is not strongly established, and (b) even if the measures were well validated, they would often be awkward and highly expensive to use. Improvements in *both* parent-report and observational measures are needed. Parent reports can likely be made more objective, and the subjective components can be modeled more accurately and even controlled for (see Bates, 1994). The construct validity of observational measures can also be improved. We now turn to a review of research on additional temperament-related measures assessing the neural substrates of temperament-related behavior.

## PSYCHOBIOLOGICAL RESEARCH APPROACHES

Gunnar (1990) describes five assumptions guiding psychobiological research on temperament: (1) “the assumption that temperament variation is regulated by the central nervous system”; (2) “the assumption that measures of peripheral systems inform us about the physiological bases of temperament because peripheral activity is regulated centrally,” allowing the use of noninvasive measures such as heart rate or electrodermal response; (3) “the assumption that fundamental temperament and emotional processes reflect a common mammalian heritage (Panksepp, 1982),” allowing research on animal models; (4) “the assumption that the aspects of central functioning related to temperament variation are those linked to broad or general behavioral tendencies”; and (5) “Finally, as reflected in Rothbart and Derryberry’s theory (1981), concepts such as reactivity or arousal and self-regulation or inhibition are central to most physiological theories of temperament” (all quotations from p. 393). We have already adopted a number of these assumptions in the course of this review, and they are further illustrated in this section.

### Behavioral Genetics

One reason for adopting a psychobiological approach to temperament is the considerable body of research indicating genetic contributions to the development of temperament and personality. Results of this work are reported extensively by Caspi and Shiner (Chapter 6, this *Handbook*, this volume), Goldsmith (1989; Goldsmith, Losoya, Bradshaw, & Campos, 1994), Plomin (Plomin, Chipuer, & Loehlin, 1990), Bouchard and Loehlin (2001), and for animal studies, Wimer and Wimer (1985). Because these reviews are available elsewhere, we briefly review findings that appear promising for an understanding of temperament and social development. Heritability estimates from behavioral genetics studies calculate the proportion of phenotypic (observable) variance in a characteristic attributable to genetic variation in a population, and heritability has proven to be substantial for most broad temperament and personality traits. In the area of personality, broad traits tend to show heritability estimates in the vicinity of .50 (Bouchard & Loehlin, 2001).

Tellegen et al. (1988) reported studies of adult monozygotic (MZ) and dizygotic (DZ) twins who had been reared either together or apart. Overall correlations of traits for MZ twins reared apart were surprisingly of a magnitude usually found for identical twins raised together (average  $r = .49$ ), with heritability estimates of about .50. Correlations for MZ twins raised apart were .61 for stress reaction, .48 for sense of well-being, .50 for control, .49 for low risk taking, and .46 for aggression. For the three superfactors of Positive Emotionality (extraversion), Negative Emotionality (neuroticism) and Constraint (effortful and fearful control), only Positive Emotionality showed evidence of higher correlations for MZ and DZ twins raised together in comparison with twins raised apart (MZ apart  $r = .34$ , together = .63; DZ apart  $r = -.07$ , together = .18).

Goldsmith et al. (1997) have reviewed developmental behavioral genetics research and presented their own findings. Reviewing major twin studies, Goldsmith et al. (1997) reported that parent-report measures yield MZ twin correlations ranging from .50 to .80, with DZ correlations ranging from zero to .50. For scales based on Buss and Plomin’s (1984) Emotionality, Activity, Sociability (EAS) measure, DZ correlations are typically less than half MZ correlations and often near zero, creating problems for heritability estimates. Although this pattern could also be due to the interactive effects of multiple genes, it seems more likely to be due to perceptual tendencies to contrast fraternal twins (Saudino, 2003). Despite the tendency for contrast effects to spuriously inflate heritability estimates, there is substantial evidence of heritability. For example, Silberg et al. (2004) showed heritability for ICQ traits in infants, even controlling for contrast effects.

Evidence for larger DZ correlations that are more in line with expected values has been found using observational methods (see Kagan and Fox’s discussion of the genetics of behavioral inhibition, Chapter 4, this *Handbook*, this volume), and for parent-report studies employing the IBQ (Goldsmith, 1993) and the TBAQ, but not the CBQ (Goldsmith et al., 1997). Research employing these last three measures also suggests shared family influence, as did the MacArthur Longitudinal Twin Study (Plomin et al., 1993) for parent-reported positive affect and approach (Goldsmith et al., 1997). Goldsmith and Gottesman (1977) have also found evidence for genetic and shared family influences on CBQ effortful control scales.

In a study involving 3- to 16-month-old infants using the IBQ and a laboratory supplement at 9 months, genetic and shared environmental effects depended on the particular dimensions of temperament studied (Goldsmith, Lemery, Buss, & Campos, 1999). Additive genetic effects accounted fully for Distress to Limitations, Fear, and Activity Level measures, shared family effects accounted for Soothability, and genetic, shared, and nonshared environmental effects accounted for Smiling and Laughter and Duration of Orienting. The covariation of mother and father report and lab measures of stranger distress reflected chiefly genetic influences. Arseneault et al. (2003) similarly combined data across multiple reporters and settings, finding stronger genetic effects for antisocial behavior across than within situations in 5-year-old children. Saudino and Cherny (2001) found that covariation between mother and father reports on the CCTI shyness scale in infants from 14 to 36 months was mediated by genetic factors, but to a lesser extent than it was mediated by nonshared environment factors.

Goldsmith's positive affect/approach findings are congruent with Tellegen et al.'s (1988) study of MZ and DZ twins raised together and apart, in that shared family effects are found for positive emotionality. The shared environmental effect on effortful control reported by Goldsmith et al. (1997) requires replication, but shared family experience may also prove to be important in the development of attentional control. These findings may stimulate research into conditions that promote approach, orienting, positive affect, and self-control in the child's early social environment. Silberg et al. (2004) support the finding of a shared environment effect in addition to genetic influence on an aggregated sociability and positive affect scale on the ICQ. They also found evidence for a shared environment effect in unadaptability (novelty distress), as well as genetic heritability.

Although behavior genetics research indicates strong heritability of individual differences in temperament in the populations studied to date, these findings are based on the usual environmental circumstances experienced by developing children, and any heritability estimates reflect genes and environment operating together. The results do not tell us what *might* be accomplished via environmental intervention. They also do not reveal the specific developmental processes involved in temperament and personality outcomes. To learn more about the latter questions, studies furthering our understanding of temperament and development are essential. Zuckerman

(1995) addressed the question of "What is inherited?" and proposed this answer:

We do not inherit personality traits or even behavior mechanisms as such. What is inherited are chemical templates that produce and regulate proteins involved in building the structure of nervous systems and the neurotransmitters, enzymes, and hormones that regulate them. . . . How do these differences in biological traits shape our choices in life from the manifold possibilities provided by environments? . . . Only cross-disciplinary, developmental, and comparative psychological research can provide the answers. (pp. 331–332)

We now recognize that experiential and environmental processes themselves build changes in brain structure and functioning (Posner & Raichle, 1994), both before and after birth (Black & Greenough, 1991). This situation is a far cry from the view that genetics gives us hardwiring that determines our future temperament and personality, and it demands developmental research. An exciting recent approach takes advantage of new methods of molecular genetics, and we review briefly some of the research in this area.

## MOLECULAR GENETICS AND TEMPERAMENT

The mapping of the human genome has provided a promising new direction for studying genes and environment in development (G. Carey, 2003; Plomin & Caspi, 1999). Genetic alleles identified in previous adult research, for example, have been examined in children. An association between the 7-repeat allele of the dopamine D4 receptor (DRD4) and novelty seeking in adults was reported in 1996 (Benjamin, Ebstein, & Belmaker, 1996; Ebstein et al., 1996), although replication of these results has been inconsistent. In addition, variation in the 5-HTTLPR, a serotonin transporter gene, had been associated with Five Factor Model Neuroticism scores and with measures of fear and harm avoidance (see review by Lesch, Greenberg, Higley, Bennett, & Murphy, 2002). In a recent imaging study, presentation of fear stimuli also resulted in increased activation of the right amygdala in adults with the l/l or s/s form of the 5-HTTLPR gene (Hariri et al., 2002).

Ebstein and his colleagues used a longitudinal sample to investigate these two genetic polymorphisms in relation to neonatal and later infant behavior (Auerbach

et al., 1999; Ebstein et al., 1998). Ebstein and Auerbach used the Neonatal Behavioral Assessment Scale (NBAS) to measure temperament during the neonatal period, and the IBQ to measure temperament at 2 months (Auerbach et al., 1999; Ebstein et al., 1998). In the newborn examination, the DRD4 long variant that has been linked to sensation seeking in adults was associated with orientation, range of state, regulation of state, and motor organization. In addition, an interaction was found between DRD4 and the 5-HTTLPR polymorphisms. The serotonin transporter gene *s/s* polymorphism that has been linked to fear and distress in adults was related to lower orientation scores, but only for neonates who did not have the long repeat variant of DRD4. For those who did, presence of the 5-HTTLPR *s/s* genotype had no effect.

Newborns who demonstrated high orientation and motor organization showed lower negative emotionality at 2 months. In addition, 2-month-old infants with long repeat DRD4 alleles had lower scores on IBQ negative emotionality and distress to limitations. Infants with the *s/s* 5-HTTLPR genotype previously related to fear and distress in adults had higher scores on negative emotionality and distress, and infants who shared both short repeat DRD4 alleles and short repeat 5-HTTLPR alleles showed the highest levels of negative emotionality and distress. Thus, the balance between orientation and distress found at the behavioral level (Harman, Rothbart, & Posner, 1997) may also be reflected at the genetic level. Finally, at 1 year of age, infants with the long DRD4 allele had lower negative emotionality scores, and showed less fear and less social inhibition (Auerbach et al., 1999).

Suomi and his colleagues have recently reported interactions between genes and environment in rhesus monkey studies of the 5-HTTLR gene and development (Barr et al., in press; Bennett et al., 2002). A standardized temperament assessment was carried out at 7, 14, 21, and 30 days of age, and monkeys with the 5-HTTLR short repeat allele showed higher levels of distress, as in human studies (Bennett et al., 2002). In human infants, the short allele was also linked to lower orientation scores (Auerbach et al., 1999; Ebstein et al., 1998), but analysis of monkey data revealed an environment by gene interaction. The short repeat allele was related to lower orientation scores, but only for monkeys who had been nursery-reared with peers, not for mother-reared monkeys. The authors note that a number of factors may account for the interaction. One is that a general tendency

to distress related to being reared in the nursery may be related to their distractibility; another is that mothers may buffer their infants' experience so as to moderate the expression of the genetic characteristic. Bennett et al. (2002) further reported an interaction between the short repeat form of the 5-HTTLR genotype and rearing condition in relation to CSF concentrations of 5-HIAA, a marker for a disposition to aggressive behavior.

Barr et al. (in press) found that nursery-reared young monkeys engaged in more social play than mother-reared monkeys, but if they had the short form of the distress-related 5-HTTLR allele, nursery-reared monkeys showed lower levels of social play, similar to the amount of play of mother-reared monkeys. Nursery-reared animals with the *l/s* genotype were more aggressive than either the mother-reared or *l/l* nursery-reared animals, suggesting the involvement of serotonin in development of aggression, but only in animals exposed to early life stress and maternal deprivation. The authors note that human research also supports both genetic and environmental contributions to the etiology of aggressive disorders (e.g., G. Carey, 1996; Dodge & Pettit, 2003).

In a study of 4-year-olds, Schmidt and Fox (2002) found a relation between the long repeat form of DRD4 and high scores on observed disruptive behavior and parent-reported aggressive and delinquent behavior. Schmidt, Fox, Perez-Edgar, Hu, and Hamer (2001) also found a link between the long repeat form and mothers' reports of attention problems. No links were found between serotonin transporter alleles and shyness, although they had been predicted. Children with the long 7-repeat allele of DRD4 related to sensation seeking in adults show behavioral aspects of ADHD, but do not demonstrate deficits in conflict performance as measured by the color-word Stroop task (Swanson et al., 2000). Sensation seeking might well be a prominent characteristic in at least some children diagnosed with ADHD. Evidence from evolutionary studies suggests that the 7-repeat allele is under positive selective pressure (Ding et al., 2002), which might be related to its association with sensation seeking, a possible advantage during human evolution (Ding et al., 2002).

In research on individual differences in attention (Posner & Fan, in press), the anterior cingulate, associated with executive attention, is only one synapse away from the ventral tegmental area, a major source of DA, and the five types of DA receptors are all expressed in the cingulate. The Attention Network Task (ANT), which assesses efficiency of alerting, orienting, and executive

attention, was used in a small-scale twin study (Fan, Wu, Fossella, & Posner, 2001). In this study, the executive attention network score showed high enough heritability (.89) to justify the search for specific genes. At least two candidate genes were found to be related to executive attention (Fossella, Posner, Fan, Swanson, & Pfaff, 2002): the DRD4 gene and the monoamine oxidase A (MAOA) gene, related to the synthesis of DA and norepinephrine. In a neuroimaging study, these genes also were related to differences in brain activation in the anterior cingulate gyrus (Fan, Fossella, Sommer, Wu, & Posner, 2003). The presence of the more common 4 repeat allele, rather than the long repeat allele of DRD4 that has been related to sensation seeking, was associated with greater difficulty in resolving conflict (Fossella et al., 2002).

These findings are all recent and require further confirmation and extension, but they indicate the possible utility of relating genetic differences to specific brain networks and temperamental characteristics. It will be particularly interesting to look at relationships at different ages and in connection with different life experiences. Human studies have also identified significant interactions between gene and environment in maladaptive outcomes, and we discuss these in the Temperament and Adjustment section.

### **Approach/Withdrawal and Hemispheric Asymmetry**

We now consider developmental research taking a psychobiological perspective and employing psychophysiological indicators. In the first of these, differences in cerebral hemispheric activation have been related to temperamental tendencies toward approach versus inhibition-withdrawal. Evidence from electrophysiological (EEG) and lesion studies has related higher anterior left hemisphere activation in response to stimulation to increased positive affect and/or decreased negative affect (see reviews by Davidson et al., 2003; Davidson & Tomarken, 1989). The reverse relationships—higher anterior right hemisphere activation related to higher negative affect and/or decreased positive affect—have also been reported. Resting EEG asymmetries have also been related to positive and negative emotional reactivity (e.g., Davidson & Fox, 1989; Tomarken, Davidson, Wheeler, & Doss, 1992). Harmon-Jones and Allen (1997), for example, reported greater left than right-frontal cortical activity in women subjects with higher scores on Carver and

White's (1994) BAS questionnaire. The BIS measure was not related to asymmetry. Buss et al. (2003) found relations between extreme right EEG asymmetry and high basal and reactive cortisol, replicating previous primate findings from Kalin and his colleagues (Kalin, Larson, Shelton, & Davidson, 1998).

Fox, Calkins, and Bell (1994) reported that infants with stable right frontal EEG asymmetry between 9 and 24 months of age displayed more fearfulness and inhibition in the laboratory than other children. At 4 years, children who showed more reticence and social withdrawal were also more likely to show right frontal asymmetry. Calkins, Fox, and Marshall (1996) also found that children selected for high motor activity and negative affect to laboratory stimulation at 4 months showed greater right frontal asymmetry at 9 months, greater mother reports of fear at 9 months, and more inhibited behavior at 14 months. However, no concurrent relation was found between behavior and frontal asymmetry at 9 and 14 months, and greater activation of both right and left frontal areas was related to higher inhibition scores at 14 months. The authors (Calkins et al., 1996) suggest a need to differentiate between fearful and angry distress, as discussed earlier in the Structure of Temperament section. They also hypothesize that high motor/high negative affect and high motor/high positive affect may be associated with later different kinds of problems. For high motor/high positive affect, the problems would be associated with difficulties in self-control.

### **Autonomic Reactivity and Self-Regulation**

By assuming central controls on peripheral reactivity, psychobiological researchers have developed models of centrally regulated systems that can be studied early in life. In this section, we consider briefly some of the research on electrodermal responding, heart rate, and vagal tone.

#### ***Electrodermal Reactivity***

Several early studies reported a relationship between electrodermal response and introversion (see review by Buck, 1979). Jones (1960), for example, compared the 10 highest and 10 lowest electrodermal responders age 11 to 18 in the Berkeley Adolescent Growth Study. High electrodermal responders were described as showing high emotional control, quiet, reserve and deliberation, and as being calm and responsible. Low electrodermal

responders were rated as more impulsive, active and talkative, more attention seeking, assertive and bossy. Adult studies have also found stable individual difference in electrodermal reactivity to be negatively related to measures of extraversion (e.g., Crider & Lunn, 1971). Fowles (1982) reported that electrodermal responding, but not heart rate reactivity, was related to measures of Gray's Behavioral Inhibition System. Indeed, Fowles and Kochanska (2000) found that electrodermal reactivity served as a substitute for laboratory and mother report fear, moderating relations between socialization and conscience development at age 4.

Fabes et al. (1994) studied kindergarten and second-grade children's facial expressions of distress and skin conductance (SC) reactivity to a film about children being hurt in an accident. For both ages, SC reactivity, used as a marker of personal distress, was positively related to facial distress and negatively related to helping. Results were seen to reflect an interference of personal negative affect with children's prosocial behavior. In a study of older children (third and sixth graders), SC was positively related to facial expressions of distress to a film and negatively related to mothers' report of dispositional helpfulness, but for girls only (Fabes, Eisenberg, & Eisenbud, 1993). Evidence has thus been found for electrodermal response as both a sign of distress and behavioral inhibition. Lang and his associates (Lang, Bradley, & Cuthbert, 1997), however, have found that adults' SC to viewing pictures increased for *both* aversive and pleasant stimuli, so that the sympathetic response measured in SC may be more general than previously thought.

### ***Heart Rate and Vagal Tone***

A good deal of recent research has focused on heart rate and on vagal tone as a measure of parasympathetic cardiac control. In her review of heart rate (HR) research, Von Bargen (1983) reported HR reactivity to stimulation to be the most stable and reliable of HR measures. As noted by Kagan (1998), HR variability has been linked to low behavioral inhibition in some, but not all, studies. Fabes, Eisenberg, Karbon, and Troyer (1994) found HR variability to be positively related to kindergarten and second-grade children's instrumental coping to a baby's crying. Fabes et al. (1993) also found positive relationships between HR variability and measures of sympathy (dispositional sympathy for girls, concerned attention to others' distress for boys) in third and sixth grade children.

Cardiac vagal tone has also been related to temperament (Bornstein & Suess, 2000; El-Sheikh, 2001). Respiratory Sinus Arrhythmia (RSA), the fluctuation in heart rate occurring at the frequency of respiration, has been used to assess parasympathetic control via the vagal nerve (Porges, 1986). There is an increase in HR during inspiration and a decrease during expiration that is extracted from HR variation, and Porges argued that variability in RSA reflects individual differences in tonic parasympathetic vagal tone. Higher baseline vagal tone is also related to greater vagal suppression to stimulation, although some infants with regulatory disorders show high RSA but do not demonstrate suppression of RSA with attention (DeGangi, DiPietro, Greenspan, & Porges, 1991). Vagal suppression is often seen as reflecting attentional strategies to cope with the environment or respond to stress (Huffman et al., 1998). Berntson, Cacioppo, and Quigley (1993) note RSA is not a direct equivalent to tonic vagal control of the heart because it is determined by multiple peripheral and central processes. They nevertheless conclude that RSA is an important noninvasive measure that "shows a high degree of sensitivity to psychological and behavioral variables" (p. 193).

Keeping these concerns in mind, we can consider some of the findings relating vagal tone or RSA measures to temperament variables. Porges, Doussard-Roosevelt, and Maiti (1994) reviewed studies relating newborn vagal tone to irritability and found that young infants with high baseline levels of vagal tone were also highly reactive and irritable. Later in development, however, vagal tone has been found to be related positively to interest and positive expressiveness and negatively to internalizing distress (for a more extensive review of these findings, see Beauchaine, 2001; Porges, 1991). Thus, RSA after 5 to 6 months tends to be associated with positive emotionality and approach as well as irritability. Richards and Cameron (1987) found that baseline RSA was positively correlated with parent-reported approach at 6- and 12-months, and Fox and Stifter (1989) reported more rapid approach to strangers in infants with higher RSA at 14 months. Stifter, Fox, and Porges (1989) found that 5-month-olds with higher RSA looked away from the stranger more during a strangers' approach and showed higher levels of interest and positive affect, although this pattern was not found at 10 months. Evidence of stability of vagal tone is only found after about 9 months of age (Porges & Doussard-Roosevelt, 1997).

Stifter and Corey (2001) found that greater suppression of vagal tone to cognitive challenge in 12-month-olds was associated with experimenter ratings of approach, and Fox and Field (1989) reported more rapid adjustment to preschool in 3-year-olds with higher vagal tone; these children also showed higher positive affect and greater adaptability. Katz and Gottman (1995) found that children with low vagal tone at age 5 showed a stronger correlation between marital hostility at age 5 and problem behaviors at age 8 than children with high vagal tone ( $r_s = .65$  and  $.25$ ), although the interaction was not significant. Katz and Gottman saw their finding as congruent with a buffering effect of higher vagal tone that might operate through attentional self-regulation. El-Sheikh, Harger, and Whitson (2001) also found an interaction: 8- to 12-year-olds with higher vagal tone appeared to be buffered against anxiety related to high verbal marital conflict. Finally, El-Sheikh (2001) found that higher vagal suppression to a taped argument in 6- to 12-year-olds was related as a protective factor to internalizing, externalizing, and other social problems related to parental problem drinking, whereas negative affectivity was a vulnerability factor in the effects of parental drinking.

Beauchaine's (2001) interpretation of developmental findings is that higher vagal tone is associated with more adaptive functioning at any given age: in the neonate, it is linked to irritability; in the older infant and child, it is linked to approach and positive affect as well as to irritability. Later higher vagal tone is associated with more appropriate social behaviors and adaptation to stressors, along with lower depressive and anxious psychopathology (see review by Beauchaine, 2001). However, the links between attentional regulation and vagal tone or suppression suggest more specific interpretations of these findings. In infancy, irritability and anger are positively related to approach, positive affect, and duration of orienting (Rothbart & Derryberry, 2002), and infants high in vagal tone may be showing a stronger approach system linked to parasympathetic function in these responses. Later, infants high in vagal tone and vagal suppression may be showing stronger attentional regulation. At 9 months, Porges, Doussard-Roosevelt, Portales, and Suess (1995) found vagal tone to be positively correlated with ICQ fussy/difficultness. For a small longitudinal sample, however, even after partialling out 9-month ICQ difficulty, 9-month vagal tone predicted lower difficulty at 3 years, possibly re-

lated to attention regulation and even to the development of the executive attention system across this period. Research with adults has recently linked high heart-rate variability to performance on tasks involving executive attention (Hansen, Johnsen, & Thayer, 2003), and children with higher vagal tone have been found to show greater ability to sustain attention (Suess, Porges, & Plude, 1994). In sum, relations between vagal tone and temperament vary depending on the age of the child and include both reactive and self-regulative processes.

### Cortisol Reactivity

Another approach that takes into account both reactivity and self-regulatory control is the work of Gunnar and others on cortisol reactivity. During stress reactions, the adrenal cortex secretes steroid hormones, including the glucocorticoids, cortisol and corticosterone (Carter, 1986). These hormones increase blood glucose and work with catecholamines to produce glucose from free fatty acids, also serving an anti-inflammatory function for injury and disease. Gunnar and her associates have investigated cortisol reactivity in relation to individual differences in temperamentally based self-regulation, and have reviewed links between stress hormone activity and development (Gunnar & Cheatham, 2003). Decreases in cortisol reactivity are found between 2 and 4 months, and further decreases between 6 and 18 months (Gunnar, Brodersen, Krueger, & Rigatuso, 1996; Lewis & Ramsay, 1995).

Both temperament and child care are related to cortisol levels. Dettling, Parker, Lane, Sebanc, and Gunnar (2000) found that children high in temperamental negative emotionality and low in self-regulation showed the greatest increase in cortisol levels when they were in less than optimal child-care situations. Donzella, Gunnar, Krueger, and Alwin (2000) investigated stress responses to competition in 3- to 5-year-olds. Children played against a familiar adult experimenter and initially won 3 games, but then lost 3. Temperamental surgency assessed via teacher report was related to both positive affect during winning and to tense and angry affect during losing. Although most children did not show increases in cortisol to competition, the 15% who did were higher in temperamental surgency and lower in effortful control. The authors concluded that more extraverted, surgent children are most vulnerable to stress

during competition. This is an important finding, because it indicates links between stress hormones and positive affect as well as negative affect systems.

Gunnar (1994) also found an initially surprising relation between cortisol levels and preschool children's adjustment to a group setting. Rather than finding higher levels of cortisol for 3- to 5-year-old inhibited (and presumably more stress-prone) children early in the school year, Gunnar found that measures of cortisol reactivity to the school experience were related to mother-report CBQ (Rothbart et al., 2001) surgency measures of high activity, stimulation seeking, and impulsivity, with a trend toward less shyness. Teachers also reported fewer internalizing problems, greater popularity, and independence for children with higher cortisol levels. Later in the school year, however, higher cortisol reactivity was associated with teacher reports of greater internalizing behavior and CBQ reports of sensitivity to discomfort.

Gunnar (1994) suggests that temperamentally linked coping activities of children may mediate their cortisol reactions so that more shy children will be less likely to experience stressful interactions initially because of avoidant or inhibitory coping strategies. More outgoing children will be more likely to seek out stress and show its effects in early, but not later, group experience when they may have mastered the social challenge (Gunnar, 1994). Gunnar's work indicates the importance of studying reactive measures in the context of regulatory coping. In more recent research, peer reactions to a child's behavior have also been found to be related to cortisol function. Gunnar, Sebanc, Tout, Donzella, and Van Dulmen (2003) reported that children with higher cortisol levels in the nursery school classroom were those whose temperamentally based behavior (high surgency; low effortful control) led other children to reject them. These findings reflect recent increases in complexity of temperament-environment relationships that we discuss later in the chapter.

### **Summary**

Behavior genetics research supports the idea that the chemical templates we inherit are reflected in our temperament, social, and personality characteristics, and recent research suggests that gene-environment interaction may be particularly important in relation to personality and social development. More developmental research is needed, however, to specify how developing brain mechanisms interact with environmental events to

support these outcomes. In research linking temperament to psychophysiology, recent investigations have related tendencies toward approach and withdrawal to left and right hemisphere brain activity, respectively. In addition, electrodermal responding has been linked to reserve and negative emotionality. HR variability and vagal tone have also been studied, with the latter taken as a measure of parasympathetic function. HR variability has been linked to prosocial responding and inversely, in some studies, to behavioral inhibition. Vagal tone has been linked to behavioral irritability, approach, positive affect, and attention, with the direction of the linkage varying depending on the age of the child. Both vagal tone and cortisol research stress the importance of both reactive and self-regulative variables in the understanding of psychophysiology and development, and all of these approaches are promising for tracing links between genetic inheritance, experience, and behavioral outcomes.

## **TEMPERAMENT AND DEVELOPMENT**

Early theorists of temperament stressed the importance of finding stability of temperament over time. Thus, for Buss and Plomin (1975), to qualify as a "temperament," a characteristic must demonstrate stability from its early appearance to late in life. More recent approaches to the field, however, have noted that temperament itself develops, and the study of this development allows us a greater understanding of both normative and individual differences (Goldsmith et al., 1997; Rothbart, 1989b; Rothbart & Derryberry, 1981). Temperamental measures can fail to show normative stability, for example, but genetically related individuals may show strong similarities in their patterns of change. These results have been found in behavioral genetics work on both activity level (Eaton, 1994) and behavioral inhibition (Matheny, 1989).

Even for dimensions showing normative stability, expressions of temperament are likely to change over time. In measuring negative emotionality, for example, 6-year-olds spend much less time crying than do 6-month-olds, but worry a good deal more. To appropriately assess stability of temperamental characteristics, it is necessary to establish continuity in the temperament constructs studied across time. Pedlow, Sanson, Prior,

and Oberklaid (1993) assessed the ATP sample at intervals from infancy to 7 to 8 years of age. By using structural equation modeling, they identified factors that applied across the entire age range (Approach/Sociability, Rhythmicity), or across several of the time intervals studied (Irritability, Persistence, Cooperation-Manageability, and Inflexibility). A model correcting for error of measurement was then used to assess individual stability on these factors from year to year, and estimates were considerably higher than those previously reported, mostly in the range of 0.7 to 0.8. Even with these levels of stability, however, there is considerable room for individual change in their children's relative position on these characteristics.

Since our last review, an important meta-analysis of studies on the stability of personality traits, including temperament, has been carried out by Roberts and DelVecchio (2000). This review was organized according to the Five-Factor model, and began with studies of temperament and personality in infancy. Considerable stability was found in measures of these variables after about the age of 3 years, with estimated cross-time correlations for 0 to 2.9 years = .35; 3 to 5.9 years = .52; 6 to 11.9 years = .45; and 12 to 17.9 years = .47. The increase at 3 to 6 years is of interest, given evidence for the rapid development of executive attention and effortful control during the first 3 years of life, possibly related to early instability. As attention systems stabilize, controls over earlier more reactive tendencies may increase prospects for stability of temperament and personality. Beyond childhood, levels of stability continue to increase through adolescence and young adulthood, not peaking until after the age of 50 (Roberts & DelVecchio, 2000).

In the next section, we consider issues of temperament stability and change in relation to social-emotional development and the development of personality. We review research examining the development of temperament in the areas of positive affect/approach and inhibition, distress proneness, activity level, and effortful control. Individual differences in emotional and motor reactivity can be seen early in life, and they will be influenced over time by the development of more regulatory systems, one of their emotionally based (fear or behavioral inhibition), the other more directly self-regulative (effortful control). The first system develops earlier than the second, and both are developing during the period when Roberts and DelVecchio (2000) reported the lowest levels of normative stability.

## Contributions of Temperament to Development

Temperament constructs are fundamental to thinking about trajectories of social-emotional and personality development (Rothbart, Ahadi, et al., 1994). As noted earlier, temperament is implicated in social learning, with some children more responsive to reward, others to punishment. Some children will be highly responsive to both. Temperament is also closely linked to the development of coping strategies. If one child tends to experience high distress to strangers, for example, and another child little distress, coping strategies involving avoidance of strangers may be elicited and reinforced for the first child, but not for the second. If the second child also experiences delight in the interaction with a stranger, more rapid and confident approach to interactions with strangers is likely in the future. Thus, the practice and reinforcement of children's temperamentally based responses may serve to magnify initial differences through a positive feedback process. Individual differences in temperament also promote the child's active seeking or avoiding of environments. Scarr and McCartney (1983) describe these genotype/environment interactions as "niche picking." The child who stays at the edge of a nursery school class or a party is selecting a different experience than the child who goes directly to the center of social excitement.

In Gray's (1991) theory, extraverts, high in positive affect and approach (the BAS), are seen as more susceptible to reward, and introverts, high in fear and shyness, to punishment (the BIS). This model suggests that caregiver treatment may have differing developmental outcomes, depending on differences among children. In other models, optimal level theories (e.g., Bell, 1974; Strelau, 1983) stress individual preferences for high or low levels of stimulation. A child easily overwhelmed by stimulation will try to keep things quiet, whereas a child who requires high levels of stimulation for pleasure will attempt to keep things exciting. Mismatches in optimal levels between a parent and child, or among siblings, may require major adaptations from one or more of the children or parents. Situational challenges, such as an intense day-care experience for an easily overstimulated infant, or demands for extended quiet time for a stimulus-seeking older child, may lead to problems for both child and caregiver.

Scarr and McCartney (1983) also describe evocative interactions where the child's temperamental characteristics elicit reactions from others that may influence the

child's development. Thus, a positive and outgoing disposition may serve as a protective factor eliciting the support of others in a high-risk environment (Werner, 1985). Radke-Yarrow and Sherman (1990) noted that in a high-risk situation, a buffering effect can occur when the child's characteristics meet the needs of the parent (these needs may be quite idiosyncratic). Acceptance by adults can then lead children to feel there is something special or important about them personally. This notion is very similar to Thomas and Chess's (1977) "goodness-of-fit" argument.

Because temperament itself develops (Rothbart, 1989b), new systems of behavioral organization (e.g., smiling and laughter, frustration, executive attention) will also come "online" over time. Any new systems that serve to regulate action and emotion will also come to modulate characteristics that were previously present, yielding potential instability of temperament across the developmental transition. In addition to the direct effects of developing control systems of fear and effortful control, children who develop a given control system early in life may have quite different experiences than children who develop the system later (Rothbart & Derryberry, 1981). For example, the child who develops fear-related inhibition late is likely to experience a greater number of interactions with potentially threatening objects or situations than the child who develops fearful inhibition early. The child who is fearful and inhibited to potential dangers early in development may spend more time watching and making sense of events in the environment than the less inhibited child. We now consider some of the major dimensions of temperament in a developmental context.

### **Extraversion/Surgency versus Shyness and Behavioral Inhibition**

By 2 to 3 months, infants show a pattern of smiling, vocalization, and motor cycling of the limbs described by Kistiakovskaia (1965) and termed the "animation complex, including smiling, quick and animated generalized movements with repeated straightening and bending of hands and feet, rapid breathing, vocal reactions, eye blink, and so on" (p. 39). These reactions appeared to increase in duration and decrease in latency into the second and third months of life (Kistiakovskaia, 1965). Werner (1985) reviewed cross-cultural evidence for both an increase in smiling between 2 and 4 months and in vocalization at 3 to 4 months. This cluster of intercorre-

lated behaviors (smiling and laughter; vocal and motor activity) is also found in parents' reports of temperament and in home observations (Rothbart, 1986). It is displayed toward exciting and novel objects as well as toward people (Bradley, 1985). However, Aksan and Kochanska (2004a) used confirmatory factor analysis to determine that observed social and non-social positive affect at 7 months formed two separate factors.

Beyond 3 to 4 months, positive affect shows normative increases in probability and duration across the first year of life, both in home observation and parent-report data (Rothbart, 1981, 1986). Stability has also been found for individual differences on a composite positive emotionality measure including smiling and laughter, motor and vocal activity, as assessed by parent-report and home observation between 3 to 9 months, and stability of a laboratory measure of smiling and laughter between 3 and 13.5 months of age (Rothbart, 1986). Smiling and laughter in infancy as observed in the laboratory also predicted both concurrent (Rothbart, 1988) and 6- to 7-year-old approach tendencies (Rothbart et al., 2001). Pedlow et al. (1993) also found stability from infancy to 7 to 8 years on their dimension of Approach/Sociability.

Later in the first year, an important form of inhibition and control over approach develops: some infants who were highly approaching at 5 or 6 months now come to inhibit their approach responses when the stimuli are unfamiliar and/or intense (Rothbart, 1988; Schaffer, 1974). In our laboratory, we found increases in infants' latency to grasp novel and intense toys from 6.5 to 10 months of age (Rothbart, 1988). Infants' approach latency to low-intensity stimuli showed stability from 6.5 months to later ages (10 and 13.5 months), but to high-intensity stimuli, it did not. This finding is congruent with the idea that behavioral inhibition is developing late in the first year, with the inhibitory reactions particularly evident in response to high-intensity stimuli. Once inhibition of approach is established, longitudinal research suggests that individual differences in approach versus inhibition to novelty or challenge will be a relatively enduring aspect of temperament. In familiar or low-intensity situations, however, chiefly positive activation will be evident. The inhibiting aspect of fear qualifies it as a control system that modulates other response tendencies, and we elaborate this argument in discussing Kochanska's (1993) research later in the chapter.

By early childhood, social inhibition with strangers shows moderate stability (Asendorpf, 1993; Gest,

1997). Honzik (1965) also noted that longitudinal Fels subjects' scores on "spontaneity" versus "social interaction anxiety" were stable and predictive over long periods for both males (the first 3 years to adulthood) and females (6 to 10 years to adulthood; Kagan & Moss, 1962). Bayley and Schafer (1963) found their most stable and persistent category between infancy to 18 years to be "active, extraverted" versus "inactive, introverted" behavior. Tuddenham (1959) reported stability on scales indexing "spontaneity" versus "inhibition" for subjects from 14 to 33 years in the Oakland Growth Study. Finally, Honzik (1965) found that for the period between 21 months and 18 years of age, the two most stable dimensions were "introversion" versus "extraversion" and "excessive reserve" versus "spontaneity."

These results can be added to evidence from Kagan (1998; Kagan & Fox, Chapter 4, this *Handbook*, this volume) on stability of behavioral inhibition, and to Caspi and Silva's (1995) and Pfeifer, Goldsmith, Davidson, and Rickman's (2002) recent work on stability of outgoingness and inhibition. In Pfeifer et al.'s (2002) research, children were examined at 4 and 7 years with laboratory, TBAQ, and CBQ assessments of behavioral inhibition and uninhibited behavior. At the younger age, children were classified as extremely inhibited, extremely uninhibited, or intermediate. Close to half the children remained in their original subgroup over the 3-year period. More than half changed subgroup, but the change tended to be to the intermediate group rather than to the other extreme. Caspi and Silva (1995) identified a group of children high on approach or confidence at age 3 to 4, who were outgoing and eager to undertake tasks, and adjusted easily to challenging situations. At age 18, these children were relatively low on self-reported control (i.e., more impulsive) and high on social potency (leadership and low shyness). Children identified in the preschool period as inhibited (fearful, with problems in sustaining attention) were, at age 18, high on harm avoidance, notably low on aggression, and low on social potency. Caspi and Silva's (1995) finding that inhibition or fearfulness served as a protective factor against the later development of aggression is also congruent with the positive correlations found between temperamental fearfulness and the development of conscience described later.

In summary, evidence for approach tendencies related to positive affect can be seen early in development. Later in infancy, behavioral inhibition related to fear develops. Once established, tendencies toward approach versus inhibition demonstrate significant stability over

relatively long developmental periods, with important implications for social development and for the measurement of temperament (Rothbart & Sheese, in press).

### *Activity Level*

Another major temperamental characteristic that can be measured early in development is activity level. Using both ultrasound imaging and mothers' reports, activity level can also be measured prenatally, and evidence for temperamental stability has been found over the short periods that have been measured (Eaton & Saudino, 1992). In early research, Fries (Fries & Woolf, 1954) and Escalona (1968) identified activity level as a major dimension of individual differences among infants. Birns, Barten, and Bridger (1969) found no stability of activity level from the newborn period to ages 3 and 4 months, but some stability was found from 4 weeks to later assessments.

A possible explanation for instability of early activity level is the tendency for activity to be linked to both negative and positive emotional reactivity. When high levels of activity occur in the newborn, they are often linked to the expression of negative affect (e.g., Korner, Hutchinson, Koperski, Kraemer, & Schneider, 1981). Escalona (1968) observed that newborns engage in their highest motor activity during distress; positive states were associated with quiescence. Later in development, however, the infant often becomes motorically aroused while in an alert and nondistressed state, as noted by Kistiakovskaia (1965), and activity frequently occurs when the infant is orienting toward novel objects or receiving caregiver stimulation (Wolff, 1965). Links between activity and newborn expression of negative affect may account for its failure to predict later activity. Indeed, when Korner et al. (1985) measured nondistress motor activity in the newborn, vigor of activity predicted high daytime activity and high approach scores on the BSQ at ages 4 to 8 years. Another finding is that activity at 4 months, coupled with negative affect, predicted later behavioral inhibition (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Kagan, 1998); activity coupled with positive affect predicted later uninhibited behavior (Calkins & Fox, 1994; Fox et al., 2001).

Saudino and Eaton (1995), using actometer measures in a twin study, did not find normative stability in activity level from 7 to 36 months. Nevertheless, in Saudino and Eaton's (1995) study, MZ twins were more similar than DZ twins at both ages, and MZ twins were also more concordant in their changes in activity from 7 to

36 months than were DZ twins. Lower levels of stability of activity level from the first year to later periods have also been reported. Roberts and DelVecchio (2000) found the lowest mean levels of stability for activity level among other temperament/personality dimensions studied ( $r = .28$ ); other dimensions ranged from .35 to .47 in consistency over time.

At least two explanations are possible for early instability. One, presented earlier, is that activity can be related to both positive and negative affect, so that the two kinds of activity should be differentiated. Second, the onset of inhibition as an aspect of fearfulness late in the first year may lead to lower activity for a number of children under conditions of novelty or high intensity. A second form of control over impulsive activity will also be developing beginning late in the first year and during the preschool years. This is the effortful control system, related to the development of executive attention, to be discussed later in this section. Its development coincides with normative decreases in activity level, which in a meta-analysis of activity level studies showed a peak between 7 and 9 years (Eaton, McKeen, & Campbell, 2001).

### Attentional Orienting and Effortful Control

Attention has both reactive and self-regulative aspects. In reactive attention—orienting to exogenous stimulation—consistency of rates of infant looking have been found across three quite different measures in 3-month-olds: (1) a visual discrimination paradigm, (2) an auditory discrimination paradigm, and (3) rate of looking toward the mother in social interaction (Coldren, Colombo, O'Brien, Martinez, & Horowitz, 1987). Byrne, Clark-Touesnard, Hondas, and Smith (1985) also reported stability from 4 to 7 months in average looking time and duration of first look in visual habituation tasks.

A developmental shift in visual orienting appears to occur late in the first year of life. Kagan, Kearsley, and Zelazo (1978) noted a U-shaped developmental pattern of fixation times to clay faces with scrambled and unscrambled features in both North American and Guatemalan children. From 4 to 8 months, there is a steep decline in the amount of time children spend looking at both kinds of faces. Between 13 and 36 months, however, there is an increase in looking time that is stronger for scrambled than for unscrambled faces. Kagan et al. (1978) argue that “stability of duration of orienting from 8 to 13 and 13 to 27 months, without comparable 8 to 27 month continuity, suggests

that determinants of fixation time change between 8 and 27 months” (p. 81). No stability was found between 4 months and later measures. These changes are in keeping with findings that signs of executive attention begin to emerge toward the end of the first year (Kochanska, Murray, & Harlin, 2000), allowing increased attentional control and planning, and presumably changing the meaning of individual differences in looking at objects (see also discussion in Ruff & Rothbart, 1996).

The development of effortful control—the efficiency of executive attention—including the ability to inhibit a dominant response and/or to activate a subdominant response, to plan, and to detect errors, also appears to be linked to the child's developing ability to maintain a sustained focus of attention. Krakow, Kopp, and Vaughn (1981) studied sustained attention to a set of toys in 12- to 30-month-old infants. Duration increased across this period, with stability of individual differences between 12 and 18 months, and between 24 and 30 months. Sustained attention was also positively related to self-control measures, independent of developmental quotient, at 24 months. In a major longitudinal study, Kochanska (Kochanska & Knaack, 2003; Kochanska, et al., 2000) used multiple methods to assess effortful control and emotionality. Mother report of effortful control was aggregated with laboratory measures, which included delay, slowing motor activity, lowering the voice, suppressing and initiating activity to a signal, and effortful attention at 22, 33 and 45 months of age. Focused attention at 9 months predicted children's later effortful control, and effortful control was related to regulation of anger at 22 and 33 months and joy at 33 months (Kochanska, et al., 2000). Measures of effortful control showed increasing coherence and stability across 22 to 45 months, so that between 33 and 45 months, stability was equivalent to that of IQ. Children who had shown more regulated anger and joy and more fear-related inhibition at 22 months demonstrated later higher levels of effortful control (Kochanska & Knaack, 2003). The link between inhibition and later effortful control was further supported by Aksan and Kochanska (2004b). These are exciting findings, worthy of future replication.

Krakow and Johnson (1981), using measures of self-control under verbal instructions with children age 18 to 30 months, found large age effects in inhibitory control. They also found moderate levels of stability of inhibitory self-control across the 12-month period. Vaughn, Kopp, and Krakow (1984) reported on two aspects of self-control: delay and compliance. Cross-task

consistency and coherence across the two broader measures increased across age, and the authors concluded “that individual differences in self-control emerge and are consolidated during the 2nd and 3rd years of life” (p. 990). Reed, Pien, and Rothbart (1984) found strong age effects in two measures of self-control (a pinball game and Simon-Says game) in a cross-sectional study of children aged 40 to 49 months. These studies together indicate increases in self-regulation across 18 to 49 months of age. In our research using the Stroop-like spatial conflict tasks described earlier, children began to demonstrate effective management of conflict at 30 months, and 36-month-old children who showed greater interference in reaction time for conflicting responses were reported by their mothers as exhibiting lower levels of inhibitory control (Rothbart et al., 2004). Less accurate children were also reported as showing higher levels of anger/frustration in the IBQ (Gerardi-Caulton, 2000), suggesting attentional control over emotion as well as action. Additional research with conflict tasks indicates development of conflict performance between the ages of 2 and 7 (see review by Rothbart & Rueda, 2005).

Murphy, Eisenberg, Fabes, Shepard, and Guthrie (1999) studied children longitudinally at 4 to 6, 6 to 8, 8 to 10, and 10 to 12 years of age, using parent and teacher report. Children were reported as increasing control over attentional shifting and inhibitory control across age, and girls also decreased in impulsivity. With the exception of attention shifting, the measures of self-regulation showed considerable stability across this period of development.

### **Attention and Distress**

A consistent theme of the relation between attention and distress is that the two mutually influence each other. In a study of attentional orienting and soothing in 3- to 6-month-old infants (Harman et al., 1997), infants were first shown a sound and light display; about 50% of the infants became distressed to the stimulation. They then strongly oriented to interesting visual and auditory soothing events when these were presented. While the infants oriented, facial and vocal signs of distress disappeared. However, as soon as the orienting stopped, for example, when the object was removed, the infants' distress returned to almost exactly the levels shown prior to its presentation. Apparently, the loss of overt signs of distress is not always accompanied by a genuine loss of distress. Instead, some internal system, which we termed the *distress keeper*, appears to hold a computation of the initial level of distress. Repeating the soothing

stimulus also appeared to reduce its soothing effectiveness (habituation) at 6 months, but not at 3 to 4 months.

Regulatory behaviors were studied in a longitudinal study of 66 children seen at 3, 6, 10, and 13 months of age (Rothbart, Ziaie, & O'Boyle, 1992). The infants were presented with stimuli that varied in intensity and predictability, and children showed considerable active coping with their own distress and excitement. At 6 months, children's disengagement of attention could be reliably coded. Overall disengagement of attention was not stable from 6 to 10 months, but from 10 to 13 months, children demonstrated stability in their tendency to disengage from distress-producing visual stimuli such as masks and mechanical toys. Infant disengagement was also related to lower levels of negative affect at 13 months. Stability from 10 to 13 months was also found in infants' use of mouthing, hand to mouth (e.g., thumb sucking), approach, and withdrawing the hand, suggesting that some of the infants' self-regulation strategies were becoming habitual by this time.

Direct links have also been found between children's disengagement of attention and decreases in negative affect (Stifter & Braungart, 1995). Correlations also have been found between infants' use of self-regulation in anger inducing situations and their early childhood ability to delay responses (Calkins & Williford, 2003), suggesting that mechanisms used to cope with negative emotion may later be transferred to control of cognition and behavior, as suggested by Posner and Rothbart (1998). Further support of this idea was found by Mischel and his colleagues (Sethi, Mischel, Aber, Shoda, & Rodriguez, 2000). Toddlers were briefly separated from their mothers and children's coping strategies coded. Later, at age 5, their behavior was observed in a situation where they could delay gratification for a more valued reward. Children who used more distraction strategies during the maternal separation at the younger age were later able to delay longer.

Long-term stability in the ability to delay gratification and later attentional and emotional control has been reported (Mischel, 1983). In Mischel's work, the number of seconds delayed by preschool children while waiting for rewards that were physically present (a conflict situation) significantly predicted parent-reported attentiveness and ability to concentrate when the children were adolescents (Shoda, Mischel, & Peake, 1990). Children less able to delay in preschool were also reported as more likely to “go to pieces” under stress as teenagers, and to show lower academic competence in SAT scores,

even when controlling for intelligence (Shoda et al., 1990). In follow-up studies, preschool delay predicted goal setting and self-regulatory abilities when the participants reached their early 30s (Ayduk et al., 2000), suggesting remarkable continuity in self-regulation.

In Caspi and Silva's (1995) study, preschool children characterized as "well adjusted" were described as flexible in orientation, and "capable of reserve and control when it was demanded of them" (p. 492). These children's flexibility of responsiveness may have been linked to greater executive attention and effortful control, as well as to higher ego resiliency (Block & Block, 1980) as described later. At age 18, children earlier identified as "well adjusted" by Caspi and Silva had high scores on Social Potency, including leadership and low social shyness. Interesting positive links have been found between activity level as assessed through actometers and children's performance on motor conflict tasks (Campbell, Eaton, & McKeen, 2002). Active 4- to 6-year-old children, especially the younger children, showed better performance on tasks that required them to inhibit a habitual response to perform a nonhabitual response. Their "paper highlights . . . the potentially functional, yet much neglected role that physical movement may play in young children's development" (p. 295).

Attention thus shows major developments over the first years of life, with a more self-regulative system added to a more reactive one (Rothbart, Posner, & Rosicky, 1994). As noted earlier, Caspi and Silva's (1995) Factor 1 (Lack of Control), including a combination of irritability and lack of self-regulation at age 3 to 4 years, was strongly related to negative emotionality at 18. Studies are now underway exploring contributions of both temperament and parent treatment to the development of self-control, as in Silverman and Ragusa's (1992) study predicting 4-year-old self-control from 24-month child temperament and maternal variables. Olson, Bates, and Bayles (1990) have also found relationships between parent-child interaction at 13 months and 2 years (but not at 6 months) and children's self-control at age 6.

### Two Control Systems

Early individual differences in motor and emotional reactivity thus appear to be influenced by development of at least two temperament-related control systems: One is part of an emotional reaction (fear and behavioral inhibition), the other is more completely self-regulatory (attentional control), with the first system developing earlier than the second. This view is related to the the-

ory of ego-control and ego-resiliency developed by Jean and Jack Block (Block & Block, 1980). The Blocks posited two control systems: (1) ego-control, involving fearful or inhibitory control over impulsive approach; and (2) ego-resiliency, defined by flexible adaptation to changing circumstances. The latter system is related to the temperamental characteristic of attentional effortful control, and research by Eisenberg et al. (1996) supports the predicted relationship between ego-resiliency and CBQ attentional control in kindergarten to third grade children. Resiliency was also related to social status and to teacher-reported socially appropriate behavior. Effects of self regulation were also significantly stronger for children who were high in negative emotionality (Eisenberg et al., 1996).

Eisenberg et al. (2004) have studied parent- and teacher-reported effortful control and impulsivity in relation to ego resiliency in children 4.5 to 8 years, with a 2-year follow-up. At both ages, effortful control and impulsivity predicted unique direct variance in resiliency and externalizing, and they also predicted internalizing problems indirectly, through resiliency. A moderating effect was also found on teacher-reported anger and the relation between effortful control, impulsivity, and externalizing. All relations held in predictions from Time 1 to Time 2, except the path from impulsivity to externalizing.

In the Blocks' theory, resiliency or flexibility contributes to the development of adaptation and mental health. As Block and Kremen (1996) put it:

Adaptability in the long-term requires more than the replacement of unbridled impulsivity or *under-control*, with categorical, pervasive, rigid impulse control. This would be *over-control* of impulse, restriction of the spontaneity that provides the basis for creativity and interpersonal connection. Instead and ideally, *dynamic and resourceful regulation and equilibrium of impulses and inhibitions* must be achieved. It is this *modulation of ego-control* that we more formally mean by *the construct of ego-resiliency*. It can be said that the human goal is to be as under-controlled as possible and as over-controlled as necessary. (p. 351)

In the ego-control construct, when fear and its correlates develop into a relatively constricted life, approach tendencies are strongly opposed, and rigid functioning may result. Ego-resiliency, alternatively, is strengthened by a set of life experiences that build on capacities for both expression and control of impulses. Effortful control appears to provide an important underlying system

for the development of ego resiliency, with impulsivity also related. The Blocks' theory stresses the importance of experience in the development of adaptation, with endogenous control systems allowing cultural influence on the behaviors, thoughts, and emotions that are controlled, as well as on the particular self-regulatory capacities and strategies used by the child.

### *Summary*

Because temperament systems themselves develop, in this section we have presented a brief account of the early development of aspects of positive affect and approach, activity level, and distress in relation to attentional control. (For further information on the development of temperamental distress, see Rothbart & Bates, 1998.) Some of these developmental changes lead us to expect temperamental stability in only limited time windows. Early reactive systems of emotionality and approach become overlain by the development of at least two temperamentally linked control systems. The first, fearful inhibition, is linked to developments in fearfulness late in the 1st year of life. The second, effortful attentional control, develops across the preschool period and shows considerable stability. Another likely control mechanism for the support of socialization is the development of a social reward system, connected with children's desires to please and to refrain from hurting their parents and other persons, likely linked to temperamental affiliativeness. Any failure of these controls may be linked to the development of behavior problems. Because these temperamental systems are open to experience, appropriate socialization will be necessary for positive outcomes.

## **TEMPERAMENT AND THE DEVELOPMENT OF PERSONALITY**

Life experiences influence connections between children's emotional reactions, their conceptual understanding of events, and their use of coping strategies to deal with these events. These mental habits are influenced by the child's temperament, expectancies, beliefs, values, goals, self-evaluations, appraisals, as well as understandings of the situation, the self, and/or others (Mischel & Ayduk, 2004; Teglasi & Epstein, 1998). In Mischel and Ayduk's (2004) model, individuals differ in the "ease of accessibility" of

cognitive-affective units and in the organization among them.

Coping strategies, which may have been originally based on temperamental predispositions, become part of these units, and may be consolidated or inhibited depending in part on their consequences. Mischel and Ayduk (2004) give the example of individual differences in rejection sensitivity (RS):

RS is a chronic processing disposition characterized by anxious expectations of rejection and a readiness to encode even ambiguous events in interpersonal situations [e.g., partner momentarily seems inattentive] as indicators of rejection that rapidly trigger automatic hot reactions [e.g., hostility-anger, withdrawal-depression, self-silencing]. Probably rooted in prior rejection experiences, these dynamics are readily activated when high RS people encounter interpersonal situations in which rejection is a possibility, triggering in them a sense of threat and foreboding. (Mischel & Ayduk, 2004, p. 118)

As RS becomes habitual, the person's attention may become quite narrowly focused on the likelihood of rejection, and defensive behaviors (e.g., anger or preventative rejection of the other) may develop to fend off the expected rejection. Different levels of generality of such a disposition are also possible. RS, for example, might extend to a wide range of human relationships, but the sensitivity may also be more specific so that only rejection by the child's peers, but not by adults, has been sensitized. RS may be so specific that it is limited to a single person in a single kind of situation. Mental habits are particularly likely to develop in connection with intimate relationships, as in the family, but they may be carried over to new relationships when more positive expectations and coping methods are lacking. Thus, the experience of early criticism and rejection, which may have its strongest impact on children prone to distress, can have long-term consequences for problems in development.

Mischel and Ayduk's (2004) analysis of RS describes an anxious or defensive set, but alternatively, children's experiences with others may be generally of acceptance. If so, the child will be less likely to be on guard about rejection or to show a defensive perceptual set. Instead, the child's attention can be directed more broadly, allowing greater conscious awareness of the state and needs of others. More distress prone, fearful, and irritable children may be more likely to develop such habits as RS, but after experiencing high levels of

rejection, even a low distress-prone child would be likely to develop RS. Surgent and approaching children may also be more likely to expect acceptance, but even the more distress prone child may lack the conditions for becoming sensitive to rejection when others are not critical and rejecting. This model stresses temperament-environment interactions for a number of social-emotional processes that are likely to be differentiated by context, and we review some of these important interactions in the next section.

When repeatedly exercised, habitual activations of clusters of thoughts, emotions, and action tendencies to a particular stimulus or situation become very likely to occur and difficult to change. When mental habits involve distress, how might they be weakened or disconnections achieved in the habit? In Eastern traditions, this is done partly through diminishing the role of the ego so that situations can become less threatening to the self. Mental discipline and meditation also allow weakening of links between thoughts and emotions or thoughts and action tendencies. Western therapy similarly works through the clients' patterns of reaction, attempting to reconstruct previously consolidated patterns and provide new frameworks for meaning. Taking a developmental view, however, one would wish to give the child the kinds of experiences that will form favorable and noninjurious mental habits in the first place.

Socialization in the United States and other Western cultures often strongly emphasizes habits related to the individual or ego, promoting the pursuit of individual security, satisfaction of individual desires, and achievement of a positive self-concept. In other cultures, the shaping of the child's mental habits can be quite different. Mascolo, Fischer, and Li (2003) suggest, for example, that the biological mechanisms on which pride and shame are based are similar across cultures, while the responses can be shaped in quite different directions:

For example, in American dyads, pride experiences develop as socialization agents praise children's accomplishments; shame experiences develop in social contexts in which children are made aware of their flawed identities. In contrast, in China, modest self-harmonization develops as parents efface their children's accomplishments while relatives and other significant others praise them; shame is a normative emotion that develops as parents use explicit shaming techniques to socialize filial piety in children. (pp. 401–402)

In this view, the biological equipment or temperament is similar across cultures, but the mental habits and representations of self, the world and other, will vary from culture to culture, and, we would add, context to context. By the time a child is a well-socialized member of the society, more biologically based temperament will have been shaped into a set of values, goals, and representations of the self and others that specify what is good and bad for the person. Even for children who are not well-socialized, values stressed by the culture may nevertheless have an effect. Children in the United States, for example, may still attempt to promote a positive self-concept, and pursue it though a delinquent peer group, even when the goals and values followed to achieve the positive concept may not be socially acceptable ones.

Shiner and her colleagues have recently been studying the continuity of personality from the period 8 to 12 to 20 years (Shiner, Masten, & Tellegen, 2002) and 30 years (Shiner, Masten, & Roberts, 2003). The 8 to 12 year variables, taken from parent and child interviews and teacher questionnaires, included measures of mastery motivation, academic conscientiousness, surgent engagement, agreeableness, and self-assurance versus anxious insecurity. Adaptation in childhood and adulthood was assessed by academic achievement, rule abiding conduct versus antisocial behavior, and social competence. Adult measures employed self- and parent-report questionnaires, including the Multidimensional Personality Questionnaire (MPQ; Tellegen, 1985), as well as data on academic achievement, rule compliance, social competence, job competence, and romantic competence.

Tellegen's self-report MPQ contains three broad personality factors: (1) Positive Emotionality (PEM) includes scales for well-being, achievement, social potency, and social closeness; (2) Negative Emotionality (NEM) includes scales for stress reaction, alienation, and aggression; and (3) Constraint (CON) includes scales for control, harm avoidance, and traditionalism. PEM was moderately predicted at age 20 by mastery motivation, surgent engagement, and self-assurance in middle childhood (Shiner et al., 2002). PEM was also related to concurrent social and romantic competencies at 20 years, but adult PEM was not linked to any of the childhood measures of adaptation. NEM at 20, however, was related to low adaptation in all areas in childhood, and to all concurrent adaptation measures except romantic competence. Even controlling for childhood personality, lower academic achievement and greater conduct problems in childhood continued to predict adult NEM.

Childhood mastery motivation and surgent engagement were also inversely related to NEM in adulthood. At age 20, CON was predicted by earlier lower self-assurance and higher academic competence, but when childhood personality was controlled, it was not related to childhood adaptation.

Shiner et al. (2002) suggest that positive emotionality may be more closely linked to current adaptation, whereas negative emotionality shows more continuity with earlier adaptation. In our section on adjustment, we note strong links between negative emotionality and psychopathology, both in childhood and adulthood. Negative emotionality is also particularly linked to behavior problems when effortful control is low (Caspi, 2000; Eisenberg, Fabes, Guthrie, & Reiser, 2000). Shiner et al. (2002) note that adults high on negative emotionality tend to be particularly upset by daily problems (Suls, Martin, & David, 1998). How might the development of mental habits contribute to these findings? First, habits related to distress may have involved attempts to decrease distress through mental processing, which in turn may have included repeatedly thinking about problematic events. Positive experiences would be less of a challenge and tend to be less intense, so they are likely to have been less rehearsed. When mental habits have been tied to difficult and painful situations in the past, one faces not only current problems, but also representations in memory that bring forward the mental habits linked to similar situations. Well-practiced associations may make negative affect, cognition, and action links stronger. Thus, early failure, for example, poor achievement in school, may create the possibility of long-term negative affect or neuroticism that extends to achievement situations later in life.

Caspi, Harrington et al. (2003) linked observations of 1000 children at age 3 to their self-reported personality at age 26 (96% of the original sample). Undercontrolled children (10% of the sample) had been temperamentally impulsive, restless, distractible, and negativistic at age 3; Confident children (28%) were friendly, eager, and somewhat impulsive; Inhibited children (8%) were fearful, reticent, and easily upset; Reserved children (15%) were timid but not extreme in shyness; Well-adjusted children (40%) appeared to be capable of self-control, adequately self-confident, and did not become upset during testing. At age 26, previously Undercontrolled children were higher in negative emotionality, more alienated, and subject to stress reactions. They also tended to follow a traditional morality. Formerly Inhibited and Reserved children were high in harm avoid-

ance, low in social potency (less vigorous, dynamic, forceful), and low in achievement. Both previously Undercontrolled and Confident children were low in harm avoidance. Confident children were high on social potency as adults; Inhibited children were high in Constraint and low in Positive Emotionality.

Caspi, Harrington, et al.'s (2003) findings provide evidence that the temperament of the child truly provides the core of aspects of the developing personality. Undercontrolled children, who combined extraversion/surgency, negative affect, and low attentional control at age 3, showed neurotic and alienated tendencies as adults. Confident extraverted children were confident and unfearful as adults. More shy and fearful Inhibited and Reserved children maintained their caution and harm avoidance into adulthood and were low in social potency, whereas the more extreme Inhibited children were also high in Constraint (a mixture of fearfulness and self-control) and low in Positive Emotionality and social support. The most interesting aspect of the results, however, goes beyond temperament to touch on alienation, traditional values, and social support.

Kubzansky, Martin, and Buka (2004) related children's personality/temperament at age 7 as derived from observer ratings to self ratings at age 35. Children's behavioral inhibition did not predict adult functioning, but their anger proneness (Distress) predicted adult Hostility/Anger, and inappropriate interpersonal self-regulation in childhood predicted adult Interpersonal Sensitivity. Strong relations were found between child Distress Proneness and adult somatization, another very intriguing finding. Overall, we expect that these studies will inspire more contributions to the longitudinal literature related to these variables in the future.

## TEMPERAMENT AND ADJUSTMENT

In the preceding section, devoted to temperament and personality, we have begun to consider temperament and some aspects of adjustment. In this section, we consider in more detail theoretical models and research findings relating temperament to individual differences in adjustment. By *adjustment* we mean not only psychopathology but also positive behaviors including the development of conscience. We are more interested in dimensions of adjustment than in categorical diagnostic systems, and think of adjustment as adaptation to particular contexts. A child may carry temperament traits from one context to another, but their implications for adjustment will depend on the specific context and expectations of the par-

ent, peer, or teacher (Chess & Thomas, 1984; Lerner & Lerner, 1994), in connection with experiences and adaptations to specific situations as suggested in the mental habits model described previously.

### Does Temperament Predict Adjustment?

Meaningful patterns of relationship exist between constructs of temperament and constructs of adjustment in the development of children. This was clear by the late 1980s (Bates, 1989a) and has become more firmly established since then, with many studies showing temperament links with psychopathology (e.g., see reviews by Eisenberg et al., 2000; Lonigan, Vasey, Phillips, & Hazen, 2004; Rothbart & Bates, 1998; Rothbart & Posner, in press; Sanson, Hemphill, & Smart, 2004; Wachs & Bates, 2001). In these studies, temperament and adjustment have been measured in a variety of ways, including parent reports, teacher reports, and direct observation, with adjustment assessed at home and at school, using both cross-sectional and longitudinal designs. In this review, we focus primarily on patterns of relations that indicate a differentiated view of how temperament might contribute to the child's adjustment. We mention two methodological and conceptual issues before describing findings.

The issue of measurement "contamination" (Sanson, Prior, and Kyrios, 1990) has been of continuing interest to researchers. Sanson et al. argued that relations observed between a temperament measure and an adjustment measure might be an artifact of content overlap between the two supposedly distinct measures. Item content in a temperament scale, for example, might concern behaviors that are the same as those in the measure of psychopathology or vice versa. Bates (1990) argued that adjustment and temperament should actually have some conceptual overlap. The child's adjustment could reflect a component of temperament, and psychopathology could be, at least in part, an extreme point on a temperament dimension. For theoretical reasons, however, we tend to regard temperament and adjustment as separate concepts.

Temperament characteristics may also be contributors to adjustment rather than equivalent to adjustment. This possibility can be supported, if studies show that temperament-adjustment links exist even after correcting for content overlap, or if studies show links between temperament and adjustment that transcend the simple content overlap model. Studies where expert raters and psychometric principles are used to remove items with overlapping content do demonstrate links between tem-

perament and psychopathology even after "decontamination" (Lemery, Essex, & Smider, 2002; Lengua, West, & Sandler, 1998; Oldehinkel, Hartman, de Winter, Veenstra, & Ormel, 2004). The second way of supporting a distinction between temperament and adjustment is shown by a variety of studies. One study, for example, found that therapy led to changes in parents' descriptions of their children's psychopathology but not their temperament (Sheeber, 1995). Other studies address the question of the developmental processes through which temperament and adjustment are related, and these are discussed after considering the second methodological issue.

The second methodological issue is source bias. As we have argued, caregivers' reports do show validity. However, when a conceptual relation is inferred between two constructs measured via the same source, for example, parents, the possibility exists that relations are due to preconceptions in the minds of the informant rather than the behavior of the subject. Bates and Bayles (1984) have nevertheless argued (on the basis of many different tests of subjective and objective components in parents' perceptions of their children) that measures of subjective bias do not account for more of the variance than measures of objective phenomena. In addition, as is detailed later, the different measures are related to one another within and across time in a differentiated pattern, for example, with early novelty distress predicting later novelty distress or internalizing problems more than externalizing problems. Recent studies have also shown credible levels of objectivity in caregivers' descriptions of children's temperament, even when subjective factors, such as depression, play some role (e.g., Bishop et al., 2003; Forman et al., 2003). Thus, source biases are not as powerful as one might have feared, and caregivers perceive children's behavioral traits in relatively differentiated rather than global or unitary ways. This brings us to the central question: How does temperament predict adjustment?

Temperament might be involved in the development of behavior problems in a number of ways. Clark, Watson, and Mineka (1994) listed four ways in which mood and anxiety disorders might be related to personality characteristics (also see Shiner & Caspi, 2003):

1. A *vulnerability model*, where there is a predisposition to the development of disorders (e.g., in response to stressors)
2. The *pathoplasty model*, a variant of vulnerability in which personality shapes the course of a disorder

(e.g., by producing an environment that maintains the disorder)

3. The *scar hypothesis*, in which a disorder produces enduring changes in personality (e.g., increased levels of insecurity)
4. The *spectrum or continuity hypothesis*, where the psychopathological condition is an extreme manifestation of the underlying personality trait

Clark et al. (1994) point out that the four models need not be mutually exclusive. These models may also extend to behavioral disorders, and to positive outcomes as in:

1. A *protective model*, where the person is predisposed to deal adequately with challenging situations
2. The *boost from positive adaptation model*, in which the experience of overcoming challenge strengthens feelings of optimism and well-being
3. The *spectrum or continuity model*, in which the positive outcome is itself the manifestation of an underlying set of characteristics, such as a positive outlook on experience

These and other possible processes linking temperament, risk conditions, and psychopathology are listed in Table 3.4. Generally, available evidence does not allow for a choice among the models, but, in recent years, behavioral and molecular genetics research is offering the promise of choices (e.g., Eaves, Silberg, & Erkanli, 2003).

### Direct Linkage

Most studies of the relations between temperament and adjustment have considered direct, linear effects, where a particular temperament trait contributes to the development of an adjustment pattern. Additive effects of multiple temperament traits are also possible, as when two or more temperament traits linearly increase the risk of some disorder, such as negative affectivity and lack of impulse control predicting behavior problems (Eisenberg et al., 1996), both negative emotionality and fearfulness predicting levels of young boys' internalizing problems (Gilliom & Shaw, 2004), or both impulsivity and negative emotionality associated with adolescents' antisocial behavior (Stice & Gonzales, 1998).

In evaluating direct linkage models, studies considering multiple temperament traits in relation to multiple dimensions of adjustment are critical. According to current theories of psychopathology, individual differences

in specific temperament-related brain circuits are linked to specific forms of motivation or functioning (Bates et al., 1994; Clark et al., 1994; Fowles, 1994; Gray, 1991; MacDonald, 1988; Rothbart, Derryberry, et al., 1994; Rothbart & Posner, in press), as discussed earlier. There is some, but not complete, agreement on the specific systems and how they map onto behavioral traits. In previous sections, we discussed systems controlling inhibition to novelty and conditioned signals of punishment and nonreward, as well as unconditioned fear, positive affectivity and reward seeking, sensitivity to social rewards, and attentional control. We now use these systems as general constructs to organize the evidence on temperament and adjustment. At this time, only a limited number of studies permit a differentiated view of temperament-adjustment linkages, and none of the studies are methodologically strong enough to stand alone in support or rejection of a psychobiological systems model. However, enough convergence exists that we are confident about the broad outlines of direct linkage models.

### Theoretical Expectations

Direct linkage models will become more detailed as neurobehavioral systems are better understood and as measures of adjustment are meaningfully differentiated. For now, a researcher would expect early irritability, or general tendencies toward negative affect, to predict a wide variety of adaptive difficulties, including internalizing, or anxiety problems, and externalizing, or conduct problems, as well as deficits in positive social competencies. As measures of irritability are more finely differentiated, however, more clearly defined pathways to later adjustment may be identified. For example, sensitivity to minor aversive stimuli might predispose a child to both internalizing (e.g., whining and withdrawal) and externalizing (e.g., reactive aggression) behavior problems, whereas irritability to frustration of reward or of stimulation-seeking behavior (Rothbart, Derryberry, et al., 1994) would likely pertain more to externalizing tendencies than to internalizing ones.

Temperamental tendencies toward fearfulness in novel or potentially punishing situations should predict internalizing-type adjustments most directly, although they may also serve to predict externalizing problems in inverse or interactive ways, as discussed later. A finer differentiation of fearfulness will ultimately be important for predicting different kinds of internalizing adjustment. For example, separation distress may differ in some ways from novelty fear (see Fowles's, 1994, dis-

TABLE 3.4 Processes That May Link Temperament and Adjustment

Processes	Examples
<b>A. Direct, Linear Effects</b>	
1. Temperament extreme constitutes psychopathology or positive adaptation.	Extreme shyness, Attention-Deficit/Hyperactivity Disorder High attentional control
2. Temperament extreme predisposes to a closely related condition.	Fearfulness → Anxiety Disorder, Agoraphobia/Panic Disorder High attentional control → good social adjustment
3. Temperament characteristics affect particular symptomatology of a disorder.	Anxiety versus hopelessness in depression
<b>B. Indirect, Linear Effects</b>	
1. Temperament structures the immediate environment, which then influences development of positive adjustment or psychopathology.	High stimulation seeking → leaving home early, marrying poorly High attentional control → planning → good school adjustment
2. Temperament biases others to behave in ways that provide experiences leading to risk factors, pathology, or more positive outcome.	High positive affect → attention from caregivers in institutional situations Infant irritability → coercive cycles in parent-child interactions
3. Temperament biases processing of information about self and others, predisposing to cognitively based psychopathology or positive adjustment.	Negative affectivity → negatively biased social information processing → aggression Positive affectivity → positively biased social information processing → optimism about others
<b>C. Temperament × Environment Interactions</b>	
1. Temperament buffers against risk factors or stressors.	Fear protecting against aggression or criminal socialization Positive affect protecting against peer or parent rejection
2. Temperament heightens response to event.	Negative affectivity augmenting response to stress, increasing risk of depression or likelihood of post-traumatic stress disorder Attentional orienting augmenting response to teachers' instructions.
<b>D. Temperament × Temperament Interactions</b>	
1. Self-regulation of a temperament extreme qualitatively changes its expression.	High surgency with nonregulation → Attention-Deficit/Hyperactivity Disorder, whereas same trait with good regulation → high competence High negative emotionality with low attentional control → sensitization and increasing anxiety, whereas negative emotionality plus high attentional control → no maladjustment
2. One temperament trait protects against risk consequences of another temperament-based trait.	Fearfulness or higher attentional control protecting against impulsivity
<b>E. Miscellaneous</b>	
1. Different temperament characteristics may predispose to similar outcomes.	Shyness, impulsivity, lack of affiliativeness, and negativity may each predispose to development of social isolation
2. Temperament or personality may be shaped by psychopathological disorder.	Anxiety Disorder → increased dependency

Source: Adapted from "Temperament, Attention, and Developmental Psychopathology" (pp. 315–340), by M. K. Rothbart, M. I. Posner, and K. Hershey, in *Manual of Developmental Psychopathology*, Vol. 1, D. Cicchetti and J. D. Cohen (Eds.), 1995, New York: Wiley. Some of the wording and examples have been changed. Note that many of the examples are theoretically plausible, but not based on empirical evidence.

cussion of theories placing separation fear in a panic or fight/flight brain system and novelty fear in a behavioral inhibition system, and see our sections on Panksepp's, 1998, psychobiological theory).

Positive affectivity or surgency, involving activity, stimulation seeking, assertiveness, and possibly some

aspects of manageability, should be involved more closely in externalizing than in internalizing problems, except that depression has a strong component of low positive affectivity (Tellegen, 1985). However, a trait of prosocial tendency, affiliation and agreeableness, perhaps involving sensitivity to social rewards (MacDon-

ald, 1992), might prove separable from the more general extraversion or surgency (positive affectivity) system, as Rothbart and Victor's (2004) findings suggest. Low levels of prosocial interest and concern would be expected to be associated with the development of externalizing and not internalizing problems, and perhaps with the failure to acquire positive social competencies independent of behavioral problems.

Finally, systems controlling attention, especially the executive attention system described earlier, would be expected to be related to both externalizing and internalizing, but to have more to do with externalizing problems than with internalizing ones. As with fear systems, attentional control should also play an additive or interactive role with other temperament characteristics. In addition, a well-functioning set of attentional controls is likely to be linked to more positive developmental outcomes.

### *Empirical Findings of Direct Linkage*

A number of studies provide support for the models just described. In general, predictive relations between temperament and adjustment are of modest to moderate size. Correlations between infancy measures and adjustment in late preschool and middle childhood tend to be smaller, and those between preschool or middle childhood and later periods larger. Even though the correlations may be modest to moderate in size, they have been well replicated, and they are clearly not chance findings. Moreover, the size of the relations is usually not less than and sometimes greater than predictions from other theoretically linked variables, such as parenting quality. Lytton (1995), for example, performed a meta-analysis of studies predicting conduct disorder (a diagnosis of extreme externalizing problems) and criminality, finding child temperament variables to be the single most powerful predictor of the outcomes, even in comparison with qualities of parenting.

In the Bloomington Longitudinal Study (BLS), infancy and toddlerhood ICQ temperamental difficulty (frequent and intense negative affect and attention demanding) predicted later externalizing and internalizing problems as seen in the mother-child relationship, from the preschool to the middle-childhood periods (Bates & Bayles, 1988; Bates, Bayles, Bennett, Ridge, & Brown, 1991; Bates, Maslin, & Frankel, 1985; Lee & Bates, 1985). Early negative reactivity to novel situations (unadaptability) predicted less consistently, but when it did, it predicted internalizing problems more than external-

izing problems. Early resistance to control (perhaps akin to the manageability dimension of Hagekull, 1989, and perhaps at least partly related to the construct of effortful control) predicted externalizing problems more than internalizing problems. This was also found in predicting externalizing problems at school in both the BLS and a separate longitudinal study, the Child Development Project (CDP; Bates, Pettit, Dodge, & Ridge, 1998).

In a structural modeling analysis of CDP data, dealing with the overlap in externalizing and internalizing symptoms, Keiley, Lofthouse, Bates, Dodge, and Pettit (2003) separated mother and teacher reports of behavior problems across 5 to 14 years into pure externalizing, pure internalizing, and covarying factors, and then considered early childhood predictors of each of these factors. Resistant temperament (unmanageability) predicted the pure factors of mother- and teacher-rated externalizing problems, but not the pure internalizing factors. Unadaptable temperament (novelty distress) predicted positively both mother and teacher pure internalizing factors, and to a lesser degree, and *negatively*, the pure mother and teacher externalizing factors. That is, unadaptable temperament predicted higher levels of internalizing problems and, less strongly, lower levels of externalizing problems. Although a disposition to fearfulness would not necessarily constrain dispositions to aggressive and uncooperative behaviors, it is intuitively reasonable that children who are fearful and sensitive to potential punishment would be likely to inhibit externalizing behavior (Bates, Pettit, & Dodge, 1995). And finally, difficult temperament (negative emotionality and demandingness) predicted, in this multivariate context, none of the pure factors, but only the covarying externalizing plus internalizing factor in mothers' reports.

These predictions are all consistent with models where temperament extremes either constitute pathology dimensions or predispose to risk for these conditions. The linkages are of modest size, but they obtain from early in life, and are not eliminated by the inclusion of family and parenting characteristics in prediction, so they are not simply artifacts of family functioning. Also supporting the general pattern, Gilliom and Shaw (2004) found that, in a sample of preschool-age boys from low-income families, high levels of negative emotionality were associated with initial levels of both externalizing and internalizing problems, whereas high levels of fearfulness were associated with decreases in externalizing problems over time. High initial levels of internalizing problems were associated

with increases in internalizing problems over time. In partial contrast, Russell, Hart, Robinson, and Olsen (2003) found that negative emotionality as measured by parent report on the EAS did not predict preschoolers' adjustment as rated by teachers. However, EAS shyness was related to both lower prosocial behavior and lower aggressive behavior at preschool.

Lemery et al. (2002) also provide support for a differential linkage model. Composited mother CBQ ratings of child temperament at 3 and 4 years predicted both mother and father reports of behavior problem symptoms at age 5, in a differentiated pattern. Whether or not the temperament scales were "purified" by removing items overlapping with preschool-age behavior problems, early anger predicted later externalizing problems more strongly than it predicted later internalizing problems, early fear and sadness predicted later internalizing problems more strongly than they predicted later externalizing problems, and early inhibitory control inversely predicted later externalizing or Attention-Deficit/Hyperactivity Disorder (ADHD) problems more strongly than it predicted later internalizing problems.

The Dunedin Longitudinal Study (Caspi & Silva, 1995), mentioned previously in the context of personality development, provides further support and extends measures of temperament from parent to experimenter ratings. Ratings based on the child's behavior during testing sessions, aggregated from 3 and 5 years, predicted aggregated ratings of parents and teachers in late childhood (over ages 9 and 11) and early adolescence (over ages 13 and 15). Early approach (outgoing responses to strangers and test materials—the inverse of inhibition) predicted, inversely, internalizing problems better than externalizing problems for boys. It did not predict either kind of problem for girls. Early sluggishness (a factor combining lack of positive affect, passivity, and wariness/withdrawal from novelty) predicted later internalizing and externalizing problems for girls, but not boys, as well as the relative absence of positive competencies for both girls and boys. It is not clear how approach and sluggishness emerged separately from a factor analysis describing similar dimensions, but whatever the underlying distinction between the two dimensions, they predicted outcomes differently for the two genders. A third temperament dimension, combining lack of control, irritability, and distractibility (corresponding approximately to the resistance to control or manageability factors from parent-report questionnaires), predicted, for both genders, externalizing prob-

lems more strongly than internalizing problems or positive competencies. The discovery of differentiated patterns in studies such as the BLS, CDP, and Dunedin study has occurred despite the tendency for externalizing and internalizing adjustment scores to be somewhat correlated with each other, making the pattern all the more remarkable.

In other recent studies, Morris et al. (2002) found that irritable temperament was positively associated with first and second graders' externalizing and internalizing problems equally, whereas effortful control was negatively associated with externalizing more strongly than internalizing problems. Patterson and Sanson (1999) found that 5-year-olds' low persistence (attentive and on-task) was associated with externalizing, whereas low approach to people and novel objects was associated with internalizing problems. Lengua, Wolchik, Sandler, and West (2000) found 9- to 12-year-old impulsivity (CBQ) to be associated with conduct problems and not with depression and positive emotionality Dimensions of Temperament Survey (DOTS) to be negatively associated with depression, an association stronger than with conduct problems. In partial contrast to the general pattern, however, Lengua et al. also reported that negative emotionality (DOTS) was associated with depressive symptoms more strongly than with conduct problem symptoms.

Mun, Fitzgerald, von Eye, Puttler, and Zucker (2001), also using the DOTS, reported that withdrawal tendencies at 3 to 5 years were more strongly predictive of internalizing than externalizing problems 3 years later. Their negative emotional reactivity scale also failed to confirm the general pattern of roughly equal associations with both externalizing and internalizing problems, instead predicting externalizing more strongly than internalizing problems. Murphy, Shepard, Eisenberg, and Fabes (2004) found that both negative emotionality and self-regulation (whether assessed by teacher or parent questionnaires) in middle childhood predicted social competence and behavior problems in early adolescence as rated by teacher or parent reports. And Eisenberg et al. (2001) found that anger, impulsivity, and low self-regulation (observed and parent/teacher-rated) were more strongly associated with externalizing problems (parent/teacher-rated), whereas sadness and low impulsivity were more strongly related to internalizing problems.

Also notable is the study by Rothbart, Ahadi, et al. (1994). Temperamental negative affectivity (CBQ) was

concurrently associated with a full range of social traits in 6- to 7-year-olds, including aggressiveness, guilt, help seeking, and negativity (e.g., in response to suggestion of a new activity). However, subcomponents of the general negative affect factor were associated with the social traits in a more differentiated way: Fear and sadness were more related to traits such as empathy and anger, whereas discomfort was more related to aggression and help seeking. A small subsample in the Rothbart, Ahadi, et al. (1994) sample had been tested in the laboratory as infants. Temperament as assessed in the laboratory 5 to 6 years earlier showed a somewhat similar pattern of linkage with the social behavior outcomes: Infant laboratory activity (again, usually regarded as part of surgency or positive affectivity) predicted aggressiveness and negativity, as did early smiling (another component of surgency); infant anger/frustration predicted both higher aggressiveness and help seeking; fear predicted lower levels of aggressiveness and higher levels of empathy and guilt/shame. A number of other studies also deserve mention for addressing the question of differentiated linkages between temperament and adjustment, including Biederman et al. (1990); Guerin, Gottfried, Oliver, and Thomas (1994); Hagekull (1994); Hegvik et al. (1982); McClowry et al. (1993); Rende (1993); Teglasi and MacMahon (1990); and Wertlieb, Weigel, Springer, and Feldstein (1987). These studies considered clinical as well as community samples of children at different ages and in different countries. In broad overview, their findings converge with the general, differential linkage pattern.

Several additional studies whose designs do not permit a full test of the differential linkage model because they lack a full range of temperament or adjustment variables can be interpreted as roughly conforming to the pattern described here. Among a number of examples, Prior, Smart, Sanson, and Oberklaid (2000) found that children who were stable in shyness had a higher likelihood of being diagnosed with an anxiety disorder in adolescence. Eisenberg et al. (1996) found correlations between teacher and parent ratings of emotional and behavioral low self-regulation, lower baseline heart rate, and acting-out behavior problems. Keane and Calkins (2004) measured self-regulation differences in toddlers by suppression of heart-rate variability associated with respiration, which theoretically reflects vagal regulation and indexes sustained attention and active coping. Low vagal regulation in challenging tasks at age 2 years predicted high levels of mother-rated externalizing behavior and emotional negativity and lability at age

4. In another longitudinal study with a low-income Pittsburgh sample, Keenan and Shaw (1994) found that an ICQ composite of difficultness and resistance to control predicted laboratory measures of aggression in 18-month-old boys, but not girls. Also, in a low-income Pittsburgh sample restricted to only boys, Shaw, Gilliom, Ingoldsby, and Nagin (2003) showed that a persistently high trajectory of conduct problems across ages 2 to 8 years was predicted by fearlessness in the laboratory at age 2.

In the Quebec longitudinal study, Vitaro, Brendgen, and Tremblay (2002) studied the antecedents of extreme groups of reactively aggressive, proactively aggressive, combined reactive and proactive, or nonaggressive children at age 11 and 12. Reactive aggression involves response to provocations and anger, whereas proactive aggression involves less negative emotion and more concern with material and social gain. Vitaro et al. (2002) found that temperament at age 6 (parent report on the DOTS) predicted in ways at least partly consistent with the differential linkage model. Reactively aggressive children were lower on attention span, higher on distractibility, and more motorically active and intense in responses than both nonaggressive and proactively aggressive children. However, both reactively and proactively aggressive children were more approaching and adaptable to novelty than the nonaggressive group: Note that our interpretation here, based on the DOTS scoring instructions (by R. Lerner, dated May 7, 1982), is opposite to Vitaro et al.'s (2002), who assumed that the scale signified withdrawal rather than approach. Thus, both forms of aggression can be seen as reflecting consistency with temperamental roots. Proactively aggressive children were temperamentally similar to nonaggressive children, except for being more outgoing, whereas reactively aggressive children, consonant with the dysregulated, emotional nature of their aggression, had been, in addition to highly outgoing, also more active, intense, and less attentive or well-regulated.

The focus of this section has been primarily on psychopathology or negative adjustment, consistent with the emphasis of the literature. However, positive adjustment (including empathy, conscience, intelligence, self-regulation, resiliency, and cooperation) is an area of at least equal importance in development. In our sections on Psychobiological Approaches and Temperament and Development, we have presented additional evidence on such constructs (also see the Temperament and Attachment section in Rothbart & Bates, 1998). Conceptually, there are two ways in which positive and negative adjust-

ment can be distinguished. The first one is by the positive or negative valence of the trait or behaviors (e.g., cooperative versus defiant). More interesting, the second is whether a given prosocial construct reflects chiefly the inverse of a negative adjustment trait (e.g., in the relation between cooperation and aggressive-disruptive behavior problems), or whether the construct is substantially independent of standard negative adjustment items. This question has only occasionally been addressed (e.g., Bates et al., 1991). Future research may discover how temperament antecedents of positive and negative adjustment components vary, in ways paralleling the differentiation between internalizing and externalizing (see also discussion by Rothbart, 1989b, and Rothbart and Hwang, 2005, on the development of mastery motivation). Nevertheless, there is evidence that measures of positive adjustment are related to temperament in understandable ways. One key example is the work on moral development by Kochanska (1997). For example, Kochanska and Knaack (2003) found that effortful control, assessed in laboratory tasks at ages 2 and 3, predicted more advanced conscience development at age 4, indexed by both laboratory tasks and child self-report, and fewer mother-reported externalizing behaviors at age 6.

### **Summary**

In summary, the literature on temperament and adjustment supports a direct linkage model. With a few exceptions, specific temperament dimensions also relate in a differentiated way to internalizing and externalizing adjustments, with early inhibition relating more to later internalizing, and early unmanageability relating more to later externalizing, and with early negative affect relating to both outcomes. Positive adjustment dimensions are not as clearly articulated, nor measured often enough to demonstrate differential linkages at this point.

Evidence at this point also does not yet answer the question of which of the direct linkage models listed in Table 3.4 applies best to the observed relations between temperament and adjustment. Given generally modest predictive relations, we would favor a vulnerability or predisposition model; a spectrum/continuity model might also apply. However, early individual differences likely become transformed, via developmental processes that include experience, into the more complex forms of adjustment in later years, and these processes must shape adjustment outcomes. Many child temperament researchers seem to agree with Thomas, Chess, and Birch (1968) that temperament in itself does not constitute a negative versus positive adjustment, but that it

conditions developmental processes that determine adjustment. This concept fits a vulnerability model better than a simpler continuity (or spectrum) model.

### **Empirical and Theoretical Limits on Continuity**

As noted, predictive correlations tend to be modest to moderate in size, especially when temperament is assessed in early life. This is likely due to several factors. Measurement error is almost always a problem, but when power is sufficient, it can be controlled in structural models. However, even with such a statistical control for measurement error, there will be limited predictive power (e.g., see Keiley et al., 2003). Limited predictiveness can also occur because of conceptual limitations in the measure of either temperament or adjustment. For example, the sample of situations used in a set of items may not be sufficient to capture the relevant construct. One particular problem is accounting for the lower levels of prediction from temperament at home to adjustment at school. This is sometimes ascribed to parental rating biases, but many differences in incentive conditions are present at home and school, and even if a child's temperament is measured accurately, the child's expression of that temperament could differ in the two settings. For example, the same child could be resistant and angry with the mother and yet inhibited and adequately compliant at school, a pattern seen empirically by Dumas and LaFreniere (1993) and clinically in our treatment program for young children with oppositional behavior problems. It is not that such a child is inconsistent in temperament, but rather that a child with a disposition toward anxiety can be quite uncooperative and disruptive in familiar situations and more reserved in the highly stimulating and more novel school setting. Alternatively, a child with an anxiety-prone temperament could be angry as a way to reduce anxiety aroused in a chaotically stressful home, by gaining a sense of control, and be calm in the well-ordered, supportive school environment. The habit model described earlier (linking thoughts, emotions, and actions) allows for different experiences across situations that differ in the constraints they offer for temperament expression and for different histories of experience that may be relatively idiosyncratic.

Another factor in limiting prediction is that temperament itself can change in the course of development, as a result of either experience or later-emerging traits such as attentional control. It remains an interesting possibility that we may discover laws to account for changes in

temperament. Asendorpf (1994) found that the adaptive behavior of shy children who were highly intelligent improved more over development than that of shy children who were less intelligent. Fox et al. (2001) found that negatively reactive infants, at high risk for behavioral inhibition, were more likely to show continuous behavioral inhibition across age 14 months to 4 years if they also showed right frontal EEG asymmetry (indicating in another way a strong disposition to negative affect), and they were also more likely to be continuously inhibited if they were exclusively in the care of their parents rather than receiving some nonparental care.

It is also possible that the limited size of prediction from temperament to adjustment is due to the action of other major factors in development such as parenting, family stress, or school environment. In other words, temperament might be linked to adjustment through one of the indirect processes listed in Table 3.4. These include mediator models, as when a child's negative temperament influences negative parenting, which, in turn, plays the dominant role in producing the child's aggressive behavior problems, or moderator models, as when a child's negative temperament has one implication for development of adjustment in the context of negative parenting and another in the context of positive parenting. We next consider such processes, most sharply focusing on temperament  $\times$  environment moderator models.

### Moderated Linkage

Rothbart and Bates (1998) discussed two possible indirect processes by which temperament and adjustment could be related. The first was mediated linkage in which temperament influences transactions with the environment, which, in turn, shape the child's developing adjustment. For example, a child's negative emotional reactivity might evoke hostile responses from caregivers, which build habitual frustration and hostility in the child. Research showing such temperament-parenting-adjustment processes was generally lacking at the time the 1998 chapter was prepared, especially longitudinal research, and relatively few studies have explored this kind of process in the intervening years. There have been some careful evaluations of mediation between one temperament trait and another temperament trait in accounting for adjustment, such as the structural modeling work of Eisenberg and her colleagues (Eisenberg et al., 2000; Eisenberg, Guthrie, et al., 2000). However, space does not permit review of this work.

The second indirect process we considered was moderated linkage in which we are primarily interested in how temperament and a feature of the environment might interact in the development of adjustment. For example, a child with high temperamental negative emotionality exposed to stress might be more likely to develop behavior problems than a less reactive child. In 1998, there were more relevant studies on moderated than mediated linkage, and, subsequently, there has been a striking growth in studies of moderated linkage. This direction in research is especially exciting because developmental theory discussed in the early sections of this chapter has emphasized the likelihood of temperament-environment interaction. Although these connections have been posited for decades, they are just now beginning to take empirical shape.

Rothbart and Bates (1998) identified three subtopics of moderated linkage: temperament  $\times$  environment interactions, temperament  $\times$  temperament interactions, and temperament  $\times$  gender interactions. In recent years, the greatest empirical growth has occurred in the first of these, temperament  $\times$  environment interaction. Temperament  $\times$  temperament interaction findings are more slowly growing, and would be worth review if space were available. Most notably, Eisenberg's research team and others have shown that relations between effortful control and externalizing and prosocial behavior are stronger for children high in negative emotionality than for children low in negative emotionality (Belsky, Friedman, & Hsieh, 2001; Diener & Kim, 2004; Eisenberg, Fabes, et al., 2000; Eisenberg, Guthrie et al., 2000; Stifter, Spinrad, & Braungart-Rieker, 1999).

Temperament  $\times$  gender interactions were somewhat numerous as of the time of the Rothbart and Bates (1998) chapter and have continued to accumulate at a moderate pace. However, our previous impression of a nonsystematic pattern of temperament  $\times$  gender findings appears to still hold. So, to allow more space for discussing the more dynamic temperament  $\times$  environment interaction literature, we leave the temperament  $\times$  gender findings for another review. In the following, we review recent temperament  $\times$  environment interaction findings extensively. In addition to Rothbart and Bates (1998), consider other reviews by Bates and McFadyen-Ketchum (2001); Gallagher (2002); Putnam, Sanson, and Rothbart (2002); and Sanson et al. (2004). Wills, Sandy, Yaeger, and Shinar (2001) have also reviewed a substantial portion of the literature in connection with an empirical report.

Researchers sometimes focus on how a temperament trait's association with adjustment is moderated by an environmental characteristic, as in parental hostility moderating the relation between child negative emotionality and adjustment. They also focus on how an environmental feature is moderated by the child's temperament, as in self-regulation tendencies moderating the adjustment implications of family stress. Choice between perspectives reflects the basic interests of the researchers, but an interaction from one perspective could often have also been described from the other perspective, although the results may not always be identical.

A bigger methodological challenge, however, is simply to find the interaction effect. Nonexperimental studies typically have to deal with correlated predictor and moderator variables, problems in the joint distributions of the variables, and insufficient statistical power for detecting effects (McClelland & Judd, 1993; Stoolmiller, 2001; Wachs & Plomin, 1991). Sometimes, interaction effects may be present but not found by statistical tests or statistically significant effects may be sample-specific or spurious. For these reasons, we focus especially on effects that have been replicated in some fashion. Because research in our area so seldom exactly repeats the methods of even the most fundamental studies, it is too much to require full replication. However, the literature is beginning to show some interesting patterns.

We also describe a few failures to find interaction effects, especially when they might constitute nonreplications of a previously found pattern. Given the assumed statistical bias against finding possible interaction effects, we focus mostly on positive findings. Many, but not all, consider the interaction of temperament and environment in the context of the main effects, and not all control for these effects by entering an interaction term in a multiple regression equation following entry of the main effects terms. We concentrate more on the substantive patterns of results than on methodological features (see Bates & McFadyen-Ketchum, 2001, for more discussion of methods).

Most of the emerging literature concerns three kinds of temperament trait: Those related to (a) lack of self-regulation, including low effortful control, unmanageability, and resistance to control, and probably related to the Big Five personality dimensions of agreeableness and conscientiousness; (b) negative emotional reactivity, sometimes called difficult temperament; and (c) novelty distress, fear, or unadaptability. Depending on how they are assessed, these constructs often partially

overlap with one another, but for conceptual purposes, they are separated here. As developmental scientists, we are especially drawn to studies showing temperament  $\times$  environment interaction effects in longitudinal studies of development of adjustment, but some useful cross-sectional findings have also emerged.

### Self-Regulation $\times$ Environment

Temperamental tendencies toward dysregulation, such as impulsivity or resistance to control, may be rooted not only in underdeveloped effortful control systems, but also in the behavioral approach system, or surgency, as we have previously discussed. Such tendencies have shown direct associations with adjustment, especially with externalizing problems, as also discussed. At least twenty recent studies show traits in this broad domain interacting with characteristics of the rearing environment in the development of adjustment, and most of these consider the effects of temperament and parenting.

One theme emerging across studies is that dysregulation traits are more highly associated with problem behavior when parenting is negative or harsh rather than gentle. Calkins (2002) found that 18-month-old children high on distress and resistance in frustrating situations were likely to be high on angry and aggressive behavior in similar situations at 24 months when their mothers were low in positive parenting, but not when their mothers were highly positive. Rubin, Burgess, Dwyer, and Hastings (2003) measured children's self-regulation in laboratory tasks at age 2 and mother reports on the TBAQ at age 2. They also measured intrusive and hostile mothering in a snack situation and by mother report. Poor child self-regulation predicted mother-reported externalizing behavior problems at age 4 to a greater extent for children who at age 2 received higher levels of intrusive and hostile mothering. This pattern was found cross-sectionally at age 2 in the same study, but only for boys (Rubin, Hastings, Chen, Stewart, & McNichol, 1998).

Other cross-sectional examples of the pattern include the finding that positive parenting as measured by interview and incidental observations mattered more for temperamentally unmanageable children's preschool adjustment than for less resistant children (Bates, Viken, & Williams, 2003). Morris et al. (2002) found that children rated by their mothers as low in effortful control (CBQ) showed an especially strong relationship between mother hostility (child report) and

teacher-reported externalizing behavior, whereas Patterson and Sanson (1999) reported that mother-rated temperamental inflexibility (negative emotionality and resistance to demands) was more strongly associated with mother-reported externalizing problems when the mothers described themselves as relatively high in harsh punishment.

The general pattern also extends to a prosocial behavior—expression of sympathy. Valiente et al. (2004) found that parents' expressivity of negative emotion (self-rated and observed) was associated with children's self-reported sympathetic responses, but only when the child was high in effortful control (parent and teacher ratings on the CBQ and observation). This was true for self-rated general dispositions and personal distress responses to an empathy-inducing film, but not for sympathy responses to the film. In a sample of children who had experienced divorce, inconsistent maternal discipline (mother and child report) was more strongly associated with both depression and conduct problems in children who had impulsive temperaments (mother and child report on the CBQ) than for those who were not impulsive (Lengua et al., 2000). Finally, elementary school children's self-described externalizing behavior problems were more strongly associated with angry discipline by both mothers and fathers, when the children described themselves as low rather than high in agreeableness (Prinz et al., 2003). This pattern was essentially replicated by Van Leeuwen, Mervielde, Braet, and Bosmans (2004) using parent ratings of child personality and adjustment and both parent and child descriptions of parenting.

A second theme that has emerged in the literature is supported by fewer studies, but it raises an important possibility—that disciplinary responses by parents can have positive rather than adverse implications for children with temperamental or personality tendencies toward dysregulation. Stice and Gonzales (1998) found that adolescents' ratings of parental control and support were positively correlated and that, for highly impulsive youths, high levels of parental control and support were more associated with low levels of adolescent antisocial behavior than for nonimpulsive youths. Even more clearly showing that control can be especially effective for dysregulated children, Stoolmiller (2001) found that boys who were highly unmanageable (disposed to have tantrums) in their early years showed a stronger relationship between maternal unskilled discipline and increasing externalizing problems (as rated by teachers

from elementary school to middle school) than boys who were low or medium in their unmanageability.

Bates et al. (1998) found, in two separate studies with community samples, that early childhood temperamental resistance to control (mother report on the ICQ) better predicted externalizing behavior problems in middle childhood (mother and teacher reports) for children who received low levels of parental control (observed in the home) than for children receiving high levels of control. Parental control was measured as reactions to misbehavior, and these reactions were sometimes but not always negative, for example, scolding. The researchers almost never saw harsh discipline such as spanking. Although hostile parenting and lack of warmth might well make it more likely that children's dysregulated temperament traits will become acting-out behavior problems, the findings of Stice and Gonzales (1998) and Bates et al. (1998) suggest that parental control might also serve to lessen the likelihood that dysregulated temperament will lead to problem behavior if unmanageability is overcome by high levels of parental management effort. However, high levels of parental control may not be ideal for all children: Bates et al. (1998) also noted that high levels of maternal control with highly manageable children sometimes resulted in higher levels of externalizing behavior than would have been predicted by temperament alone, with the possibility that the mothers' control somehow prevented the development of truly internalized self-control.

A third theme concerns a somewhat different trait, not discussed in the main temperament literature, the core psychopathy trait, *callous-unemotional*, which involves tendencies to be nonempathic, manipulative, and lacking anxiety and guilt. This pattern seems likely to be a form of temperamental dysregulation, even though its regulatory core appears to concern low prosocial orientation more than reward-sensitive impulsivity or low effortful control. It may also be related to very low levels of fear, but this does not seem likely to be the dominant component. Wooten, Frick, Shelton, and Silverthorn (1997) found in a combined clinical and normal sample that when children were described by parents and teachers as low on the callous-unemotional scale, less positive parenting, as described by parent and child, was associated with greater conduct problems as measured by parent and teacher report. When high on the callous-unemotional scale, however, children were high on conduct problems whether the par-

enting was positive or not. This pattern was replicated, in essence, by B. O'Connor and Dvorak (2001) in a community sample, and by Oxford, Cavell, and Hughes (2003) in a sample more similar to that of Wooten et al. (1997).

The findings of regulatory temperament  $\times$  parenting interactions are interesting, and it is encouraging that some common patterns of findings have been found that can be interpreted as reflecting differential effects of parenting on children with different temperaments. However, especially when interaction effects are not found, the studies cannot provide sufficient evidence on developmental process. The parent and child are also genetically related, and interaction effects might be confounded or obscured by gene-environment correlation. This makes it valuable to have relevant findings from studies considering variables other than standard temperament/personality, behavioral adjustment, and parenting. One example is the Hart, Atkins, and Fegley (2003) study, which shows, among other things, that Head Start experience was especially beneficial in developing academic skills for children with resilient (well-regulated) personalities living in highly stressful family environments. Bates et al. (2003) found that disrupted sleep schedules (mother daily report) and lack of positive parenting (mother interview) had stronger paths to children's maladjustment in preschool (teacher reports) for children who were high in resistance to control (mother report on the ICQ).

Lengua and Long (2002) reported that children in a community sample showed a stronger association between family stress and internalizing behavior problems when the children were low in self-regulation (on the CBQ and Early Adolescent Temperament Questionnaire [EATQ]), all measures based on child and mother reports. Fabes et al. (1999) found that preschool children whose teachers rated them high in effortful control (CBQ) had an adaptive advantage compared to less self-regulated children, with lower levels of negative emotion and higher competence in peer interactions, but only in high intensity interactions (vigorous, highly emotional games). Effortful control did not make much difference when the peer interaction events were of lower intensity. Finally, Goodnight, Bates, Newman, Dodge, and Pettit (2004) found that teens, especially boys, with impulsive tendencies in a laboratory card-playing task, showed a stronger linkage between having antisocial friends (teen and parent report) and increases in their own externaliz-

ing behavior problems (teen and parent report) than did teens with nonimpulsive tendencies.

Considering studies with nonstandard measures of temperament-related traits, El-Sheikh et al. (2001) found that high vagal tone (a measure of self-regulation via the parasympathetic nervous system, described earlier) reduced the risks of externalizing and internalizing behavior and health problems for children exposed to frequent marital quarrels. Although not showing an interaction as such, Donzella et al. (2000) put preschool children in a competitive game and found that those who showed a cortisol increase, as opposed to those who did not, were described by teachers on the CBQ as high in surgency and low in effortful control. Booth, Johnson, Granger, Crouter, and McHale (2003) measured testosterone, which could indicate temperament-like dispositions toward surgency, in children and adolescents. Testosterone levels were not directly related to adjustment, but when quality of mother-child and father-child relationship (parent- and child-rated) was low, higher levels of testosterone were associated with higher levels of conduct problems and lower levels of depression. These relationships were lower and opposite in direction when relationship quality was high.

Finally, we consider a study that measured particular genes with relevance to individual differences. The Dunedin study of a birth cohort in New Zealand (Caspi et al., 2002) showed that boys (and in supplemental analyses, girls) who had a less active allele for MAOA (a gene on the X chromosome coding for an enzyme that metabolizes neurotransmitters such as dopamine and influences aggressive behavior) showed a stronger relationship between the experience of adverse experiences in the family (harsh and indifferent parenting, loss of primary caregiver, and retrospectively reported abuse) and later antisocial behavior. The study (Caspi, Sugden, et al., 2003) also showed that those with two copies of the short allele of the 5-HTT gene (a gene that influences the efficiency of serotonin functioning in response to stress and consequently anxiety responses) had a stronger relationship between the number of stressful life events they had experienced from age 21 to 26 years and their level of depression than those with a short and a long or two copies of the long allele of the gene. Both of these genes can be seen as affecting emotional and behavioral self-regulation traits of individuals, and both showed interactions with stressful experience in predicting adjustment outcomes.

### Summary

In summary, research has begun to demonstrate that child characteristics related to the temperament domain of dysregulation interact with a range of environmental qualities in the development of competencies and problems. In general, negative experiences and the absence of positive experiences appear to have less adverse effects on the development of children with stronger self-regulatory tendencies, and greater effects on the development of children with weaker self-regulation. Ten years ago, this pattern was essentially undiscovered. Now, after an inspiring flurry of scientific activity, we can begin to envision research on the actual developmental processes by which temperament and environment moderate one another's effects on child adjustment. What are the limits of the phenomena? More precisely, which environmental factors interact with which particular child characteristics? What are the developmental processes by which these effects are found? What are the psychological products of the temperament and environment? In the next subsections, we review comparable literatures on interactions involving negative emotional reactivity and novelty distress traits, and features of the environment.

### Negative Emotionality $\times$ Environment

Negative emotionality traits, which tend to predict both internalizing and externalizing adjustment outcomes, also interact with environment characteristics in shaping the development of children's adjustment. To an even greater extent than the preceding section, this section is not conceptually pure: Temperament measures classified as negative emotionality often include other temperament constructs that might better be treated separately. For example, sometimes a negative emotionality measure may reflect not only the general negative reactivity but also the correlated, yet conceptually separable, discomfort in a novel situation. Or a measure might combine negative emotionality and poor self-regulation. Nevertheless, for the sake of simpler organization, studies with such measures are placed here.

The majority of studies in this section concern negative emotionality in interaction with measures of parenting, consistent with the strong emphasis on parenting in the social development literature. Belsky, Hsieh, and Crnic (1998) found that intrusive and negatively affective parenting during toddlerhood was more predictive

of externalizing behavior at age 3 for boys who as infants were high rather than low in negative emotionality (parent IBQ ratings and lab observation of both frustration and fear). The Belsky et al. (1998) study also provides an important illustration of the fact that although externalizing problems are often found to be substantially correlated with internalizing problems in children, the two kinds of problems may have different antecedents (Bates, 1989a). Belsky et al. (1998) found that temperamentally negative infants who received more negative and less positive fathering were *less* inhibited in the laboratory at 3 years, whereas the relation between fathering and inhibition was nonsignificant for infants low in negative emotionality.

The Belsky et al. (1998) finding resembles a finding of Arcus (2001) in which infants observed in the laboratory to be high in negative reactivity were less likely to show behavioral inhibition in the laboratory at 14 months if their mothers were observed to be high in limit setting. Arcus also found that negatively reactive infants with boisterous and annoying siblings were less likely to show behavioral inhibition than those experiencing less intrusive behavior from siblings, even beyond the effect of maternal limit setting. Arcus suggests that mild frustrations and challenges, such as those from firm mothers and intrusive siblings, may promote reactive infants' self-regulatory abilities better than a highly accommodating environment.

In contrast, a study by Pauli-Pott, Mertesacker, and Beckman (2004) appears to find, at least partially, the opposite of the Arcus pattern: Maternal insensitivity at 4 months predicted infant stranger distress at 12 months more strongly for infants who had been high rather than low in negative emotionality in the lab at 4 months. The discrepancy could be due to many different aspects of sample and procedure, but the difference may be related to: (a) slight but potentially important developments taking place between 12 and 14 months, (b) differences in the meaning of an assessment battery confronting the child with a wide variety of novel objects versus one centered on only a strange person, or less likely (c) subtle cultural differences between the United States and Germany. Paralleling the Pauli-Pott et al. (2004) findings, although with more of an externalizing outcome, Feldman, Greenbaum, and Yirmiya (1999) found that mother-infant affect synchrony in play during the first year, likely related to maternal sensitivity, was more predictive of toddlers' self-control (compliance with do and don't commands) observed at age 2 years when the

infants had been high rather than low on negative emotionality (mother ICQ and lab observations).

Related patterns have also been found with older children. Morris et al. (2002) reported that mothers' overt hostility (child-rated) showed stronger associations with teacher reports of externalizing behavior problems for children temperamentally high in anger to frustration (mother CBQ) than for less irritable children. More irritable children also showed a stronger relation between child-rated maternal covert hostility and intrusive control of the child's feelings and teacher reports of children's internalizing. In a similar effect, high levels of mother-reported family conflict were associated with high levels of teacher-reported externalizing and internalizing problems, but only for children rated by teachers on the Keogh Teacher Temperament Questionnaire as high on a composite of negative emotionality and dysregulation (Tschann, Kaiser, Chesney, Alkon, & Boyce, 1996). Also showing how difficult temperament might change the implications of stressful environments are findings of Kilmer, Cowan, and Wyman (2001).

Further supporting the general trend of negativity  $\times$  family environment effects, Gilliom, Shaw, Beck, Schonberg, and Lukon (2002) reported that toddlers' negative emotionality (ICQ difficulty) was more predictive of relatively ineffective self-regulation in a gift-delay task 2 years later when their mothers had been observed to be high in negative control and low in warmth than when the mothers had been low in negative control and high in warmth. Hemphill and Sanson (2001), in a preliminary report, described a related effect. Lengua et al. (2000) did not find an interaction between negative emotionality (mother and child reports on the EAS) and parenting. They did, however, find that low positive emotionality (mother and child reports on the DOTS) was associated with stronger relations between maternal rejection (ratings by mother and child) and child externalizing behavior and depression (mother and child ratings). The latter finding is described here because it is one of very few interactions reported between positive emotionality and environment in relation to child adjustment.

Returning to interactions involving negative emotionality, if one assumes that a mother's negative emotionality is genetically transmitted to her child, the findings of T. O'Connor, Caspi, DeFries, and Plomin (2003) confirm the general finding that negative emotionality predisposes a child to be more susceptible to negative rearing conditions. O'Connor et al. found that

adopted children's biological mothers' negative emotionality (EAS) predicted the children's behavior problems at age 12, but only if the children's adoptive parents had separated. This effect was statistically significant for parent reports of externalizing and internalizing problems, in the same direction but not significant for teacher reported problems, and significant for observer ratings of low social responsibility. In a different adoption study, Stams, Juffer, and van Ijzendoorn (2002) found that adopted children with the combination of disorganized attachment and challenging temperament (composite of all ICQ factors) in the early years showed lower levels of cognitive development and less optimal ego control at age 7 than those with none or only one of these risk factors. Stams et al. (2002) interpreted the disorganized attachment as reflecting a less optimal relationship with the mother, and this is plausible. However, the meaning of the disorganized attachment construct is not well developed (Thompson, 1998). In addition to stressful or abusive rearing conditions (Thompson, 1998), it has sometimes also been interpreted as due to infants' neural development having been compromised (Green & Goldwyn, 2002). Therefore, the temperament  $\times$  environment interpretation in this instance needs to be provisional.

Adjustment is typically measured at a point in time, but increasingly as trajectories across time. Owens and Shaw (2003) provide a rare example of an interaction between child temperament and rearing environment in forecasting change in adjustment. They showed that the expected decline in externalizing behavior across age 2 to age 6 (e.g., Keiley, Bates, Dodge, & Pettit, 2000) was slower for children who had been observed at 18 months to be high on negative emotionality and who had mothers with high levels of depression, than for children with depressed mothers but lower levels of negative emotionality. This is consistent with the general trend emerging in the literature for negative emotionality to amplify environmental risk factors for behavior problem development. However, to enrich the picture, Owens and Shaw (2003) also found that with mothers who had been low in depression across early childhood, children observed to be highly negative at 18 months showed a slightly steeper decline in externalizing behavior problems than low negative children. At age 2, the high negative children with nondepressed mothers had about 20% more symptoms than low negative emotionality children with nondepressed mothers, but by age 6, they were practically as low in symptoms as the low negative children.

Wills et al. (2001) provide another example of temperament-environment interaction forecasting growth in problem behavior. Because of the nature of the temperament composites, this study could also have been reviewed in the self-regulation  $\times$  environment section. In a large sample of youths followed from age 11 to 13, Wills et al. (2001) found a pattern in which negative temperament (negative emotionality plus high activity level) amplified relations between parenting risk factors, such as parent-child conflict and parent tobacco and alcohol use, and both intercept level and slope of youths' substance use. The reverse applied to positive temperament (positive emotionality with task orientation): High positive temperament reduced the relations between parenting risk factors and the intercept and slope of youths' substance use. These findings obtained for both self- and teacher-report measures of temperament. The findings are comparable to those of Mun et al. (2001), who found stronger links between some preschool-age temperament variables (parent report on the DOTS) and parent reports of middle childhood behavior problems when the parents were high in alcohol and antisocial behavior problems than when they reported low levels of these problems. Although activity level and distractibility showed this moderator effect, emotional reactivity and unadaptability did not.

Finally, we consider two studies using biological measures and interactions between temperament-like characteristics and nonfamily environmental factors. Dettling et al. (2000) asked how diurnal patterns of cortisol in response to the stresses of day care were affected by temperament. When at home, children's cortisol levels peak in the early morning and decline over the day, but children in day care often show increases from morning to afternoon. Dettling et al. (2000) found that day-care children higher on a composite parent- and day-care teacher-report (CBQ) measure of negative affectivity and low effortful control showed a greater increase in afternoon cortisol than those lower on this temperament composite, even after controlling for quality of day care the children received. Finally, a study by Quas, Bauer, and Boyce (2004) concerned psychophysiological reactivity measured in the laboratory in 4- to 6-year-olds, which we interpret as a temperament index. The environmental variable was whether an interviewer took a supportive or nonsupportive approach to the child, and the "adjustment" variable was the child's performance in recalling episodes that occurred in the lab. Quas et al. (2004) found that children high on autonomic reactivity gave more correct answers in the

memory task when the interviewer was supportive than when she was unsupportive. For low-reactive children, however, interviewer supportiveness did not make a difference in recall, although the low-reactive children did offer more "don't know" answers to a supportive than to an unsupportive interviewer.

### Summary

In summary, although explicit replications are largely lacking and even approximate replications are sometimes not found, there appear to be some general patterns in the findings reviewed. First, negative emotionality traits tend to foreshadow externalizing behavior problems, but to be more strongly linked to externalizing behavior problems in the presence of adverse rearing environments. Conversely, environmental adversities tend to predict child behavior problems more strongly in the presence of negative child temperament. Perhaps we can adapt coercion training theory (Patterson, Reid, & Dishion, 1992) to envision a "Velcro" process by which this interaction effect operates so that negatively emotional children tend to acquire coercive tendencies more easily than less irritable children because they have the relevant "hooks." These coercive tendencies are especially established when there are environmental triggers and responses to this irritability, such as a hostile parent. And these behavioral and emotional habits become dysfunctionally habitual and generalized.

This complements an older, fairly well-established pattern of findings (Bates, 1989a), showing that more difficult infants develop less well cognitively in noisy homes than do easy infants (e.g., Wachs, 1987). However, in the latter findings, strong emotional responses may impair the child's ability to extract meaningful information in a confusing environment rather than to selectively respond to and elicit negativity from the social environment. Second, negative emotionality often foreshadows internalizing problems, but environmental adversities may play a different role here, with moderately challenging, directive and unsupportive behavior reducing the chances of development of anxious behavior patterns. Arcus's (2001) suggested process makes sense here, with moderate challenge forcing an otherwise withdrawing child to develop more adaptive regulatory abilities.

As in the self-regulation  $\times$  environment area, empirical progress in describing negative emotionality  $\times$  environment moderator effects has been striking. However, much work remains to be done. More consistent and precise operational definitions of negative emotionality will

be important in clarifying which aspects of temperament are interacting with the environment. As always, definition of the crucial aspects of the environment would help as well (Wachs, 2000). As patterns of interaction become more firmly established, it will also be important to identify the developmental processes by which an interaction effect is mediated. Finally, although not all articles mentioning the search for interactions found them, and not all of those reported follow the same pattern, consistent-enough patterns of moderator effects have been reported in recent years that it seems unlikely that "file drawer" nonreplications will swamp the published effects. Nevertheless, it might also be helpful if researchers were to reserve a portion of their work for explicit attempts to replicate intriguing interaction effects, and if journals reserved space for notes on the success or failure of these attempts. It will be theoretically valuable to identify not only consistently found moderator effects, but also those that are consistently *not* found, despite methodologically plausible attempts.

### **Fearfulness $\times$ Environment**

Our final section on temperament  $\times$  environment interaction concerns temperamental fearfulness. Temperament constructs in this domain describe distress and withdrawal or slow adaptation to novel or potentially harmful situations. Theoretically, as discussed earlier, they are rooted in individual variations in brain circuits, especially those comprising the fear system. Empirically, there is evidence that highly inhibited, fearful, unadaptable young children are sometimes at greater risk of developing anxiety problems, and that unusually fearless young children are at greater risk of developing conduct problems, as discussed. In studies of the interaction of fearful temperament and environment, the temperament measures have been more typically pure representatives of the focal concept than in the other kinds of temperament-environment interaction we have reviewed. However, even here there remain some methodological uncertainties. For example, measures of low levels of behavioral inhibition could reflect not only the primary construct, lack of fear, but also high approach or low levels of self-regulation. Fearful temperament was the topic for which there was the most compelling evidence for a temperament-parenting interaction in the development of children's adjustment at the time of Rothbart and Bates (1998) original review. In sheer numbers of relevant studies, this literature has not grown as fast in the intervening

years as the other two topics we have reviewed. However, there has been progress.

Kochanska (1991) showed that highly fearful 8- to 10-year-old children showed more signs of conscience when their mothers used gentle rather than harsh control, whereas the gentleness of maternal control did not make a difference for the relatively fearless children. This finding was consistent with a theoretically based assumption that highly anxious children are susceptible to overarousal, impeding their cognitive processing and internalizing of rules in harsh discipline encounters, whereas fearless children are not as susceptible to overarousal. More recently, this finding has been supported with a slightly older sample of boys, by Colder, Lochman, and Wells (1997). Temperamentally fearful children whose parents used harsh discipline showed more teacher-rated aggression than either low-fear children with harsh parents or high-fear children with gentle parents.

Kochanska (1995) replicated and extended this finding in a study of younger children. She reported that gentle discipline mattered more in the self-control of children above the median on novelty fear than for the children below the median on fear. Moreover, and very importantly, she also reported that a positive mother-child relationship, indexed by the attachment Q-sort, mattered more in the self-control of relatively fearless children than for the relatively fearful ones. The latter finding was predicted by a model assuming that fearless children could be more easily motivated to acquire social rules by positive and enjoyable aspects of the parent-child relationship. Kochanska (1997) also extended the pattern of findings by following the toddlers in her 1995 study at two further time points. Temperamental fearfulness was still measured at Time 1 (average age 33 months) by a composite of mother reports on the CBQ and observations in standard laboratory challenge situations, and maternal discipline was measured by observations in toy clean-up situations at home and in the lab. At Time 2 (average age 46 months), Kochanska (1997) found that relatively fearful children's conscience (resistance to temptation to cheat in a game and responses to hypothetical moral dilemmas) was more advanced if their mothers had been gentle in their control rather than harsh.

Relatively fearless children's conscience was not dependent on gentle versus harsh discipline, but instead was predicted by how securely attached they had been. At Time 3 (age 60 months), however, Time 1 gentle control did not matter for the conscience of fearful children,

and Time 1 attachment security did not matter for the fearless children, although Time 1 maternal responsiveness, which is conceptually and empirically related to attachment security, did predict conscience at Time 3 for fearless children. Interestingly, Fowles and Kochanska (2000) found, in the same sample, that when fearfulness was defined by electrodermal reactivity, the pattern of findings was fairly similar to those based on the behavioral definition of temperament, even though there was little convergence between the two measures.

Independent replications of the Kochanska temperament  $\times$  parenting interaction effects in predicting indexes of moral development were attempted by van der Mark, Bakermans-Kranenburg, and van Ijzendoorn (2002) and van der Mark, van Ijzendoorn, and Bakermans-Kranenburg (2002) in a study of girls at 16 and 22 months. Fearfulness was assessed in the laboratory and committed compliance and empathy responses were the measures of moral development. However, van der Mark et al. did not find temperament-parenting interaction effects. These nonreplications may have been due to the very young age of the children in the study, to the fact that the sample was restricted to girls and relatively high in socioeconomic status, or to a variety of other method differences. Although not explicitly attempting to replicate the Kochanska (1997) pattern, findings in a preliminary report by Hemphill and Sanson (2001) could be interpreted as showing that highly punitive parenting appeared to amplify a small group of uninhibited children's risk for externalizing problems, in potential contrast with Kochanska's (1997) finding that harsh control was not predictive of conscience development for uninhibited children. Maternal punitiveness at age 2 was not different for the groups of children moderate or high on inhibition and with or without behavior problems.

The accumulating literature provides both replications and nonreplications of the rich fear  $\times$  parenting pattern. The meaning of the nonreplications is not established, because key methodological issues are not resolved. On balance, the fear  $\times$  parenting effect is well replicated for such a complex pattern, and it is potentially of considerable theoretical importance. However, further replications, using a variety of methods, will be needed for the pattern to become a solidly established developmental phenomenon. And, despite the exceptionally well-developed theoretical background for the pattern, studies will also be needed to identify the processes mediating the observed interaction effect.

Next, we ask how fearful temperament interacts with rearing environment in the prediction of more standard behavior problem symptoms. First, considering possible moderator processes in development of internalizing behavior, Tschann et al. (1996) found that preschool children relatively low on approach, as rated by their teachers on Keogh's questionnaire, were more likely to be observed as socially withdrawn when their mothers described low levels of family conflict than when their mothers described high levels of family conflict. High-approach children, alternatively, showed the lowest levels of social withdrawal when their families were low in conflict. This is conceptually similar to the effect previously discussed, where negative emotionality predicted behavioral inhibition less when parents were more rather than less directive or challenging, although the effect is concurrent rather than longitudinal, as in the Arcus (2001) and Park, Belsky, Putnam, and Crnic (1997) studies. Bates (2003) presented preliminary analyses from two longitudinal studies that partly converge with this effect: Mother-rated temperamental unadaptability (ICQ) in early childhood predicted mother-rated internalizing problems across middle childhood more strongly in families where the mothers had been observed to be low in control than where they had been observed to be more highly directive and restrictive.

In partial contrast, however, a rather different kind of temperament  $\times$  parenting interaction was found by Rubin, Burgess, and Hastings (2002). Rubin et al. found that inhibited tendencies with a peer observed at age 2 predicted social reticence with unfamiliar peers at age 4, but only for children whose mothers were observed at age 2 to be high in psychological control—derisive or intrusive with affection or help on a task. Inhibition at age 2 was not predictive of social inhibition at age 4 for children who received less psychological control from their mothers. A possible key to reconciling the earlier studies is to note that Rubin et al. (2002) may have captured dimensions of parenting that either underchallenged or overchallenged children with fearful temperament, whereas the Arcus (2001) and Park et al. (1997; or Belsky et al., 1998) and Bates (2003) studies may have measured parenting dimensions more consistent with Arcus's (2001) model of optimal challenge accelerating self-regulation of anxiety responses. This interpretation is consistent with the more clinical insights of Chess and Thomas (1984), who observed in their longitudinal study that withdrawing children developed best when parents provided repeated and firm, but not overwhelming,

ing, challenges to their children to deal with novel situations, with overprotectiveness not as beneficial.

Finally, Eaves et al. (2003) offer an interesting perspective on the question of how gene-environment interaction and gene-environment correlation can be simultaneously modeled in a twin study. This is of importance to the study of temperament  $\times$  environment interactions because we assume that some portion of temperament is based on the genome. One important window on processes where genes and temperament-relevant expressions of genes influence psychological outcomes is gene-environment interaction. These interactions have become of great interest in developmental psychopathology recently, as evidenced by the frequent mention of the findings by Caspi et al. (2002; Caspi, Sugden, et al., 2003) described previously. Children of contrasting genotype might be differently affected by a similar environment.

However, equally important for understanding developmental process is the phenomenon of gene-environment correlation. A child with a given genotype might be exposed to a particular environment associated with the development of behavior problems because close relatives share the same genotype, or a child's genotype might lead to temperament traits that elicit environmental responses that, in turn, promote the development of behavior problems. Interpreting gene-environment interaction effects in human studies is often difficult because it is difficult to assume that the environment dimension is not at the same time also a function of the genotype. In the past, this issue was dealt with by only evaluating gene-environment interaction effects where it could be demonstrated that there was no correlation between environment and gene (e.g., Caspi et al., 2002). Eaves et al. (2003), however, developed a Bayesian approach to simultaneously model gene main effects, gene-environment interaction effects, and gene-environment correlation effects.

Using this approach in a longitudinal study of adolescent twin girls, Eaves et al. (2003) found that genes explained the development of depression in several paths. Some genes influenced depression specifically. Other genes affected anxiety early on, and then depression later, through three pathways: (1) a genetic main effect in which girls' early anxiety increased their risk of later anxiety, (2) a gene-environment correlation in which girls at high risk for anxiety were especially likely to be exposed to depressogenic life events, and (3) a gene-environment interaction in which girls with this higher

genetic risk of anxiety and exposure to stressful events are more sensitive to the depressogenic life events. This study is only indirectly relevant to temperament per se, but it is exciting to consider how studies with early measures of temperament and environment in a genetically informative sample might help advance our understanding of the processes involved in the development of children's adjustment.

### *Summary and Future Directions*

To conclude this section, it is greatly encouraging to have seen such a rapid accumulation of temperament-environment interaction findings. The field has gone from mostly thinking about complex processes in theoretical writings to vigorously instantiating such effects in empirical work. As we have shown, there are several patterns with some broadly converging support. As usual in our complex field, these replications are far from exact or widespread, but some patterns are beginning to stand out, and they are not always patterns that would have been intuitively expected. As mentioned previously, methodological and definitional issues are important in replication studies, and more attention needs to be allocated to such studies. In addition, much work remains in detailing the mediating processes by which temperament-environment interactions have their role in development.

It also may be valuable to more extensively explore interactions between multiple temperament variables and environmental variables simultaneously. As of about 10 years ago, the typical limit of complexity was to consider temperament and environment variables' main effects as linear, additive contributors to a developmental outcome. Currently, the typical limit considers main effects plus the interaction of one temperament variable and one environment variable as predictors of an outcome, or main effects plus the interaction of two temperament variables (e.g., negative emotionality  $\times$  effortful control) as predictors. However, for reasons suggested earlier, where the meaning of a given temperament variable in isolation is not always clear, it might be helpful to consider the effect of a profile of temperament variables as moderating or moderated by an environmental variable (see also Rothbart & Sheese, in press).

For example, fearful temperament might have different implications depending on both its temperament context, such as the tendency toward dysregulation, and its environmental context such as family stress. Not coincidentally, this example is a direction we have been

exploring (Bates, Sandy, Pettit, & Dodge, 2000), and we hope to have useful findings to offer in the next edition of this handbook. Similarly, profiles of environments, such as parental harsh discipline in the context of warm involvement versus minimal involvement, might also be important in understanding the interactions with temperament. However, in a chapter on temperament, we should not go further in thinking about this direction. Future progress on understanding the role of temperament will require both relatively mundane replications and new, more exciting, highly complex studies.

## CHAPTER CONCLUSIONS AND FUTURE DIRECTIONS

Over the past 2 decades, there has been considerable progress in identifying the broad outlines and the more specific dimensions of temperament in childhood. The general framework for temperament now constitutes a revision of the NYLS dimensions, and includes broad dimensions of Positive Affect and Approach, Negative Affectivity, including subconstructs of Irritability and Fear, Effortful Control, and possibly Affiliativeness or Social Orientation. These broad dimensions share similarities with four of the Big Five Factors of Personality (Extraversion, Neuroticism, Conscientiousness, and Agreeableness), and with all of the Big Three broad factors of personality (Extraversion, Neuroticism, and Conscientiousness), but they are by no means identical. Research establishing linkages between measures of these dimensions of early temperament and later personality has now begun to accumulate, and will continue to be one of the major continuing tasks for our area, as will further differentiating our temperament and personality measures.

### Differentiating Temperament Dimensions

In our previous review, we suggested the importance of differentiating between fearful and irritable distress, and in this review we note that both biological and clinical studies have benefited from this distinction. Findings on the psychobiology of temperament showing overlap between networks subserving defensive fear and defensive aggression may help to account for findings of general neurotic tendencies, and they may also suggest further means of differentiating reactive and instrumental aggression in relation to temperament.

Further evidence links anger and early surgency/extraversion to the development of externalizing problems and indicates that fear may be a protective factor against aggression and other externalizing problems as well as a contributor to the early development of conscience. A great deal of recent research has established connections between effortful control and the regulation of both affect and behavior. Future research will consider the limits of fearful and effortful control on adaptation, in connection with the Blocks' (1980) construct of overcontrol, and allow us to study the way in which effortful control may become part of a resilient approach to life's challenges.

Probably the most striking new findings in this review involve temperament  $\times$  environment interactions. In interaction studies, the child's effortful control, manageability, and agreeableness have been found to moderate the effects of adverse environments, and negative emotionality has been found to amplify the effects of adverse experience. Unexpectedly, we have found that more fearful or inhibited children appear to benefit from early challenge, at least in measures of the later strength of this system. However, fearful or inhibited preschoolers' conscience appears to develop better in the context of gentle socialization methods.

### Measures

Good measures of temperament are crucial to our theoretical understanding. Further advances in defining the structure of temperament and understanding the neural and developmental substrates of temperament will continue to rely on advances in measurement. As an additional goal of research, we advocate the further development of sound measures, using parent-report, naturalistic observation, and structured or laboratory observation measures to be used in converging and complementary ways. We have advocated an analog approach to questions of validation rather than a digital, yes-no approach to ascertaining the value of methods and measures. Aside from the important future work of comparing results of alternative methods, another important focus in research should be identification of *non*-relationships among constructs—tests for discriminant as well as convergent validity. Partly on the basis of differential, discriminating patterns of correlations between parent-reports of temperament and other measures, we are able to argue for the validity of parent-reports. The use of brain marker tasks in the study of development of executive attention and effortful control has made significant strides in the past 5 years. We en-

courage the continued use of marker tasks to link performance to the development of brain functioning.

## Development

As the dimensions of temperament have been further delineated and measures improved, real advances have occurred in our understanding of temperament-environment interactions. Future research is needed to examine the processes supporting these effects. There may be times when emotionality or effortful control systems are more sensitive to environmental conditions than others, or times when the child's irritable and frustrative distress might be most easily directed toward or away from coercive responses and tendencies to aggressive action. These are basic developmental questions with profound implications for our understanding of the nature of temperament and the development of personality.

Establishing closer links with our understanding of the developing neurophysiological substrate of temperament is a related task for our area. In this work, findings from each domain of study will illuminate the other. Thus, behavioral research on the developing structure of temperament helps to specify the operations necessary to link the psychology of temperament to its neurophysiology. Reviewers who relate parallel research carried out in these two domains will help in this work. The use of physiological assays, behavioral measures in research designs and the use of marker tasks will lead to further advances.

Finally, we have identified possible trajectories in the development of social and personality traits from early temperamental characteristics, most strongly in Kochanska's (1995) work on multiple routes to conscience. The task of identifying routes to other significant outcomes requires progress in all of the tasks described earlier, and it is of critical importance to our enterprise. The study of developmental trajectories requires establishing stronger links between our work and more environmentally oriented areas of our field such as social learning and social cognition research. As we have indicated, temperament constructs do not conflict with these areas of research: The temperament dimensions we have described are open to experience, although some systems are likely more open than others. In addition, the functioning of control systems will be highly dependent on what the culture indicates should be controlled. Prospects for effective longitudinal research will be much improved by an integration of the

study of individual differences, cross-cultural, social learning, and social cognition.

Developmental research in our area may also eventually answer questions like the following: To what degree is temperament plastic and susceptible to change? To what degree does experience alter only the *expression* of temperamental characteristics? If distress and maladaptive social cognitions can result from a painful life history, how much of early temperament may have been overlain by these negative experiences? Could the original core of temperament be uncovered by imaginative assays, intervention, further social experience, or even by further changes in social or physical development? We know someone who, through the aging process, lost many of her memories, including information that had troubled her over many years and led to major conflicts in herself and with others. What remained after her memory loss was a positive and expressive person, loved by all who met her. Was this the child she once was? If so, could other less serious interventions have uncovered it? Better yet, could developmental research inform both child rearing and children's prospects in society so that the accumulating pain might never have occurred? We have made much progress in our field in the past decades, but a number of questions remain. Many of these questions are hopeful about a future for us, our parents, and our children.

An unreserved acceptance of the idea that biological processes contribute to psychological phenomena has waxed and waned over time. Although attributing a feeling of fatigue to a bacterial infection is currently non-controversial, the suggestion that a dysphoric mood could be due, in part, to an inherited physiology encountered more resistance during the last century. One historical source of the skepticism was the decision by Greek philosophers two millennia ago to separate soul and body rather than to follow the classic Chinese

philosophers and assume that mental and bodily events are joined in as seamless a unity as color, shape, and motion in the conscious perception of a cloud at sunset.

The basis for denying biology a significant role in mood and behavior during the middle third of the twentieth century was the understandable desire, especially among Americans, to minimize biological variation among varied immigrant or ethnic groups. This ideology was in the service of defending the optimistic hope that proper family experience and education could create a

Institute, the COUQ Foundation, and past support from the William T. Grant and John D. and Catherine T. MacArthur Foundations. Nathan Fox thanks Peter Marshall, Louis Schmidt, and Heather Henderson, and acknowledges research support from NICHD in the form of Grant HD 17895.

community of citizens that possessed roughly equivalent ability, motivation, civility, and capacity for happiness (May, 1959).

Second, a broad conceptual moat must be jumped when the vocabularies of biology and psychology occur in the same sentence. No one has difficulty understanding “The boy ran away because he felt afraid” because everyone’s experience validates the association between a feeling of fear and the act of fleeing. But many find it more difficult to understand “The boy ran away because of a limbic discharge” because they have not consciously experienced that brain event, and, further, such a sentence occurs rarely in social discourse. Hence, both the sense and referential meanings of the second sentence are less clear and a causal association between flight and a limbic discharge seems less valid. Ease of assimilation is always easier when the statement contains ideas to which a listener is accustomed. Fifteenth-century Europeans would have experienced far less difficulty than modern ones in understanding, and accepting as true, the declaration: “The woman died because she was bewitched.”

A third obstacle to combining biological and psychological terms, which is related to the issue of different vocabularies, is inherent in all emergent phenomena; the tides offer an example. Most people who have had the relevant education believe that the changing height of the oceans during each day is due to changes in the gravitational relation between the moon and the earth, even though there is a bit of mystery surrounding the idea that the gravitational attraction between moon and earth affects the waterline at the beach. No feeling of mystery—or certainly much less—is engendered when the linked phenomena are at the same level of description, as in “The child cried after she fell,” because our phenomenology supplies the mediating feeling of pain or surprise that we know produces a cry. The contemporary public is ready to believe the recent, and surprising, declaration that a bacterium (*Helicobacter pylori*) can cause ulcers because it is easy to imagine how swarms of bacteria could devour the stomach’s delicate mucosal lining. An earlier generation was considerably more resistant to the psychosomatic hypothesis that conflict over dependency could produce ulcers because it was harder to imagine how an unconscious psychological state could be responsible for this materialistic condition.

When the mind must leap from gravitational force to tides or from psychological states to ulcers, and the intermediate events are not completely clear, people must rely on faith in authority to accept both statements as

true. When knowledge of the mediating event is incomplete, as it is for most propositions that relate brain physiology to psychology, considerable faith is required. The resulting feeling of disquiet mars the aesthetic feeling that is a distinguishing feature of a completely satisfying explanation.

That is why psychologists continue to disagree on the relative contributions of genetic programs and the epigenetic events following conception to the observed phenotype, even though both influences are always formative. A gardener who plants tomato seeds in the spring cannot know the exact size, coloring, or taste of the plant picked months later because of the unpredictability of temperature, rainfall, and pests. But she knows with certainty that the fruit picked in the fall will be a tomato and not an apple.

All psychological phenotypes are the products of cascades of events, many unpredictable, but the genome of the child constrains seriously the envelope of possible profiles that a particular child might display. It seems wise, therefore, to acknowledge, as the ancients did, that genes and experience act coordinately and cease quarreling over which force is stronger.

The emergent nature of psychological events from biology is analogous to the temperature and pressure of a closed container of gas. Pressure and temperature describe the emergent consequences of large numbers of molecular collisions and are inappropriate terms for a single molecule. The assumption that every psychological phenomenon can be explained by or derived from the activity of particular neuronal ensembles, as the temperature and pressure of a vessel of gas are explained by equations describing the collisions of large numbers of atoms, is flawed because the motion of each atom is assumed to be independent of the motion of every other atom. This assumption does not apply to brains for each neuron is influenced by the activity of others. Anxiety is a property of a person and not of the neurons that participate in that emotional state. Thus, the scholar who acknowledges that thought, feeling, and action depend on and emerge from brain events but who insists that these events must be described in a language different from the one that describes underlying brain processes is not a metaphysical dualist. All of nature cannot be described with one vocabulary because brains have qualitatively different structures than schemata and semantic networks.

This argument is not a rejection of attempts to understand the biological contributions to psychological processes. Even though complete translation of the lat-

ter events into the language of the former is probably impossible, research that looks for the biological correlates has advantages. First, the products of this work deepen our understanding of the molar events. The discovery that connections between temporal and frontal structures mature during the last half of the 1st year implies that there should be major improvements in working memory at this time, and that inference leads to a new conceptualization of the phenomenon Piaget called object permanence (Diamond, 1990).

A failure to find expected correspondences between brain and behavior often provides fruitful seeds for new ideas. The fact that lesions of the dorsolateral prefrontal cortex impair working memory, but do not impair the retrieval of motor habits invites a distinction among different kinds of memories. The fact that an intact amygdala is necessary for a rat to display a potentiated startle reflex to a loud sound presented after a conditioned stimulus, but is not necessary for the startle reflex invites a distinction between two types of startles. Thus, learning more about the relation of brain activity to psychological events contributes to theory, even though a complete translation of mind to brain is probably not possible.

One reason why the description of a profile of neuronal activation cannot be a substitute for psychological structure is that the context and the agent's past experience determine which particular neural patterns, and therefore which psychological structures will be activated. No sample of adults of the same age, sex, social class, and health, tested at the same time of day produces identical profiles of brain activity to a particular stimulus because each person brings a different history to the context of evaluation. Two groups of adults subject to similar torture provide a more complex example of this principle. One group comprised well-educated political activists, the second consisted of less well-educated, apolitical men. Although all prisoners experienced similar acts of torture, more of the apolitical men developed anxiety, depression, or posttraumatic stress disorder (Basoglu et al., 1997). The fact that fewer political activists developed these symptoms has to be due in part to their intellectual commitment to the causes that led to their incarceration. But the psychological state we call intellectual commitment to a cause cannot be translated into sentences whose words only describe brain processes.

A psychological representation of a class of events is a hypothetical network consisting of many interrelated features that can include representations from several

sensory modalities, motor programs, and language. The particular subset of features activated in a person at a particular time and place is not knowable until the incentive is specified. Further, different incentives will activate different parts of the large network. The features of the network for thunderstorms evoked in a person caught outside in a summer storm are different from those activated when the same person is in an office building or flying in an airplane as lightning is scarring the night sky. Thus, a summer storm can activate a large number of representations and no member of this family is knowable until the scientist intervenes with a probe to measure it. No member is more essential than any other, and none is active when the person is sipping coffee on a sunny June morning. This means that the neural pattern of activation in a person lying in a positron-emission tomography (PET) or functional magnetic resonance imaging (fMRI) scanner looking at pictures of snakes is not to be regarded as the true or only neural configuration that these stimuli would provoke. The same pictures would create a different brain state if the person were looking at them on a television screen in his living room. There is no master clock for the universe and there is no God's eye view of the brain's response to an incentive because each person has a particular frame of mind and brain state in each class of situation, and that frame affects which neuronal ensembles and representations will be activated. Put differently, a number of possible brain states are possible the moment a new event occurs. The context, the immediately prior state, and the person's temperament and past history combine to select one outcome from the set of candidates: That is the phenomenon scientists measure. Thus, probabilistic quantum principles operate the moment an event occurs; classical principles take over milliseconds later when one outcome has been chosen.

## BIOLOGY AND BRAIN MATURATION

Biological processes affect psychological growth in two obvious but very different ways. Initially, the lawful maturation of the nervous system is accompanied by universal changes in emotion, cognition, and behavior. For example, the 1st year consists of two important transitions. One occurs at 2 to 3 months, and the second at 7 to 12 months of age. The first transition is accompanied by disappearance of newborn reflexes, endogenous smiling, a decrease in crying, the appearance of circadian rhythm, and the enhancement of recognition memory.

The disappearance of the reflexes is believed to be due to cortical inhibition of brain stem neurons (Volpe, 1995). Although descending axons from the supplementary motor area reach the brain stem and spinal cord targets before birth, actual synaptic contacts do not appear until 2 to 3 months after birth (Kostovic, 1990).

The transition between 7 and 12 months is marked by the ability to activate a representation for a past event that is no longer present, hold that representation online, and relate it to features in the current situation in a hypothetical process that is called working memory. The enhancement in working memory is accompanied by a spurt of growth and differentiation in both pyramidal and inhibitory interneurons in the prefrontal cortex (Kostovic, 1990). Not surprisingly, this anatomical growth is accompanied by increased glucose uptake in the lateral frontal cortex and the dorsolateral prefrontal cortex (Chugani, 1994; Huttenlocher, 1979).

The 2nd year is characterized by the initial comprehension and expression of speech, the capacity to infer selected mental and feeling states in others, representations of actions that are prohibited, and the conscious awareness of some of the self's feelings and intentions. One basis for these changes is the growth that occurs in the neurons in layer three of the prefrontal cortex, which elongate and grow spines. Layer three represents the neurons that participate in the corpus callosum, which unites the hemispheres. When the neurons of one hemisphere make contact with those of the opposite hemisphere through the corpus callosum, the speed of integrating information from both hemispheres is accelerated (Mrzljak & Uylings, 1990).

Finally, after the 2nd year of life, over the next 3 or 4 years, there is maturation of at least five cognitive abilities: (1) the reliable integration of past with present, (2) anticipation of the future, (3) appreciation of causality, (4) enhanced reliance on semantic categories, and (5) detection of shared relations between events and categories. These changes are accompanied by a dramatic increase in the total cortical surface so that the human brain attains 90% of its adult weight by the time the child is 8 years old (Giedd et al., 1996). Further, the balance between the number of new synapses formed and the number eliminated shifts after the sixth birthday to a ratio that favors the latter process. There is a parallel increase in myelination and an increase in the interconnectedness that involves both hemispheres, anterior and posterior cortical sites, as well as cortical and subcortical structures. This story is being told in several chapters in this *Handbook*.

## BIOLOGY AND TEMPERAMENT

Some of the stable psychological variation found among children in all cultures represents a second domain in which biology influences growth. This idea, which is the sense meaning of the concept *temperament*, comprises the primary focus of this chapter. However, the biological processes and psychological experiences that mediate the maturation of a particular class of behavior are usually different from those that are responsible for the variation in that behavior. Fear of unfamiliar adults in infancy provides a nice example of this claim. It is believed that the display of distress to and avoidance of strangers appears in most children by 7 to 9 months as a result of maturation of circuits from limbic sites to the frontal lobe (Diamond, 1990; Kagan, 1994). The variation in the intensity and chronicity of fearful behavior to strangers is believed to be due to differences in the chemistry of the amygdala and experiences with strangers rather than completion of the circuits that link the limbic structures with the frontal lobe (Kagan, 1994). Although inquiry into human temperaments is becoming more popular, there is no consensus on basic terms, measurement procedures, or robust generalizations. Hence, it is not possible in one chapter to summarize, in an integrative style, all that has been published. The interested reader is referred to several books that present the diverse views on this theme; they include Kohnstamm, Bates, and Rothbart (1989), Strelau and Angleitner (1991), Bates and Wachs (1994), and Plomin and McClearn (1993). The first task in every science is to categorize the phenomena that define its domain with concepts that capture nature's plan. Four cognitive biases interfere with this assignment. These include (a) the tendency to award priority to easily observed features, (b) the desire to honor parsimony by inventing categories with the fewest number of features, (c) a preference for concepts that imply temporal stability rather than change, and (d) the urge to believe that the inferred category refers to a real entity in nature and not simply a clever invention.

The sense meaning of temperament held by many, but not all, scientists refers to a biologically based bias for correlated clusters of feelings, thoughts, and actions that appear during childhood, but not always in the opening months, and are sculpted by varied rearing environments into a large but still limited number of traits that comprise an individual's personality profile. Hence, the stable variation in behaviors and emotions observed in older children, adolescents, and adults are personality

traits, not temperamental biases, although the latter make a contribution to the profile that emerges later in development. In addition, students of human temperaments exclude stable variation in cognitive functions from this category because of the typical failure to find consistent correlations between a temperamental bias and quality of perceptual, memorial, or inferential abilities. There is no good evidence to suggest that irritability, activity, or reactivity in infants predicts differences in IQ score or other cognitive abilities in later childhood. The independence of these two domains is reasonable because the presumed physiological bases for differences in perception, memory, and reasoning are different from those that mediate the temperamental biases. The biological biases that are the foundations of temperaments can be due to heritable variation in anatomy or neurochemistry or the result of prenatal events that are not strictly genetic in origin. Each of the many temperamental profiles that has been or will be discovered in the future is a concept. The more knowledge that accumulates around the concept, the more complete the cognitive appreciation of the concept and the events to which it refers. However, the biological features that enrich a temperamental concept, and are necessary for the emergent psychological profile, cannot replace it. A small number of neurobiologists believe that one day the idea of consciousness will be reduced to a particular set of neural activities, implying that consciousness is no more than a network of circuits. The reason for rejecting that premise is the same as the rationale for rejecting the idea that a chemical description of the toxins produced by the malarial parasites is equivalent to a description of the patient's malaise. A tornado has a shape, speed, direction of motion, and color, and these features are not derivable from lengthy descriptions of groups of air molecules in the tornado. Similarly, the transparent quality of a pane of glass is not explained by a description of the chemical structure of silica. Genes select or stabilize a form, but unless we know the exact conditions under which the organism is developing it is not possible to predict or understand the final form (Goodwin, 1994). "We inherit dispositions, not destinies . . . lives are not simple consequences of genetic consignments. Genetic determinism is improbable for simple acts of the fruit fly, implausible for complex human behavior" (Rose, 1995, p. 648).

The remarkable advances in neuroscience have tempted some to hope that many psychological concepts will eventually be replaced with a specification of a neural circuit. Such optimism is not warranted. A tem-

porally delimited pattern of brain activation, produced by an incentive, does not necessarily reflect a person's conscious feelings. Nor can the circuit represent the sequences of thoughts, preparation for action, and autonomic reactions that will occur subsequently. All of these events are referents for the psychological state.

The psychological meaning of *fear* is not a momentary brain state, even though a brain state accompanies the psychological state and, therefore, cannot be ignored. The neurophysiological phenomena should be given their own conceptual label. Three different sources of evidence are often used to infer a fear state: (1) a behavioral profile, (2) a pattern of physiological reactions, and (3) a self-report. At the moment, the correlations among these three referents are not high enough to treat them as redundant. There are two complementary, but different, frames for descriptions of human emotional states. One originates in phenomenology, the other in physiology. The concepts, their interrelations, and their time courses are sufficiently different in the two frames that it is wise to distinguish clearly between the words that are presumed to refer to the same state.

This position is neither a defense of traditional mind-brain duality nor an attack on biological reduction. It merely states that all psychological phenomena, including temperament, are emergent with respect to underlying biological events. A particular PET scan showing high metabolic activity in areas of the visual cortex does not explain completely why a person perceives a small, red sphere moving slowly to the right rather than a large, gray background moving slowly to the left. Each perception, behavior, emotion, and thought represents more than the brain circuits that are necessary for its actualization, a position Sperry (1977) maintained during the final years of his productive career. Thus, the description of a temperamental category is not equivalent to a description of the biological features that comprise part of its foundation. A wave is more than the moving particles of water that comprise it (Einstein & Infeld, 1938).

This chapter first presents a brief historical perspective on the concept of temperament and the reasons for its appeal, and then a description of the nodes of agreement and disagreement among investigators. The two most important controversies involve the validity of parental reports of children's behavior and whether temperamental qualities should be conceived of as continua or categories. The heart of the chapter is a summary of the most robust generalizations regarding the temperamental characteristics of irritability in infants and sociability and shyness in older children. The final

sections consider, more briefly, the relevance of temperament to attachment, psychopathology, ethnicity, and morality. The chapter focuses on infancy and early childhood and does not consider in detail the interesting research on the temperamental contributions to the behaviors of adolescents and adults.

## **HISTORICAL BACKGROUND**

The Greeks and Romans believed that a balance among the four humors of yellow and black bile, blood, and phlegm created an opposition in each of two complementary universal qualities: warm versus cool and dry versus moist (Siegel, 1968). These qualities were related to the four fundamental substances in the world: fire, air, earth, and water. The Greeks assumed—without a detailed appreciation of genetics or physiology—that the balance among these qualities created an inner state responsible for the observed variation in rationality, emotionality, and behavior. Children were impulsive and irrational because they were born with an excess of the moist quality.

Galen, an extraordinarily perceptive second-century physician born in Asia Minor, elaborated these Hippocratic ideas by positing nine temperamental types derived from the four humors (Roccatagliatta, 1986). The ideal personality was exquisitely balanced on the complementary characteristics of warm-cool and dry-moist. In the remaining four less ideal types one pair of qualities dominated the complementary pair; for example, warm and moist dominated cool and dry. These four were the temperamental categories Galen called melancholic, sanguine, choleric, and phlegmatic. Each was the result of an excess of one of the bodily humors that produced, in turn, the imbalance in qualities: The melancholic was cool and dry because of an excess of black bile, the sanguine was warm and moist because of an excess of blood, the choleric was warm and dry because of an excess of yellow bile, and the phlegmatic was cool and moist because of an excess of phlegm.

Although the concentrations of the four humors and the relative dominance of the derived qualities were inherent in each person's physiology, they were, nonetheless, susceptible to the influence of external events, especially climate and diet. The body, naturally, became warmer and more moist in the spring; hence, people became more sanguine. When the body became cooler and

drier in the fall, a melancholic mood became more prevalent. Because humans lived in different climates and ate different foods, they differed in these temperamental qualities.

Although the Chinese view of human nature articulated two millennia earlier shared some features with Galen's ideas, it differed from it in several important ways (Yosida, 1973). First, the critical balance was among sources of energy rather than the bodily humors. The energy of the universe—called *ch'i*—is regulated by a complementary relation between the active initiating force of *yang* and the more passive, completing force of *yin*. The two forces must be in balance for optimal physiological and psychological functioning. Like the Greeks, the Chinese linked the emotion of sadness with autumn, joy with early summer, and fear with winter. But the Greeks would have been surprised that the Chinese linked anger with spring—April and May are the months of Galen's sanguine temperament. However, the more important fact is that the Chinese were not interested in temperamental types. Because the energy of *ch'i* is always changing, a person's moods and behavioral style cannot be too permanent. The notion of a person inheriting a stable emotional bias was inconsistent with the Chinese premise of continual transformation. A person might be sad temporarily, but not because he or she was a melancholic type.

Galen's inferences, which remained popular in Europe until the end of the nineteenth century, were not seriously different from contemporary speculations that the brains of schizophrenics might possess an excess of dopamine while those of depressives may have insufficient norepinephrine (Healy, 1997). Kant (1785/1959) accepted Galen's four types with only minor changes but distinguished between affect and action because he recognized the imperfect relation between invisible, internal processes and overt behavior. Kant believed that humans possessed a will that could control the behavioral consequences of strong desires.

This contrast was captured in the nineteenth century in the comparison between temperament and character. The former referred to inherited emotional biases, the latter to the expression of these biases in actions that were a function of both life experiences and inborn temperament. The pragmatist, for example, was a character type who could possess either a sanguine or a melancholic temperament.

Two centuries later, Roback (1931) modernized Kant's views by suggesting that individuals inherited, to

different degrees, dispositions for certain desires and emotions. But, unlike animals, humans could control behaviors that violated their ethical standards; this is Roback's version of Freud's belief that ego tames id. The sanguine type must inhibit, occasionally, the tendency to act impulsively because of strong feelings; the melancholic must suppress the urge to become anxious and withdrawn. Thus, a temperamentally sanguine person who has made too many ill-advised decisions can become overly cautious; a melancholic who has learned to inhibit fear may appear to others to be spontaneously sociable. The idea that the character type does not always provide a reliable insight into temperament is the essence of Jung's distinction between each person's hidden *anima* and public *persona*.

Nineteenth-century essays on temperament focused on the biology of the brain and searched for visible signs of that biology on the surface of the body. Franz Gall (1835) incurred the enmity of a segment of his community by suggesting that variation in human intentions and emotions, derived from differences in brain tissue, could actually be detected with measurements of the skull. Gall's crass materialism angered many colleagues who did not believe that a person's character was determined by brain tissue and, therefore, was not controllable by each agent's will. A second reason for the hostility toward Gall is that many nineteenth-century scholars did not believe that the anatomy of the brain had any implications for human behavior because psychology was not part of natural science.

Spurzheim (1834) consolidated Gall's ideas by retaining the essential premise of a location for each primary human characteristic and, reflecting nineteenth-century prejudice, assigning more space in the cranial cavity to emotional than to intellectual processes. Love was in the cerebellum, aggression in the temporal lobe, and timidity in the upper lateral and posterior part of the head near the parietal area. The vigorous positivism in Spurzheim's arguments was motivated by the need to expunge metaphysical and religious ideas from scientific explanations of human nature; it was time to place human behavior in its proper place as a part of natural law.

Thus, by the end of the nineteenth century most scholars had accepted the fact that psychiatry rested on biology. Listen to Adolph Meyer in 1897: "We cannot conceive a disorder of the mind without a disorder of function of those cell mechanisms which embody that part of the mind" (1897/1994, p. 44).

The first transformation of these ideas was an expansion of the number of revealing physical features and, more important, an appreciation that these features were only indirect signs of the real, but still unknown, causes. In a book that enjoyed eight editions, Joseph Simms (1887) awarded the face more diagnostic power than Paul Ekman or Carroll Izard would have dared. Even American schoolteachers were indoctrinated with these ideas: Jessica Fowler (1897) wrote a manual to help teachers diagnose their young pupils' psychological qualities. A "veneration for elders" was predictable from excessively drooping eyes.

Cesare Lombroso (1911) and Ernst Kretschmer (1925), in classic treatises, suggested an association between body type, on the one hand, and crime or mental disease, on the other. Lombroso acknowledged that crime had social and climatic correlates, but claimed that adults who fell at one of the extremes of a normal body type were more often represented among criminals, and dark-haired men were more likely to be criminals than those who were blonde. Kretschmer invented new names—asthenic, pyknic, and athletic—for the three classical body physiques and awarded differential vulnerability to major mental illness to the first two body types. Schizophrenics were more often tall, thin, narrow-faced asthenics; manic depressives were more often chubby, broad-faced, pyknic types.

These speculations formed the basis for Sheldon's (1940) famous book on personality and physique. Sheldon measured a large number of morphological dimensions from the photographs of 4,000 college men and collapsed the resulting 76 categories into three basic body types, each rated on a 7-point scale and each having a corresponding set of psychological qualities. The tall, thin ectomorph was an introvert; the chubby endomorph was an extrovert; and the broad, athletically built mesomorph was energetically assertive.

Sheldon's work began as the eugenics movement in America had reached a crest and was published the year that the Nazis were threatening Europe. The idea that inherited physical qualities, associated with different ethnic groups, were associated with human behavior was too close to Hitler's version of Aryan types, and this research, as well as a growing eugenics movement, stopped suddenly. Promotion of the formerly popular idea that the obvious physical differences among Scandinavians, Italians, Jews, and Blacks were linked to intelligence and morality had become a sign of both irrationality and amoral prejudice. The abrupt end to

public discussion of these hypotheses is not surprising; tucked away in Sheldon's book is the provocative suggestion that Blacks are more often aggressive mesomorphs, whereas Jews are more often intellectual ectomorphs. Ernest Hooton's (1939) book, which suggested that some bodily constitutions were naturally inferior and linked to criminal behavior, had a defensive tone because he was aware of how unpopular this view had become to many Americans. Temperamental ideas, which had enjoyed the support of professors, presidents, and corporation heads during the 1st decade of the century, were forced underground for almost 50 years.

### Freud's Influence

Freud (1933/1965) was a critical figure in this story because he made important changes in the remnants of Galen's views. First, he substituted one bodily substance, the energy of the libido, for the four humors. This idea of psychological energy, the sense meaning of libido, was not a completely novel notion. Nineteenth-century physicians had elaborated the ancient belief that the amount of energy was an inherited personal quality. The *vis nervosa*, an idea related to the eighteenth-century notion that inanimate objects varied in their ability to retain and give off heat, was less abundant in those unfortunate persons who developed fears, depression, and neurasthenia.

Pavlov (1928) also exploited this idea to explain why some dogs became conditioned easily while others, who resisted the laboratory procedures, were difficult to condition. Pavlov thought that the former group of animals had a stronger nervous system, permitting them to be more resilient to the unfamiliarity of the laboratory conditioning procedures. Pavlov intended that description to be flattering, because functional and adaptive evaluations, which were absent in Galen, colored temperamental concepts after Darwin's seminal work. Galen had written as if each psychological type sought an adaptation to fit his or her bodily humor. Pavlov inserted the evaluative ethic of adaptation and implied that some temperaments functioned better than others. The sanguine was the best type; the melancholic, who had a weaker brain, was the least desirable.

The idea that individuals vary in psychological energy and, therefore, in strength of brain activity may seem odd to modern readers. However, norepinephrine, the primary neurotransmitter of the sympathetic nervous system, maintains body temperature by producing bodily energy (Paxinos, 1990). Current psychiatric the-

ory holds that depressives have low levels of central norepinephrine. The mechanism of one of the therapeutic drugs acts to increase the concentration of norepinephrine in the synaptic cleft. Moreover, infants differ in the vigor of motor activity and loudness of vocalizations. Some 4-month-olds thrash their limbs and squeal with delight; others lie passive and quiet. A high energy level leaps to mind as the best description of the former infants. In the classic monograph on hysteria, Breuer and Freud (1956) wrote, "Differences which make up a man's natural temperament are based on profound differences in his nervous system—on the degree to which the functionally quiescent cerebral elements liberate energy" (p. 198). The creative element in Freud's thinking was to award the free-floating energy of libido an origin and a target in sexuality, while accepting the popular view that heredity influenced the total amount of libido possessed. Although Freud's early writings awarded influence both to temperamental differences in amount of libido and excitability of the nervous system, as well as childhood experiences, the latter ascended in importance in his later writings and, accordingly, the temperamental contribution faded.

The current popularity of the premise that childhood experiences are part of the causal web in adult anxiety and depression prevents a proper appreciation of the revolutionary character of Freud's ideas. Although the ancients were open to the suggestion that psychological variation in the normal range could be influenced by childhood experience—even Plato accepted that argument—the serious mental afflictions of depression, mania, and schizophrenia were regarded as solely physiological in origin. Although the ancients believed that some environmental factors were potent, including air, diet, exercise, rest, and excretion and retention of fluid, none of these causes was social in nature.

By softening the division between serious mental disorder and normal variation in worry and sadness, Freud persuaded many that both a terror of leaving home and worry about one's debts could be derivatives of the same conflict. The assumption of an experiential basis for fears and anxieties that was appropriate for all—everyone felt guilt over sexual and hostile motives—implied that every person could develop a phobia. Freud (1909/1950) let his readers believe that "little Hans" was no different temperamentally from any other child; his extreme fear of horses was the result of very unusual experiences in his family. It is of interest that contemporary reports on children's phobias have returned to the notions prevalent decades before Freud. Clinical cases in

psychiatric journals are now described as if they were physiological diseases to be treated with drugs; there is little or no discussion of conflict, trauma, or early family experience.

Psychoanalytic theory slowly turned minds away from a category of person who was especially vulnerable to acquiring a phobia to the idea of environmental encounters that produce fear. The adjective *fearful* now became a continuous dimension on which any person could be placed. Because all individuals experienced conflict, anyone could become phobic. The idea of a vulnerable temperamental type was replaced with the notion of unusually stressful experiences.

A metaphor that captures this contrast is a bridge that collapses under a load. The traditional assumption was that all bridges must carry loads of varying weight; hence, a bridge that collapsed under a load that was in the normal range must have been structurally weak. This is the temperamental premise. Freud, and especially his followers, argued that, most of the time, the collapse was caused by an unusually heavy load. The psychological loads included childhood seduction, harsh socialization of hostility and sexuality, loss of a love object, and fear of the anger of an authoritarian parent. Even though there are many more children who are socialized harshly by autocratic parents or rejected by indifferent ones than there are hysterical patients, this theoretical stance won admirers quickly because of political factors.

Many Americans were threatened when, after World War I, a number of prominent scientists joined by influential journalists suggested that some immigrants were less fit genetically than indigenous Americans (May, 1959). An opposing group of politically more liberal scientists and journalists quieted this provocative claim by suggesting that Pavlov's discoveries of conditioning meant that all children were essentially similar at birth and conditioned experiences supplied the only shaping hand. McDougall's (1908) acerbic critique of this position in his text *Social Psychology* was drowned out by the rising voice of Watsonian behaviorism. America celebrates the individual, who, through wit and perseverance, makes or invents a reliable product that has pragmatic value. Thomas Edison and Henry Ford are prototypic American heroes. The most celebrated American scientists of this same era performed laboratory experiments yielding hard facts presumed to have implications for human life. Many American psychologists studied the phenomenon of learning in rats because this animal permitted experimental manipulations that

could produce more certain facts, and therefore, a deeper understanding of the mechanisms behind the child's learning of new habits. This knowledge would serve the needs of an egalitarian society.

The European mind at the end of the nineteenth and the beginning of the twentieth century was more friendly to temperament because it held a different ethic. The European city enjoyed greater loyalty than the same size community in geographically mobile America. The residents of Paris, London, and Florence took more pride from their cities' long history than did citizens in New York, Philadelphia, or Washington. The vitality and stability of the community had precedence over the upwardly mobile achieving individual in American society. That preference was correlated with a desire to maintain social harmony through citizen acceptance of and conformity to local mores and Europeans were receptive to the idea that variation in stability could be due to biology. Americans wanted to deny biology any force. Every person with an intact brain and body could actualize her goals if she worked hard and exploited her inherent cleverness. No person's acceptability to others or future success should be shackled by their inheritance.

The appeal and acceptability of scientific ideas are always influenced by the societal context in which they appear. Darwin's inference of natural selection, influenced by Malthus's suggestion that the increasing fecundity of populations would outstrip food supplies, overcame initial resistance quickly because many overcrowded European cities contain large numbers of very poor families producing large numbers of children. A half century later, when many east coast American cities contained crowded ghettos of European immigrants, our society had to choose between scientific declarations claiming that the foreigners were genetically compromised and the arguments of egalitarian scholars who argued that the habits and values of the immigrants were experientially based. The latter explanation became ascendant for almost 50 years until a new wave of immigrants with color arrived. But this time the American economy had less need for their labor and the biological sciences had made important discoveries.

Thus, the current receptivity to temperamental ideas cannot be understood without acknowledging history and recent theory and research in neuroscience, psychology, and psychiatry. The period from 1910 to 1970 was characterized by the conviction that, excepting the small number of brain-damaged children, most were fundamentally similar, and the development of different skills

and personalities was due, in the main, to experience, especially conditioned habits. This popular and dominant premise was shaken by several historical events.

First, the conceptual gap between the principles of classical and operant conditioning and the novel forms observed in children's speech and behavior became difficult to repress. The resulting dissonance led, over time, to a broad dissatisfaction with the traditional view, but still no replacement. At the same time, Piaget's (1950) ideas of stages of psychological development became popular. Although Piaget insisted on the importance of the child's actions in the world, his arguments imposed some constraint on the effectiveness of experience. No 2-month-old could possess an object concept no matter what his experiences. Although Piaget did not favor the biological determinism implied by the concept of maturation, his writings created a renewed enthusiasm for maturational processes. Chomsky's ascerbic critique of Skinner's explanation of language acquisition abetted the maturational argument. Thus, the community became receptive to the influences of biology and the older ideas on temperament.

When the dissemination of PET and fMRI data promised an eager audience objective quantification of the brain's biology, the dam that was repressing an enthusiasm for biology burst. Only 2 decades ago, the probability was high that a paper on behavioral genetics submitted to *Child Development* or *Developmental Psychology* would be rejected. Today, similar reports are usually accepted by referees because of a change in the community's premises. The essential data have not changed very much; what has changed is the credibility of the importance of biological processes.

There is, however, a danger in an excessive enthusiasm for biological determinism. A nativistic view of the infant, which is gaining popularity, resembles the preformationist assumption that a tiny child was hidden in each sperm. Infants are being awarded cognitive talents that psychologists would have satirized 25 years ago. The permissive attitude toward these claims could not have occurred without the prior perceived failures of behaviorism and psychoanalytic theory, just as the popularity of Picasso and other modernists required the prior idealism of Courbet and Monet. Picasso's *Nude in a Red Chair* would not have been regarded as a great work of art had not Western artists, during prior centuries, painted serene, beautiful, unclothed women.

A quarter-century ago, psychologists loyal to stimulus response learning theory invented possible explana-

tions of almost every stable behavior. Readers will recall, for example, that Skinner (1981) suggested that operant conditioning principles could explain the child's acquisition of speech. Contemporary neuroscientists are being equally creative when they propose neurophysiological bases for many diverse and complex behaviors. We do not criticize this inventive energy, but only note that, as with the earlier behavioristic accounts, most of these explanations will turn out to be either too simple or simply incorrect (Hu & Fox, 1988).

## RENAISSANCE OF TEMPERAMENTAL IDEAS

An important reason for the return of temperamental ideas was the bold, influential work of Thomas and Chess (1977). Although Solomon Diamond (1957) anticipated the current interest in temperament at about the same time that Alexander Thomas and Stella Chess published their first papers, historical forces awarded priority to the two psychiatrists because their categories were more closely related to parental experiences with infants and to later childhood pathology. It is useful to recall their strategy of discovery. Thomas and Chess (1977) conducted, at regular intervals, lengthy interviews with well-educated parents of infants and inferred nine temperamental dimensions together with three more abstract categories from those interviews. The nine temperamental dimensions were: (1) activity level; (2) rhythmicity or regularity of bodily functions like hunger, sleep, and elimination; (3) initial reaction to unfamiliarity, especially approach or withdrawal; (4) ease of adaptation to new situations; (5) responsiveness to subtle stimulus events; (6) amount of energy; (7) dominant mood, primarily whether happy or irritable; (8) distractibility; and (9) attention span and persistence.

The three temperamental categories represented a profile on two or more of the nine dimensions. The most frequent category, about 40% of the sample, was the easy child, who was regular in bodily activity and approached unfamiliar objects with a happy, engaging mood. The second, comprising about 15% of the sample, was slow to warm up and, like the children Kagan, Reznick, and Snidman (1988) called inhibited, they react to unfamiliarity with withdrawal and occasionally mild distress. The third category, comprising about 10% of the sample, was called difficult and was characterized by minimal regularity, frequent irritability, withdrawal from unfamiliarity, and poor adaptation. This

category of child was most likely to develop psychiatric symptoms—two-thirds had developed such symptoms by age 10. These three categories comprised about two-thirds of the Chess and Thomas sample; the remaining third were difficult to classify.

Continuous evaluation of the children through the 5th year revealed minimal preservation of most of the dimensions. The largest correlations, about .3, reflected stability across the preschool years. But there was not much predictability from early infancy to age 4. As a result, Thomas and Chess concluded that the nine temperamental dimensions, as phenotypes, were not very stable. They revisited these subjects when they were between 18 and 22 years of age, using clinical interviews and questionnaires to evaluate degree of adjustment. Although there was no relation between the possession of an easy or a difficult temperament in the first 2 years and later adult adjustment, the children who had been classed as difficult in the 3rd and 4th years were judged to be less able to cope with life stresses than those children who had an easy temperament. However, Chess and Thomas (1990) noted, wisely, that the outcomes of a difficult temperament depended on the goodness-of-fit—the match—between the child's temperament and the family's ideals for the child. Both must be assessed if one is to predict future pathology.

### Animal Research

The discovery that closely related strains of animals raised under identical laboratory conditions behaved differently to the same intrusions provided another set of persuasive facts. Over 35 years ago, John Paul Scott and John Fuller (1965) observed over 250 puppies from five different breeds—basenji, beagle, cocker spaniel, Shetland sheepdog, and fox terrier—at the secluded Jackson laboratories in Bar Harbor, Maine. In one assessment of an animal's timidity, a handler took a puppy from its cage to a common room, placed the puppy one or two feet away, stood still, and observed the animal's behavior. The handler then slowly turned and walked toward the puppy, squatted down, held out his hand, stroked the puppy, and finally picked it up. The puppies that ran to the corner of the room, crouched, and issued a high-pitched yelp early in the sequence were classified as timid. The five breeds of dogs differed dramatically in degree of timidity, for the basenjis, terriers, and shelties were more timid than the beagles and cocker spaniels. But the rearing environment was important: All

the dogs were less timid if they had been raised at home rather than in the laboratory. Twenty years later, Goddard and Beilharz (1985) discovered that Labradors, Australian kelpies, boxers, and German shepherds differed in the avoidance of unfamiliar objects: The German shepherds were the most timid, and the Labradors were the least fearful.

Pavlov noted over 75 years ago that some dogs in his laboratory were unusually tame with humans while others cowered when an adult made an unexpected movement. Pavlov called the former dogs excitable and the latter inhibited (Pavlov, 1928). Factor analyses of behavioral observations on over 15,000 dogs from 164 different breeds revealed a broad factor best interpreted as a shy-bold continuum (Svartberg & Forkman, 2002).

House cats, too, differ in timidity. The small proportion of cats who consistently withdraw to novelty and fail to attack rats have a lower threshold of excitability in specific areas of the amygdala than the majority of cats who do not withdraw and generally attack rats (Adamec, 1991). Similar stories can be told for a great many species. Mice, rats, wolves, cows, monkeys, birds, and even paradise fish differ, within species or among closely related strains, in the tendency to approach or to avoid novelty. A review of this variation by a team of evolutionary biologists concluded, "There can be little doubt that the shy-bold continuum is an important source of behavioral variation in many species that deserves the attention of behavioral ecologists" (Wilson, Clark, Coleman, & Dearstyne, 1994, p. 7).

It is not surprising that fearful behavior can be bred in animals, but it is surprising that it requires such a small number of generations. Some quail chicks become chronically immobile when placed on their back in a cradle and restricted by a human hand; remaining immobile is one measure of fear in birds. If chicks who display the fearful trait are bred with other fearful animals, it takes only eight generations to produce a relatively uniform line of birds that shows immobility for as long as 2 minutes (Williamson et al., 2003). It is equally easy to establish a pedigree of birds that shows very brief periods of immobility, implying minimal fear, and possible to select quail who secrete high or low levels of corticosterone. The strain with higher levels is more fearful of novelty than the strain with low levels of this steroid (Jones, Satterlee, & Ryder, 1994).

The Maudsley Reactive strain of rats was bred over generations to be emotionally reactive to unfamiliarity, where the amount of defecation in a brightly lit open

field, aversive for a rat, was the index of reactivity. A second strain of rats was bred to be minimally reactive. The differences between the reactive and nonreactive strains emerge early, by 30 days, and are not due to post-natal experiences. The reactive, compared with the non-reactive, animals have lower levels of catecholamines in body tissue and lower levels of norepinephrine in the blood, but compensate by having an increased density of beta adrenergic receptors on the heart (Blizard, Liang, & Emmel, 1980). However, later research revealed that the low reactive rats failed to defecate because they possessed higher levels of norepinephrine in the colon due to greater sympathetic activation. That condition led to constriction of the smooth muscle of the colon, and therefore, less defecation (Blizard & Adams, 2002). This fact illustrates the danger of conceptual inferences from incomplete evidence for the low reactive animals are, in fact, high reactive sympathetically.

Strain differences in the reaction to unfamiliarity exist in primate groups. South American squirrel monkeys of two different strains, reproductively isolated by only a thousand miles of jungle, vary in their morphology, physiology, and behavior (Snowdon, Coe, & Hodun, 1985). About 20% of rhesus monkeys are extremely timid in unfamiliar environments, have a tense muscle tone as infants, and show physiological reactivity in bodily targets that are linked to fearfulness (Suomi, 1987). There are even sanguine, melancholic, and choleric monkeys. When the behaviors of three closely related species of macaques were compared with respect to their tendency to approach or to withdraw from an unfamiliar human, bonnets were most likely to approach, whereas crabbeaters, the smallest of the three species, were the most fearful. The largest animals—rhesus—were the most aggressive (Clarke, Mason, & Moberg, 1988). When these three species were observed under different conditions of novelty and restraint, the aggressive rhesus were least disturbed and showed the smallest increases in heart rate. The fearful crabbeaters were the most disturbed and showed the largest increases in both heart rate and glucocorticoids. The bonnets, who are passive and avoidant, showed modest increases in both heart rate and glucocorticoids. However, when crabbeater, rhesus, and pigtail monkey infants were reared in isolation for 6 months, the rhesus displayed the most disturbed social behavior, whereas crabbeater monkeys showed almost normal social behavior (Sackett, Ruppenthal, Farenbuch, Holm, & Greenough, 1981). Thus, the influence of temperament on development

varies with the nature of the imposed stressor (Magnusson, 1988).

Temperamental factors are even linked to immune function in monkeys. One group of crabbeater males was assigned to a stable group of four or five other monkeys for the 26 months of the experiment. A second, stressed group of animals also lived with four or five other monkeys, but the composition of the group changed each month. These frequent changes generated uncertainty in the crabbeater monkey. The scientists also observed the animals twice a week for about a half hour to determine which were social and affiliative—they groomed and stayed close to other monkeys—and which were social isolates. After the 2 years of either stressful or minimally stressful social experience, the integrity of each animal's immune system was measured by drawing blood from each monkey for 3 weeks and evaluating the ability of the T lymphocytes to respond appropriately to an antigen. Lower levels of cell proliferation to the antigen index are assumed to reflect a compromised immune system. Only the animals that lived under stress and, in addition, were temperamentally prone to be social isolates showed a severely compromised immune system. The affiliative animals that had experienced the same level of stress showed a healthier immune response. This finding illustrates the principle that a disease state requires both a stress and a vulnerable organism (Cohen, Kaplan, Cunnick, Manuck, & Rabin, 1992).

The fact that very small variations in the genetic composition of closely related animals are associated with distinct profiles of behavior and physiology requires accommodation. If an animal's temperament influences its reaction to total isolation and immune competence, it is likely that similar factors are operative in human psychological functions. Thus, diverse, independent forces combined to render temperamental ideas as attractive candidates in interpretations of human behavior.

## **NEUROCHEMISTRY AND TEMPERAMENT**

It is likely that the biological bases for many, but certainly not all, temperamental categories are heritable neurochemical profiles, a hypothesis anticipated earlier in the twentieth century (McDougall, 1929; Rich, 1928). Research on voles, a small rodent, is illustrative. Prairie and Montane voles, two closely related strains, differ in a psychologically significant behavior. Males and females from the former strain pair bond following several

hours of mating, while members of the latter strain do not. Variation in the promoter regions of the genes that influence the distribution of receptors for vasopressin in males and oxytocin in females contributes to this behavioral difference (Insel, Wang, & Ferris, 1994). The DNA of the promoter region determines whether the gene will be activated in a particular site. Both strains secrete vasopressin and oxytocin and both strains have receptors for these molecules, but the strains differ in the locations of the relevant receptors. Only the prairie vole has receptors in limbic sites believed to mediate states of pleasure.

There is heritable variation in the concentration of and density and location of receptors for more than a 150 different molecules that affect brain function. This fact implies a very large number of neurochemical profiles. Even if the majority have little function or relevance for mood or behavior, given the extraordinarily large number of profiles it is likely that human populations contain many temperaments, each defined by a neurochemistry that influences the usual psychological reaction to classes of events.

Two important factors determine brain neurochemistry and, therefore, temperamental biases. First, some brain molecules are excitatory and some are inhibitory and a balance between these processes determines the brain state. For example, the balance between opioids and corticotropin-releasing hormone (CRH) in the locus ceruleus determines the organism's reaction to a stressor (Van Bockstaele, Bajic, Proudfit, & Valentino, 2001). Second, the variation in the density of receptors for a molecule can be independent of the concentration of that molecule. Some mice strains show high levels of tyrosine hydroxylase in the cortex (an enzyme involved in the synthesis of dopamine and norepinephrine) but a low density of receptors for norepinephrine. Other strains are high or low on both properties (Dyaglo & Shishkina, 2000). If we assume that the concentration of a particular neurotransmitter or modulator, and the density of its receptors, can be low, moderate, or high, there can be nine possible profiles for each molecule and, assuming 150 different molecules, at least 1400 neurochemical profiles that could reciprocally influence each other. This state of affairs implies a very large number of possible temperamental biases.

There are at least four different ways brain chemistry can affect the excitability of a particular neuronal ensemble with consequences for behavior. The ensemble can (a) secrete a greater amount of neurotransmitter or

modulator, (b) have more receptors for a particular molecule, (c) project to neurons that secrete a particular molecule, or (d) can be inhibited or disinhibited by another ensemble. Given the brain's massive interconnectivity, it is reasonable to assume a very large number of ways in which neurochemistry can influence emotion and behavior. Only some of these influences are inherited (Placidi et al., 2001).

Some molecules that appear to be significant include norepinephrine, CRH, glutamate, GABA ( $\gamma$ -aminobutyric acid), dopamine, serotonin, opioids, vasopressin, prolactin, and oxytocin. For example GABA-ergic and serotonergic circuits usually inhibit neuronal excitement. Infants born with a compromise in either transmitter system should be less effective in modulating extreme states of distress. This speculation has some support for very irritable 2-year-olds, compared with relaxed toddlers, possessing the shorter form of an allele in the promoter region for the serotonin transporter gene (Auerbach et al., 1999). It is relevant that samples of Japanese adults are more likely than samples of Europeans to possess the long version of this allele and Japanese infants are less irritable than European-Caucasian infants (Kumakiri et al., 1999). Further, adults who inherit the shorter allele show greater amygdala activity to fear-provoking stimuli, compared with adults who possess the longer form (Hariri et al., 2002); although, very shy Israeli children inherit the longer form of this allele (Arbelle et al., 2003).

The lateral nucleus of the amygdala secretes a molecule called gastrin-releasing peptide that acts on the receptors of interneurons to release GABA, which in turn inhibits neural activity. Mice without the gene for this class of receptor fail to release GABA in amygdala neurons and, as a consequence, these animals preserve traces of the association between a conditioned stimulus and electric shock for a longer period of time (Shumyatsky, 2002). It is possible that children who possess this allele will have compromised GABA activity in the amygdala and a tendency to preserve a fearful posture (Maren, Yep, & Goosens, 2001; Sanders, 2001).

Variation in dopamine release and in the density of its varied receptors are related to cortical excitability, intensity of sensory pleasure, and reaction to novelty. There is an immediate release of dopamine in the nucleus accumbens the moment a rat places his forepaws in a novel environment, which can last for as long as 8 seconds (Rebec, Christianson, Guevara, & Bardo, 1997). Further, high dopamine levels in the cortex suppress

neuronal activity in the corpus striatum. As a result, there are fewer volleys from striatum to cortex, and, therefore, a lower level of cortical excitability. In addition, higher dopamine activity in the cortex implies a smaller proportional rise in dopamine following exposure to novelty. A person sated on chocolate experiences less pleasure from a chocolate bar than one who has not tasted chocolate for several days. These facts suggest that children with higher dopaminergic activity in the cortex might have a lower preference for novel experiences than those with greater dopaminergic activity. It is of interest that females have more dopamine receptors in the cortex than males and fewer females than males seek novel experiences.

Variation in norepinephrine and its receptors modulates the preferred reaction to novelty, level of alertness, sustained attention in the face of distraction, and thresholds for detecting subtle changes in sensory signals. This variation should have consequences for psychological qualities. Rats from the Wistar strain who explore unfamiliar areas have greater norepinephrine activity in the nucleus accumbens; hence, volleys from the amygdala are enhanced when they arrive at the nucleus accumbens (Roozendaal & Cools, 1994). The amygdalar release of norepinephrine is potentiated by epinephrine acting on norepinephrine receptors in the basolateral nucleus (McGaugh & Cahill, 2003). Hence, variation in the density of receptors for norepinephrine in the amygdala and the sensitivity of the basolateral receptors to epinephrine could affect behaviors that are classified as temperamental (Cecchi, Khoshbouei, Javors, & Morilak., 2002).

Opioids modulate the intensity of visceral afferent feedback from the body to the nucleus tractus solitarius in the medulla. Hence, less opioid activity implies that the medulla's projection to the amygdala will be more intense, and, as a consequence, the orbitofrontal prefrontal cortex, a target of the amygdala, will be vulnerable to greater activation. One possible consequence of this cascade is a greater state of worry, tension, or dysphoria and/or greater difficulty extinguishing a conditioned fear (McNally & Westbrook, 2003). Individuals with greater opioid activity in the medulla should experience more frequent moments of serenity and imperturbability (Miyawaki, Goodchild, & Pilowsky, 2002; Wang & Wessendorf, 2002). It is important to appreciate that not all variation in opioid activity is genetic in origin for some can originate in prenatal events. For example, female mice embryos lying between two males, or next to a male, compared with those lying between two

females, are affected by the surge in testosterone secreted by the male embryos. One consequence of this prenatal position is increased density of mu-opioid receptors in the midbrain, which, postnatally, is accompanied by a higher pain threshold (Morley-Fletcher, Palanza, Parolaro, Vigano, & Laviola, 2003).

CRH secreted by the hypothalamus, influences many systems, but especially the hypothalamic pituitary adrenal axis (HPA). One product of activity in this axis is secretion of the hormone cortisol by the adrenal cortex. Capuchin monkeys with high cortisol levels are more avoidant than animals with lower cortisol levels (Byrne & Suomi, 2002). Further, there is evidence for a relation between an allele at a CRH locus and behavioral inhibition in children, especially among those with one or more parents with panic disorder (Smoller et al., in press). Infusion of high doses of glucocorticoids, especially to the central nucleus, potentiates the release of CRH, startles (Lee, Schulkin, & Davis, 1994), and freezing in rats (Takahashi & Rubin, 1994). It is also relevant that monkeys who exhibited high fear to novelty and had high cortisol levels showed greater relative right, rather than left, frontal activation in the electroencephalogram (EEG; Kalin, Larson, Shelton, & Davidson, 1998), and monkeys who showed extreme right frontal activation had higher levels of CRH across the interval from 4 to 52 months of age (Kalin, Shelton, & Davidson, 2000).

However, there is no simple relation between cortisol levels, on the one hand, and either the reaction to an aversive event or self-reported mood, on the other. Adults administered either 20 or 40mg of cortisol, or a placebo, were asked to rate unpleasant and neutral words and pictures and in addition to describe their mood. Although the subjects given cortisol showed a rise in circulating hormone, there was no relation between their self-reported feelings, or their ratings of the words and pictures, and cortisol level (Abercrombie, Kalin, Thurow, Rosenkranz, & Davidson, 2003).

Gunnar (1994), who has explored the ability of salivary cortisol to detect different types of children, has also concluded that biological variables are ambiguous in meaning. Salivary cortisol levels are too subject to varied temporary states to be relied on alone as a sensitive sign of a stable temperamental type. Bold, outgoing preschool children are much more active than shy, timid ones early in the school year and have occasional days with very high cortisol levels. But several months later, when the originally less active, shy children have become acclimated to the school setting and venture forth

to socialize with others, they begin to show occasional days with very high salivary cortisol levels. Thus, the variation in cortisol spikes is closely related to the child's temporary psychological state and level of activity. Our laboratory found no significant relation between early morning salivary cortisol levels in 87 infants 5 and 7 months old and reactivity, smiling, or fear (Kagan, 1994). Further, infants between 12 and 18 months of age vary in the class of event most likely to provoke the secretion of cortisol, and in the time to attain a peak cortisol level (Goldberg et al., 2003). A particular average cortisol value has no univocal meaning across samples of infants or children.

Although we have emphasized the influence of neurochemistry, some temperamental categories could be derivatives of special anatomical features. Adults with a larger than average volume of the right anterior cingulate reported more frequent bouts of worry and shyness with strangers (Pujol et al., 2002). Also relevant, the volume of the right medial ventral prefrontal cortex in monkeys, an area that is active in anxious adults, is a heritable feature (Lyons, Afarion, Schatzberg, Sawyer-Glover, & Moseley, 2002).

Unfortunately, the immaturity of current knowledge relating brain neurochemistry to human psychological states frustrates any attempt to posit a specific relation between a chemical profile and a temperament. Because genetic variation accounts for less than 10% of the variation in most complex behaviors, it is unlikely that a single allele responsible for a particular neurotransmitter level or receptor distribution will determine a temperamental type. In light of these problems, it is impossible to define any temperament at the present time by a specific neurobiological profile. Further, the number of possible neurochemical profiles that can affect behavior is much larger than the number of behavioral profiles. There is a limited number of ways a child can display shyness with a group of children on a playground. The child can stand apart from the group, remain quiet, play alone at a task, or stare vigilantly at the other children. A much larger number of neurochemical patterns could accompany each of those behaviors, just as a large number of bodily states can create a stomach cramp.

## THE COMPLEXITY OF BRAIN-BEHAVIOR RELATIONS

Scientists appreciate that the influence of a biological profile on behavior is more complex than earlier scholars expected. The earlier assumptions were based on

facts like the relation between a trisomy on chromosome 21 and the mental retardation of Down syndrome. This fact, and related discoveries, seduced many scientists into minimizing the indeterminacy, complexity, and counterintuitive quality of the intermediate processes between genes and a psychological profile (Hu & Fox, 1988). Consider the counterintuitive nature of the following fact: The activity of the sweat glands in the skin of an adult is sympathetic in origin but is mediated by cholinergic neurons. The puzzle is that the embryo's sweat gland is noradrenergic and it requires sympathetic innervation to induce a molecule that, in turn, changes the neurotransmitter from noradrenergic to cholinergic (Habecker & Landis, 1994). Very few biologists sitting quietly in their study 50 years ago would have imagined this mechanism.

Behavioral data are equally complex and it will be necessary to view variation in behaviors like aggression, affiliation, sociability, fear, and depression historically, for each phenotype can result from a different life history. Consider two rats, one unfamiliar and one familiar with mice. If the septum of the former is lesioned, the animal is likely to attack a mouse placed in its visual field. But if the rat had been first familiarized with mice, the attack is less likely following the septal surgery. Similarly, stimulation of the periaqueductal gray of a rat that formerly would not attack mice is likely to produce an attack. But the same level of stimulation applied to an experienced rat that has attacked mice in the past causes the animal to interrupt its attack when stimulation begins (Karli, 1956, 1981, 1991).

Equivalent behavioral outcomes do not always imply similar prior conditions. The concept of equivalence in physics holds that if the same mathematical description applies to an event that was produced by different conditions, the phenomena are to be considered equivalent theoretically. A classic example is the concave surface of the water in a bucket that is rotating on a table. However, if one imagines the universe rotating and the bucket remaining still, the surface of the water will appear concave. Because the mathematics that describe the concave surface is the same for a rotating bucket or a rotating universe, the two events are considered equivalent. The increased reliance on complex machines that purport to measure brain states has led some scientists to a tacit acceptance of a form of equivalence. They assume that the PET or fMRI profile reflects a particular psychological state, regardless of the conditions or the context of assessment. This assumption is probably incorrect. The unconditioned nictitating membrane reflex

to a puff of air involves a brain state different from the one activated by the conditioned form of the reflex, even though the reflex appears identical under the two conditions (the cerebellar nuclei are required for the conditioned reflex but not for the unconditioned one; R. Thompson et al., 1987).

One reason for the lack of a determinant relation in humans between an underlying biology and a psychological profile is that the person's historical and cultural context typically influences the profile. The journals of the writer John Cheever (1993), who died in the second half of this century, and the biography of William James's sister Alice James (Strouse, 1980), who died 100 years earlier, imply that both writers inherited a very similar, if not identical, diathesis that favored a chronically dysphoric, melancholic mood. But Cheever, whose premises about human nature were formed when Freudian theories were ascendant, assumed that his angst was due to childhood experiences, and he tried to overcome the conflicts that he imagined his family had created with the help of drugs and psychotherapy. By contrast, Alice James believed, with a majority of her contemporaries, that she had inherited her dour mood. Hence, she concluded, after trying baths and galvanic stimulation, that because she could not change her heredity she wished to die. The historical era of these creative writers exerted a profound influence on the coping strategies each selected and, by inference, on the quality of their emotional lives.

No single peripheral physiological measure is likely to be an especially valid index of a temperamental type because each is subject to local influences that are unrelated to central brain mechanisms that are the primary features of the temperament. However, an aggregate of different measures might do better. When the standard scores for eight peripheral physiological variables that are related to limbic excitability were averaged, the correlation between this aggregate index and behavioral inhibition was much higher than the relation between any one variable and the index of inhibited behavior (Kagan et al., 1988).

The traditional view that the relation between brain and behavior is unidirectional is being replaced with a more dynamic perspective that expects that psychological states influence brain physiology and the activity of particular genes and their products. Glucocorticoids and other chemicals produced by psychological states can turn on or off genes that control the density of receptors on neurons and, as a consequence, alter the reactivity of

the central nervous system. Each afternoon as the light fades, a gene is activated that initiates the sequence of protein synthesis (Takahashi & Hoffman, 1995). A child who inherited a physiology that biased her to be fearful (or impulsive) might, through experience, gain control of that behavior. The new profile could change both the child's psychological state and the genome that contributed to her initial behavior. An extremely inhibited 2-year-old boy in a longitudinal sample was not very fearful as an adolescent, and the reactive sympathetic nervous system he displayed as a toddler was much less apparent when he was 13 years old (Kagan, 1994). Further, the neural structures necessary for the acquisition of a conditioned avoidance or a freezing response may not be necessary for long-term maintenance of the same behavior. For example, the central nucleus of the amygdala is required if an animal is to learn to avoid a place associated with pain. But once the association has been established, the avoidant behavior can occur without involvement of the amygdala (Parent, West, & McGaugh, 1994). Thus, the physiology that is the basis for learning a habit need not be similar to the physiology that maintains it.

### **Specificity**

A principle of specificity is as important as a belief in dynamic reciprocity in probing the relation of brain to behavior. The area of the cortex that is essential for the retrieval of words that represent actions may be different from the area that is important in the retrieval of nouns (Damasio, 1994). The areas of the brain that cause a rat to avoid an electric probe that delivered shock are not the same as those that cause the rat to bury wood chips following the same experience of shock: The amygdala is necessary for display of the former, the septum for the latter (Treit, Pesold, & Rotzinger, 1993a, 1993b). The circuit that mediates defensive aggression to a noxious stimulus does not require the amygdala; the freezing response to an intruder does require the amygdala but not the hypothalamus. However, the rise in heart rate to an intruder is likely to involve the lateral hypothalamus (Fanselow, 1994).

It is a truism that the history of every scientific discipline is marked by new theoretical conceptions. It is less well recognized that changes in the evidential bases for a concept, which are the product of new methods, are equally characteristic of the history of disciplines. The microscope, for example, changed the meaning of life to

include forms that could not be seen. The radio telescope, which permitted the measurement of microwave radiation, led to the idea of dark matter and a new conception of the mass of the cosmos.

Psychology continues to be concerned with a small number of fundamental ideas that include consciousness, emotion, memory, thought, and pathology. Prior to the invention of machines that could measure brain activity, it was understood that the definitions of each of these concepts rested either on a person's phenomenological statements or observations of behavior. But after scientists gained access to the EEG, and later to the PET and fMRI, the primary referents for the psychological terms changed. It is possible that, in time, psychological information will come to be regarded as less objective, less accurate, or both. That trend is dangerous because psychological data are inherent in the meanings of words like *consciousness* and *emotion*.

Consciousness is a psychological state, not a pattern of brain activity, even though the latter is the basis for the former. An enabling condition should never be confused with its emerging products. A child's perception of a gull swooping down on the sea is not synonymous with the description of the circuits that make that perception possible. No one would confuse the tides with the gravitational attraction between earth and moon, a burning tree with the lightning that struck it, obesity with levels of lipids and carbohydrates, nor a protein with the DNA and RNA that were responsible for its manufacture. Yet, some scientists are committing the error of confusing ideas like fear, consciousness, and depression with specific neurochemistries and brain circuits. It is correct to state that a child's immobility to a spider requires a circuit that includes the thalamus, amygdala, and central gray. However, that statement is not equivalent to saying that the conscious feeling of fear is nothing more than, or identical with, discharge of that circuit. This philosophical error is chasing psychological investigations of emotion and cognition to the periphery in a legitimate excitement over the powerful advances in our understanding of the brain conditions that form the bases for a psychological state.

It is unlikely that the concepts that originate in observations of behavior will map neatly on the concepts of neurophysiology. The structure of psychological processes is different from the structure of brain processes, just as the structure of the brain is different from the molecular structure of the genes that influenced its formation. It will be necessary, as noted ear-

lier, to invent new concepts to name the neural circuits activated when certain psychological states occur rather than simply adopt the older, popular, psychological terms. For example, LeDoux, Iwata, Cicchetti, and Reis (1988) have described elegantly the brain structures necessary for a rat's acquisition of a conditioned freezing response or increase in blood pressure to a light that had been associated with electric shock. They call these brain structures a fear circuit. But this meaning of fear must be distinguished from the meaning of "fear" to describe a child who says he is afraid of failing a school examination.

### Agreements and Disagreements

Most investigators of temperamental biases agree on several issues. One is that the major structures of the limbic system—hippocampus, cingulate, septum, hypothalamus, and amygdala—and their projections to motor and autonomic targets are important participants in the variation that defines the major constructs. Second, the variation in the excitability of these brain structures is likely to be influenced by many genes rather than by a single allele. Third, the peripheral biological measurements often used to define the temperamental categories—for example, cortisol, blood pressure, heart rate, vagal tone, EEG—have only very modest associations with the behavioral components of the category (Bates & Wachs, 1994; Gunnar, 1994; Kagan, 1994). Schwartz, Snidman, and Kagan (1999) failed to find a robust relation between any one of a large number of peripheral physiological variables and temperament in a group of adolescents who had been classified as inhibited or uninhibited in the 2nd year of life.

This trio of agreements is set against four nodes of controversy. One source of tension is captured by the contrast between scientists who begin their work with *a priori* theoretical concepts and those who are comfortable with a host of tiny facts when an area of inquiry is young. The former scholars, who outnumber the latter at the present time, often begin with a theoretical view of the human temperaments and devise measures for them. The smaller group, following Francis Bacon, allows the data to guide the invention of temperamental concepts.

A second subtle issue involves the idea of essences. Some investigators conceive of a temperamental type as an essence with a fixed behavioral and physiological profile—the way many diseases are classified. One strategy treats the initial temperamental profile in the

1st year as an original, enduring structure that is preserved for life.

A less popular view holds that the child begins life with a particular temperamental profile that undergoes change as a result of experience with parents, initially, and later with teachers and peers. As each of these categories of experiences is encountered and accommodated, psychological changes occur. Thus, the category psychologists assign to a garrulous 10-year-old who was a very irritable infant should incorporate the traits of the former child. Because many behavioral changes occur in the first dozen years, the temperamental categories assigned to infants will differ from the personality constructs used to describe adolescents. Imagine two containers of glycerine, but only one contains a small drop of black ink that, having been stirred in the container, is invisible. Despite the fact that the drop of ink cannot be seen, it has altered the composition of the glycerine. An infant temperamental bias, like the drop of ink, may not be observable in adolescents, even though it can influence the mood and reactions of youth to particular events. This conception of temperament is similar to the biologists' view of evolution. Even though the evolutionary origin of all dog breeds was the gray wolf, the features of dogs are distinctly different from those of the gray wolf, and biologists differentiate the features of beagles from those of pit bulls.

There is no essential dog: Some are aggressive, some are not; some are spotted, some not; some bark, some do not. Nonetheless, all dogs share an evolutionary history and a set of anatomical structures, physiologies, and behaviors that distinguish them from cats and cows, which have also been domesticated. One day scientists will discover the critical features that define each of the many temperamental types. But because the study of temperaments is at an early stage of inquiry, most investigators rely on behavioral characteristics, each mediated by different biologies, as the critical defining features of a temperament.

## **SOURCES OF EVIDENCE**

Perhaps the most important controversy refers to the source of evidence used to define a temperamental type or bias (see Rothbart & Bates, Chapter 3, this *Handbook*, this volume). The validity of every empirically based inference is always influenced by the nature of the obser-

vations. This principle is true for all of the sciences. Estimates of the age of an animal species, or the phylogenetic relation between two species, can vary considerably if fossils rather than proteins are the basis for the judgment. Hence, the validity of a theoretical position can change when the source of information changes, even though investigators may use the same construct.

Statements about the origins and consequences of a temperamental bias can be based on three very different sources of data. The first and most common, at present, are verbal reports provided by an informant, usually a parent, but, occasionally, by an older child, teachers, or peers. A second, less frequent source is derived from behavioral observations in a laboratory or, less often, at home or in a school setting. The third, least frequent source involves biological measures, like vagal tone, heart rate, or cortisol level. Each of these sources has a unique structure and a unique set of advantages and limitations. Extensive behavioral observations are not a good proxy for parental descriptions or biology. Biological measures are not a valid proxy for behavior or parent perceptions, and parental reports are not always a good proxy for behavioral observations gathered across diverse situations.

## **Behavioral Observations**

The major advantages of gathering behavioral observations, especially when they are recorded on film, is that the information is, presumably, closer to the referent that the investigators wish to know—most theorists want to know how a child usually behaves in a particular class of settings. However, there are serious limitations on most observational data. First, the usual setting is an unfamiliar laboratory room where the child interacts with an unfamiliar adult while occasionally a parent sits nearby. Children can behave in special ways in this uncommon context. A child who is aggressive with peers might show no aggression in this setting. Second, most behavioral corpora are based on less than 1 hour of observation. It is unlikely that a majority of children will reveal signs of their important temperamental biases in such a short period. Finally, proper ethical restrictions limit seriously the incentives psychologists can present, even though these incentives might occur in the child's environment.

In general, behavioral observations are more valid when the constructs refer to cognitive competences,

usual reactions to novel social and nonsocial events, and degree of sociability with unfamiliar adults or children. Behavioral observations are far less valid if the constructs refer to beliefs, motives, conflicts, or usual emotional reactions to frustration, danger, ethical violations, or gaining a desired goal.

## ADULT VERBAL DESCRIPTIONS

Verbal descriptions provided by a parent or teacher have the obvious advantage of sampling behaviors across a variety of settings over a long period. Investigators can ask parents about their child's reaction to events that could not be simulated in the laboratory (e.g., reaction to punishment, to injury, to illness, or to attack).

The most popular questionnaires are the ICQ (Bates, 1989); the IBQ (Rothbart, 1981); the CBQ (Rothbart, Ahadi, & Hershey, 1994); the RITQ (Carey & McDevitt, 1978); and the EAS (Buss & Plomin, 1984). The questionnaires designed for infants and children usually ask about characteristics that parents are interested in and can observe easily, especially irritability, smiling, activity, shyness, and fear.

Most questionnaires do not ask about qualities that are subtle or of minimal interest to parents but nonetheless might be theoretically important; for example, how long a child takes to eat, preferred use of the right or left hand, or the fullness of each smile. Obviously, investigators cannot ask parents about qualities that are not observable, like asymmetry of cerebral activation or sympathetic reactivity. Because scientists can only ask parents about psychological qualities they understand with words that are part of a consensual vocabulary, most psychologists restrict their temperamental categories to a small number of easily understood ideas; for example, activity level, smiling, fear of strangers, crying to limitations, soothability, and duration of attention to events. However, there is a small group of infants who, in addition to being minimally irritable, smile frequently, have a low heart rate, low muscle tension, and greater activation of the EEG in the left frontal area. A psychologist who invented a novel temperamental name for this combination of qualities could not ask a mother to rate her child on this quality for the parent does not have access to the child's biology.

If a majority of parents (or teachers) consistently provided accurate descriptions of children's behaviors,

questionnaires would be a preferred and valuable source of data. But, as with behavioral observations, this class of evidence has its special set of limitations.

First, parents vary considerably in the accuracy of their descriptions, where accuracy is defined by an objective record of the child's usual reactions. This variability among parents is due to differential comprehension of the questions, an understandable desire, often unconscious, to emphasize traits parents view as desirable and to deny features that do not fit the parents' ego ideal, and variation in the extensiveness of parental retrieval of the child's past behaviors. For example, parents of 9-month-olds did not agree in their attribution of fearfulness, smiling, or sociability to their infant because the fathers interpreted high activity levels in the young child as reflecting a positive emotional mood, whereas the mothers regarded the same behavior as reflecting anger (Goldsmith & Campos, 1990).

One reason for the discrepancies between two informants, or between a verbal description and behavioral observations, is that a person's verbal products, whether answers to interview questions or checkmarks on questionnaires, have special features that are not characteristic of the phenomena the sentences are intended to describe. Sentences demand logical consistency, possess a structure different from that of the events they intend to describe, and pass through a psychological filter that evaluates their social desirability. Over 35 years ago, Charles Osgood and his colleagues (Osgood, Suci, & Tannenbaum, 1957) demonstrated that people from many different cultures use the evaluative contrast good versus bad as a first dividing principle when they categorize people, objects, and events. Most parents, too, impose a construction on their child's behavior that represents their conception of the ideal child. The parent who wants an outgoing child and is threatened by a quiet one may deny extreme shyness and exaggerate sociability. This evaluative frame colors informants' answers to all questions.

Individuals are sensitive to the logical consistency in a series of related sentences. If a mother says (or checks on a form) that her child is happy, there will be resistance to acknowledging that her child occasionally feels sad, tense, or anxious. There is no such demand for consistency in a person's behavior or physiology.

Each verbal description of a child competes with a nonverbal representation composed of prior experiences with the child. The verbal categories invite a consistency to which the perceptual schemata are indifferent.

Verbal descriptions pass through a psychological filter that removes inconsistency and exaggerates small differences to create a clearer, more consistent, and more desirable picture of the child. An infant who both smiles frequently to playful bouts but also cries to frustration presents an inconsistent profile with respect to the complementary notions of a happy or unhappy infant. As a result, many parents exaggerate one of these profiles and mute the other to avoid the inconsistency. Hence, they are likely to tell the interviewer that their baby is usually happy or usually irritable but not both (Goldsmith & Campos, 1990).

Most words refer to discrete categories of events, making it difficult to describe blends. There is no English word that describes the feeling generated when one hopes for good news about a hospitalized loved one but fears the worst, or the feeling that combines the satisfaction experienced when a misfortune befalls an enemy with the guilt over the malevolent wish. Languages are not rich enough to describe all the important feelings and behaviors that are part of the human competence. Hence, questionnaires must use the best words available, even though they may be inadequate.

Further, every sentence assumes, often tacitly, a comparison. When a parent reads the sentence "Does your child like to go to parties?" she unconsciously compares that preference with others. If one parent compares "going to parties" with an activity the child dislikes, while a second parent compares it with one that is also preferred, the former parent is more likely to endorse the item, even though both children may like parties equally well.

When the question asks about an emotion, like cheerfulness or fear, the opportunity to emphasize different features of a concept is enhanced. If the investigator and the parent have different features of the concept in mind, each will impose a different meaning on the question. Wittgenstein (1953) suggested in *Philosophical Investigations* that every sentence, written or spoken, assumes a comparison context. When a mother answers a query about her child's fear of strangers, she is unconsciously comparing her idea of fear with related concepts that might refer, for example, to anger, sensitivity, or developmental maturity. Psychologists cannot expect uniformity among parents in the outcome of those comparisons and, as a result, similar parental replies can have different meanings (see Forman et al., 2003).

Variation in the parents' experience with children can also be important. A young mother with her first infant has a less accurate base for judging her child than a parent who has had three children. The level of agreement between descriptions of infants by primiparous mothers and laboratory observations of the same child are poorer than the agreement between the laboratory observations and the reports of mothers who have had more than one child (Forman et al., 2003). Mothers with their first infants are prone to describe them as more irritable and more demanding than more experienced mothers. But if the first child of the experienced parent were extremely irritable and the second only a little less irritable, but still more irritable than most children, the mother is likely to rate the second child as less irritable than observations would reveal because the mother contrasts the second with the first child. This phenomenon occurs with mothers of fraternal twins who usually rate the two siblings as much less similar than observers do because the mother exaggerates the differences between them (Kagan & Saudino, 2001).

Every mother watching her child retreat from an unfamiliar adult does not conclude that her child is afraid of strangers. A mother might (a) generate no categorization, (b) regard the child as tired, (c) categorize the stranger as ominous, or (d) conclude that the child is behaving adaptively with a stranger. This example, and many others like it, is stored in the parent's long-term memory until the day the psychologist asks, "Is your child afraid of strangers?" The consequences of reading a question are difficult to predict because the psychologist does not know the categories a parent used to store and to retrieve the relevant past observations of their child or the parents' state at the moment they were being questioned. This suggestion is supported by the fact that the social class and personality of the parents influence their descriptions of their children. Mothers who never attended college describe their infants as less adaptive and less sociable than college-educated parents (Spiker, Klebanov, & Brooks-Gunn, 1992). Mothers experiencing stress, for whatever reason, have a lower frustration tolerance and, therefore, are prone to exaggerate their infant's irritability. Depressed mothers with their first child described their 6-week-old infants as more irritable than did experienced mothers or mothers free of depression (Green, 1991). The ratings made by depressed mothers of the irritability of their 6-month-olds were poorly correlated with laboratory observations, while

the ratings made by healthy mothers were somewhat more accurate (Forman et al., 2003).

Mothers who described their children on the Carey Temperament Questionnaire as difficult were more anxious, suspicious, and impulsive than mothers who described their children as easy (Vaughn, Bradley, Joffe, Seifer, & Barglow, 1987; see also Matheny, Wilson, & Thoben, 1987; Mebert, 1991 for similar results). On some occasions, questionnaire evidence leads to conclusions that violate both biology and common sense. One team of investigators interviewed 794 pairs of adult female twins about their physical health and emotional states. The replies to these questions posed by a stranger, revealed the surprising fact that self-esteem was as heritable as physical health (Kendler, Myers, & Neale, 2000). We suspect that had the evidence consisted of a physical examination with laboratory tests and direct observations of behavior, the results might have been different.

An exhaustive review of the degree of agreement among parents, teachers, and peers with respect to the occurrence of children's behavioral and emotional problems, in over 269 samples, revealed poor concordance among different informants as to whether a child was fearful, aggressive, or impulsive. The average correlation between two informants was less than .3 (Achenbach, 1985; see also, Klein, 1991; Spiker, Klebanov, & Brooks-Gunn, 1992).

These limitations, inherent in questionnaire data, are the major reason why the relations between parental reports and behavioral observations for apparently similar traits, are usually low to modest. For example, the stability of behavioral observations of shyness and fearfulness from 14 to 36 months in a large study of same-sex monozygotic and dizygotic twins was significantly smaller than the stability of parental ratings of the same qualities (.3 versus .6; Kagan & Saudino, 2001; see also Guerin & Gottfried, 1994; Fagot & O'Brien, 1994; Plomin & Foch, 1980). Moreover, the heritability of the behaviorally based indexes of inhibition to unfamiliarity decreased with age, while the heritability of the parental descriptions of a similar quality increased with age (Emde & Hewitt, 2001). The heritability of behavioral observations of inhibition from 14 to 36 months decreased from .51 at 14 months to .24 at 36 months, while the heritability of parental descriptions of similar behaviors increased from .21 at 14 months to .37 at 36 months. At some ages, the heritability of parental rat-

ings of avoidant behavior in the child was close to 1.0—a value so high it is likely that the parents' ratings were a serious distortion of the children's actual behavior (Kagan & Saudino, 2001; see also, Saudino, McGuire, Reiss, Hetherington, & Plomin, 1993; Rose, 1995).

A well-designed study assessing the accuracy of parental descriptions of children's behavior with strangers in an unfamiliar situation revealed that the mothers' descriptions were only accurate for preschool children who were extremely shy or extremely sociable with a stranger in a laboratory setting. The parental ratings were not correlated with the child's behavior for over 80% of the sample because many mothers who described their child as sociable had children who were very shy with a stranger in the laboratory (Bishop, Spence, & McDonald, 2003). Rosicky (1993) compared the laboratory behavior of 135 1-year-olds to four events that often elicit a fear reaction—for example, a toy spider or masks—with the mothers' ratings of their children's fearfulness to these same events. The mothers were remarkably inaccurate in predicting how their child would behave.

In one investigation, 50 firstborn infants were observed at home weekly from 4 to 6 months of age. The parents and the observers were consistent over time in their independent evaluations of the baby's dominant mood, approach to unfamiliarity, activity, and intensity of response. But the correlations between the parents' ratings and the observers' evaluations of the same qualities were low (about .2). The authors wrote, "The most important implication of our findings is . . . a cautionary message about the large published literature based on parent report of their infant's behavioral style . . . mothers are a poor source of information about their infants' behavioral style" (Seifer, Sameroff, Barrett, & Krafchuk, 1994, pp. 1488–1489).

In a similar study, observers visited the homes of 5-month-old infants on two occasions and noted the frequency of smiling, vocalizing, fretting, crying, banging, and kicking. The observers also asked the mothers to make ratings of these same behaviors in their infants. Once again, the two sources of data were in poor accord; the correlations averaged only about .2 (Bornstein, Gaughran, & Segui, 1991). There is not even a positive correlation between the degree of intentionality actually displayed by 9-month-old infants in a laboratory and the degree to which their mothers attributed intentionality to their infants on a questionnaire (Reznick, 1999).

Thus, both theoretical analyses and empirical data imply that generalizations about behavior and emotion that are based only on questionnaires (or interviews) have a special meaning. Norbert Schwarz (1999) notes that “retrospective behavioral reports are highly fallible and strongly affected by the research instrument used” (p. 100). “We view our questionnaires as measurement devices—what we overlook is that our questionnaires are also a source of information that respondents draw on in order to determine their task and arrive at a useful and informative answer” (p. 103).

The writer Julia Blackburn (2002) captures the slipperiness of words:

I suppose I have often mistrusted the spoken word. You give a quick tug on the line, and out they come from the dark continent of the mind. Those little raps of sound that jostle together, shoulder to shoulder and supposed to be able to give shape to what you really think or feel or know. But words can so easily miss the point. They drift off in the wrong direction, or they insist on providing a clear shape for something that by its very nature is lost when it is pinned down.

## SUMMARY

Even though parents have opportunities to observe their children in a variety of natural situations over long periods, and laboratory contexts are often artificial and the observations of short duration, there are unique influences on parental, teacher, or peer descriptions that are absent when behaviors requiring minimal inference are recorded on film and coded by disinterested observers.

We are not the first to question the validity of parental reports when they are intended to describe how the child behaves rather than the parents’ conceptions of their children’s behaviors. Over 65 years ago, a team of child psychologists noted the poor relation between what actually happened during the 1st year of an infant’s life and the maternal descriptions of those events less than a year later (Pyles, Stolz, & MacFarlane, 1935; see also Yarrow, Campbell, & Burton, 1970).

It is possible that the verbal categories parents use to describe their children’s behavior, compared with the categories derived from frame-by-frame analyses of children’s behavior, are incommensurable (Goldsmith, Lemery, Buss, & Campos, 1999) because the concepts used to describe the analyses of the films do not exist in the vocabulary of the parents. For example, the language

used by Ekman (1992) and Izard (1991) to describe brief changes in facial muscles award meanings to words like *anger* or *fear* that are different from those understood by parents or observers watching one child strike another or flee from a large animal.

If asking parents about their children’s behavior and moods were an accurate source of information, the field of personality development would be one of the most advanced domains in the social sciences. Many investigators have asked parents to describe their children and have used the data to construct theories. We interpret the limited progress to mean that verbal statements by parents, teachers, or friends, have some, but limited, value. Over 20 years ago, Bates (1983) noted, “Empirical and theoretical considerations call into question the assumption that parent reports of a difficult temperament are essentially measures of characteristics residing within the child” (p. 95). Stifter and Wiggins (2004) affirmed that conclusion 21 years later, “parental reports of infant temperament and difficultness may be influenced by factors that have little association with infant emotionality and behaviors” (p. 88).

Thus, the review of empirical research that follows will not, with some exceptions, cover the very large number of reports that have relied on parental questionnaires as the only source of evidence. The preceding discussion was detailed because it is a defense of that decision.

If, as we believe, future discoveries of theoretical significance are likely to come from behavioral observations combined with parental or teacher reports, rather than from either source of data alone, we should not treat conclusions based on any one of these sources of information as having equivalent meaning to the other. Georg von Bekesy, recipient of a Nobel Prize for research on hearing, once advised a young instructor worried about his research career: “The method is everything.” The older scientist explained that he always measured a phenomenon with at least five different methods on the assumption that the features shared across them might reveal the critical properties of the phenomenon of interest (Evans, 2003). Our constructive conclusion is that each method—questionnaire, behavioral observation, or biology—provides different information and requires distinct concepts. We do not suggest that questionnaire evidence be ignored, only that investigators who rely only on this procedure recognize that the validity of their inferences is restricted to this class of information and is not a proxy for direct observation. The same caveat applies to those who rely only on behavioral data.

The authors believe, although they remain ready to be proven wrong, that future research will reveal that substantial theoretical progress will follow greater reliance on a combination of informant report and behavioral observations gathered across diverse settings.

## CONTINUOUS TRAITS OR CATEGORIES

A final source of disagreement is whether a temperamental category should be conceived of as a continuum or as a qualitative category (Meehl, 1973, 1995).

A central tension in empirical studies of individual differences is whether people differ quantitatively on the same set of dimensions—therefore, each individual is described best as a set of values on factor scores—or whether some individuals belong to qualitative groups. A strong bias for simplicity favors continuous functions over categories. The theoretical power and popular success of relativity theory in physics supports this bias. Einstein suggested that, in the frame of an observer, objects shorten as their velocity approaches the speed of light. To universalize this law in the service of parsimony, he suggested that this shortening occurs even when a person swings her tennis racket, although the velocity is so small the shortening of the object is not detectable with any instrument. However, water does not begin to form very tiny ice crystals as it cools from 30° to 28° centigrade. The function relating temperature to the formation of ice is nonlinear.

Nonlinear functions are common in the life sciences and, at transition points, novel qualities, which can be viewed as categories, emerge. For example, the behavior of a single ant, or a small number, appears random and without coherence, but, “When the density of a colony reaches a critical value . . . chaos begins to turn into order and rhythmic patterns emerge over the colony as a whole” (Goodwin, 1994, p. 189). A large colony of ants has distinct qualities that cannot be predicted from or explained by an additive model that sums the behavior of a large number of ants considered one at a time.

Nonlinear functions are common in many domains of psychology; for example, the magnitude of potentiated startle in a rat has an inverted-U function with intensity of shock during training (Davis, 1984). Thus, current statistical procedures like regression can distort relations in nature (see Hinde, Tamplin, & Barrett, 1993, for a similar position). These analytic procedures assume that the forces producing the values for the vari-

ables under study are the same at all ranges; the force varies only in magnitude. This persistent preference for continua, although tacit, has been inimical to progress in psychology. A biologist phrased the case well for qualitative categories: “The study of biological form begins to take us in the direction of a science of qualities that is not an alternative to, but complements and extends, the science of quantities” (Goodwin, 1994, p. 198).

Thomas and Chess (1977) regarded the three major types of children—easy, difficult, and slow to warm up—as categories, but treated the variation in each of their nine dimensions as continuous. They wrote about the approach-withdrawal dimension as if all infants could be placed on a continuum with respect to the tendency to withdraw or to approach unfamiliar events. By failing to say otherwise, they seemed to reject the possibility that infants who rarely approach unfamiliar people might be qualitatively, not just quantitatively, different from those who occasionally avoid strangers. It is likely, however, that extremely shy children are qualitatively different from those who are moderately shy. One reason is that extreme shyness, which is characteristic of a very small proportion of children, is linked with other characteristics that seem unrelated to shy behavior, including eye color, asymmetry of EEG activation, and sympathetic reactivity. Support for this claim is presented later in this chapter.

One reason psychologists have preferred continua over categories is a derivative of the contagion of ideas among disciplines. Before relativity theory, physicists assumed that object and energy were qualitatively different things. A burning log was distinct from the heat or energy the log emitted. Einstein suggested, however, that there was only the field and, therefore, only energy: “The difference between matter and field is a quantitative rather than a qualitative one” (Einstein & Infeld, 1938, p. 242). Surely, if a log and the heat it can emit can be placed on an abstract continuum of energy, psychologists could defend the notion that no individual is qualitatively different from anyone else on any psychological dimension.

A more obvious, and perhaps less controversial, reason is the training in statistics given to young psychologists. By World War II, the use of inferential statistics became the mark of the sophisticated social scientist. The correlation coefficient, *t*-test, and analysis of variance should be computed on continuous variables. Hence, psychologists found it useful to assume that there were no qualitative types of people; all humans could be treated

as substantially similar in their sensations, perceptions, memories, and emotions. Statistical analyses were performed on continuous scores produced by different experimental conditions, not by different kinds of people.

The domination of research in both personality and development by analysis of variance and regression has frustrated a small group of investigators who have had the intuition that some subjects are qualitatively different from the majority in their sample. However, when the group of subjects is small in number, the usual inferential statistics often do not reach the popular .05 level required for referee approval. Further, there is no consensus on an algorithm that permits an investigator to conclude that some subjects belong to a distinct group. Consider, as an example, an investigator who did not know about Down syndrome studying the relation of maternal age to children's intelligence in a sample of 600 families. The correlation between the two variables would reveal no statistically significant relation. However, examination of a scatter plot might reveal that two children with very low IQ scores had the two oldest mothers in the sample. Reflection on that fact might tempt the investigator to consider the possibility that these two children were qualitatively different from the other 598 and, perhaps, that these two families provided a clue to a relation between age of mother and intelligence of the child for a very small proportion of the population. Hence, there is an initial enthusiasm for considering individual cases and small subgroups with extreme scores.

## **CURRENT VIEWS OF THE INFANT**

Current ideas on temperament vary with the developmental stage of the subject and the sources of evidence; hence, this discussion accommodates to these factors. It is also necessary to impose a conservative attitude toward evidence. Infants and children differ on a large number of characteristics and it is unlikely that most of this variation is temperamental in origin, even though an investigator conducting a cross-sectional study may claim otherwise. Thus, we restrict this discussion to a small number of characteristics for which the evidence implies a temperamental contribution to avoid the error psychologists made a half-century earlier when they assumed that all variation was due to social experience.

Aesthetic considerations influence the selection of scientific strategies. Western standards of beauty in science celebrate two forms of discovery. In the natu-

ral sciences, especially biology and chemistry, experimental control of a phenomenon through techniques that rely on machines generates an aesthetic feeling. A second route to beauty is through elegant formal theory that presumably explains diverse phenomena. Einstein's theory of relativity is a classic example. Because no student of temperament can gain experimental control of a child's behavior, most psychologists in this domain drift toward the invention of theoretical ideas that might provide an aesthetic structure to the phenomena of interest.

It is natural to ask ontological questions when a domain of inquiry is young. The Greeks asked, "What is matter?" Twentieth-century physicists have answered that question with a set of mathematical functions that predict and, therefore, presumably explain the events that follow the bombardment of a hydrogen atom with high energy. Eighteenth-century naturalists asked, "What is a species?" Biologists answered with a set of relations among the evolutionary histories, anatomical and physiological features, and profiles of interbreeding among different animals. In most natural sciences, except psychology, a set of functions replaced abstract Platonic conceptions of an event—a set of empirical relations became the answer to the earlier ontological query.

Replacement of Platonic definitions with robust functions is moving at a slower pace in developmental psychology. Many journal reports still begin with an ontological definition of a concept, like coping, secure attachment, empathy, or reactivity rather than with a concept that was invented *a posteriori* to explain observations. Thomas and Chess (1977), for example, define temperament as the style of a person's behavior; Goldsmith and Campos (1990) regard temperaments as processes that modulate an emotional profile. These *a priori* declarations are useful early in the investigation of a domain, but they limit the scope of empirical work and should be abandoned when new evidence erodes their usefulness.

All observers recognize that variation in irritability is a moderately stable characteristic in the 1st year and psychologists could declare that irritability is a temperamental trait. However, after the second birthday, many infants who had been highly irritable lose this quality and become timid. Thus, either a new term is needed to describe this class of 2-year-old or the investigator can move up the ladder of abstraction and suggest that "ease of arousal" is the temperamental quality that explains the relation between infant irritability and subdued behavior in a 2-year-old. One problem with this solution is

that some infants display “ease of arousal” by babbling, rather than crying, and these children develop behavioral profiles different from those who are irritable.

We do not suggest that psychologists abandon ontological questions, only that they remain receptive to evidence and move toward concepts defined by a set of related functions. For example, 20% of healthy 4-month-old infants become very active and fretful to auditory, visual, and olfactory stimuli; two-thirds of these easily aroused infants become fearful in the 2nd year. This relation begins to define a temperamental type that future investigators will refine. One can emphasize the 4-month behavior and call these infants easily aroused, or focus on the timid behavior at 2 years and call these children fearful. This choice is less important than appreciating that the primary meaning of either term is a set of developmental functions. New temperamental concepts will be needed once we have learned more about development. We should not treat a temperamental bias as an essence. The psychological outcomes of each temperament will be informed by the historical era and culture in which children grow and the specific experiences they encountered. The biological conditions that are the foundation of a temperament do not produce any single or fixed profile later in life; they only set a bias for a particular envelope of outcomes.

### **Rothbart’s Dimensions**

Mary Rothbart’s bold, synthetic ideas dominate discussions of infant temperament. Rothbart (1989) posits two primary dimensions on which infants vary—ease of arousal and self-regulation—and both are controlled continually by the social environment:

Temperament [is defined as] constitutionally based individual differences in reactivity and self-regulation, with constitutional referring to the person’s relatively enduring biological makeup inferred over time by heredity, maturation, and experience. Reactivity refers to the arousability of motor activity, affect, autonomic and endocrine responses. Self-regulation refers to processes that can modulate (facilitate or inhibit) reactivity and those processes include attention, approach, withdrawal, attack, behavioral inhibition, and self-soothing. (p. 59)

### **Reactivity**

Reactivity can reflect pleasant or distressed states. The referents for the former category are vocalization, smiling,

and nondistressed motor activity; the referents for the latter are thrashing, fretting, and crying. A low-intensity stimulus usually produces vocalization and smiling; a moderately intense stimulus leads to vocalization or fretting; an intense stimulus more often provokes cries of distress. Rothbart (1989) suggests that either a pleasant or unpleasant state can be expressed through somatic, cognitive, or neuroendocrine responses and experienced as a feeling of pleasure or distress. The valence linked to the state of the reactivity—whether pleasant or unpleasant—will influence the specific self-regulatory reactions displayed. Thumb sucking, clutching a part of the body, or moving toward or away a novel incentive are three obvious self-regulatory reactions.

The idea of reactivity has obvious face validity. Fetuses and newborns differ in their reactivity to stimulation, and the variation is related to a modest degree to early postnatal behavior (Madison, Madison, & Adu-bato, 1986; Strauss & Rourke, 1978). In addition, maternal reports of fetal movements are moderately stable from gestational weeks 28 to 35 (Eaton & Saudino, 1992). DiPietro and colleagues (DiPietro, Hodgson, Costigan, & Johnson, 1996; DiPietro et al., 2000, 2002) examined the relation between fetal activity and heart rate (beginning at 20 weeks of gestation), on the one hand, and infant temperament at 3 and 6 months, using the ICQ, on the other (Bates, Freeland, & Lounsbury, 1979). High levels of fetal activity predicted irritability and a less adaptive profile (a factor on the ICQ) when the infants were 3 and 6 months old (DiPietro et al., 1996). In a separate study, individual differences in heart rate were preserved from 24 weeks of gestation through 1 year postnatal (DiPietro et al., 2000). However, the evidence on fetal activity from this second sample led to conclusions slightly different from those implied by the earlier investigation. More active fetuses showed less distress to limitations when they were 1 year old and were less behaviorally inhibited at 2 years of age (DiPietro et al., 2002).

The specific source of the arousing stimulation, whether visual, tactile, olfactory, or auditory, cannot be ignored when classifying an infant as high or low in reactivity to stimulation. Four-month-old infants who cry to the recorded voice of a woman speaking short sentences are not psychologically similar to those who cry to a moving visual stimulus. Goldsmith and Campos (1990) found no correlation between an infant’s tendency to cry when placed on the visual cliff and the following encounter with a stranger.

The nature of the response is also important in judging the infant's reactivity. Infants can cry, fret, smile, move, or vocalize to auditory stimuli; and do or do not struggle to restraint of their arms. An infant's preferred reaction to a particular incentive is due, partly, to temperamental and maturational factors that are not yet understood. For example, in a longitudinal sample of 23 infants observed at 7, 10, 13, and 16 weeks, an index of motor arousal to varied stimuli based on limb movement increased with age, while the frequency of tongue protrusions, vocalization, and crying decreased with age. Only individual variation in tongue protrusions was stable from 7 to 16 weeks (Rezendes, 1993).

Thus, a potential problem with the concept of reactivity or "ease of arousal" is an indifference to the exact nature of the incentive. The brain circuits that mediate smiling are likely to be different from those that mediate babbling or thrashing (Gainotti, Caltagirone, & Zoccolotti, 1993).

### *Self-Regulation*

The concept of self-regulation is a derivative of two older ideas: The first originates in the learning theories of the 1950s; the second in Freud's writings. Dollard and Miller (1950) suggested that a reinforcement was any event that reduced stimulation and level of internal arousal. This hypothesis is derived from Freud's suggestion that humans seek quiescence and a reduction in the vis nervosa. This hypothesis assumes, as a deep premise, that organisms naturally seek a low—or optimal—level of internal arousal. This idea remains popular despite the fact that children prefer to run rather than to sit and to explore rather than to sit quietly with a new toy.

Freud changed the internal state that caused symptoms from the popular vis nervosa to anxiety, which was attractive to many readers. Freud added that cognitive, affective, and behavioral reactions to anxiety were directed at reducing the intensity of this unpleasant state. Because anxiety is an obvious enemy, the responses to it could reasonably be called defenses. This idea, which remains popular among psychiatrists and psychologists, renders the concept of self-regulation appealing.

The idea of self-regulation, however, shares some of the same problems that burden reactivity. A 1-year-old infant who shows a wary face to a stranger and then retreats to the mother may be different temperamentally from one who also displays a wary face but does not retreat and, subsequently, vocalizes to the intruder. Even though both infants may appear to be regulating the un-

certainty generated by the unfamiliar adult, the former infant becomes more timid and shy in the 2nd year than the latter. Because all infants do something when aroused by events, most regulate to some degree. It is important to attend to both the specific source of the arousal and the specific self-regulatory behaviors that follow, because different temperamental types may be hidden in these categories.

Although self-regulation seems an apt way to describe some infant behaviors, it may be less appropriate for older children because the incentive is not an intense stimulus that produces a level of arousal, but is often an unfamiliar event. When an adult dressed as a clown enters a room where a 2-year-old child has been playing quietly, most children stop playing and stare at the intruder. This stereotyped reaction occurs because the clown is a discrepant event, not because it is an intense stimulus, and children usually react to discrepancies with cessation of activity. But it is not obvious that the immobility, even if accompanied by retreat to the mother, is self-regulating for it may not reduce the child's arousal. Indeed, staring at an unfamiliar intruder while clutching the parent may increase the child's level of uncertainty and physiological arousal.

Two eminent students of animal behavior have noted "careful attention to specific patterns of behavior . . . is prerequisite to an understanding of the relation between biological and behavioral systems . . . an adequate description of behavior must include reference to the stimuli and situations that normally produce that behavior and to its normal consequences in the environment" (Blanchard & Blanchard, 1988, p. 63).

This suggestion is not intended to replace Rothbart's creative ideas. Rather, we urge psychologists to use her fruitful hypotheses while acknowledging Whitehead's (1928) admonition that we should not reason about predicates severed from their noun and object partners. The action verb *kiss* has very different meanings in the following three sentences: (1) The woman kissed her lover, (2) The baby kissed his grandmother, and (3) The winning jockey kissed his horse.

Biologists share a consensual meaning when they use a theoretical predicate. *Bleach* describes what rods in the retina do to light. *Phagocytosis* refers to what natural killer cells do to bacteria. *Digest* is what the intestinal villi do to proteins, fats, and carbohydrates. Social scientists are looser in their use of predicates. The predicate *learn* is often applied to diverse organisms, from worms to chimps, on the assumption that the process of

learning is the same in all animals. The indifference to agents and targets is due, in part, to the fact that psychologists are primarily interested in process rather than in the agents in whom the processes occur.

Because psychology is one of the least mature of the natural sciences, its practitioners are tempted to take as a model the highly respected discipline of physics. The Newtonian declaration that force equals mass times acceleration holds for all objects—cars, stones, and snowflakes—in all earthly situations. Einstein even declared that the laws of the theory of general relativity apply to all parts of the cosmos. If psychologists were friendlier to biology than to physics, they would realize that specificity, not generality, is the more useful rule in the life sciences.

## IRRITABILITY IN INFANCY

Studies of variation in irritability dominate all other infant qualities while studies of shy-timid versus sociable-bold behavior dominate investigations of children. These facts imply that scientists who quantified other behaviors found less stable, or less coherent, results and did not publish their data. It is hard to believe that most developmental psychologists have restricted their observations to these few characteristics and more likely that irritability in infancy and a timid or sociable posture in childhood are popular targets because they are obvious, relatively easy to code, and of concern to parents.

Extreme irritability in young infants is preserved to a modest degree through part or all of the 1st year. Crying and fretting are stable over the first 4 months, and newborn irritability predicts less frequent smiling and babbling to adults at 4 months of age (Birns, Barten, & Bridger, 1969). Newborns whose cries were of high pitch and of shorter duration—and unpleasant to the ear—were rated by mothers at 3 months as more irritable and difficult (Huffman et al., 1994). Extreme distress to a heel stick during the newborn period predicted degree of distress to an inoculation 2 months later (correlation of .4; Worobey & Lewis, 1989) and was related to maternal descriptions of the 6-month-old as minimally distressed by limitations, but not to maternal descriptions of soothability or frequency of smiling at 6 months (Gunnar, Porter, Wolf, Rigatuso, & Larson, 1995). Facial expressions, coded in the Ekman-Izard scheme as either anger or sadness, to an inoculation were

moderately stable from 2 to 19 months ( $r = .5$ ; Izard, Hembree, & Huebner, 1987). However, the frequency of spontaneous irritability should not be equated with ease of being soothed by a pacifier. Newborns who took a long time to be soothed by a pacifier were rated by their mothers at 9 months as more active and less likely to avoid unfamiliar events (Riese, 1995).

Some, but not all, irritable infants develop a reserved, timid, and fearful style in the preschool years. Four-month-old infants who showed frequent irritability together with vigorous limb activity to varied classes of stimuli were more fearful to unfamiliar events in the 2nd and 3rd years than those who showed only irritability without motor activity, or only vigorous motor arousal without irritability. Newborn twins who were unusually irritable, hard to soothe, and minimally attentive to stimulation were less sociable and more labile when they were 9 to 24 months old (Matheny et al., 1987). Similarly, newborns who became extremely irritable to a chilled metal disk placed against their thigh, compared with those who were far less irritable, became children with a more serious emotional demeanor ( $r = .36$ ) and less sociability ( $r = .38$ ; Riese, 1987). However, variation in crying is not always predictive of later behavior (see M. Fish, Stifter, & Belsky, 1991, for an example).

Although the evidence implies that extreme irritability to stimulation in the opening weeks predicts a less sociable, more dour child 6 to 24 months later, the crying behavior in most of these studies was either spontaneous or a reaction to varied stimuli. In a few studies, however, the crying was produced by the frustration of restraint, typically holding the infant's hands or arms. Infants who cry to this incentive, or any other frustrating event, may not have the same temperament as those who cry spontaneously to visual or auditory stimulation. Infants who cry to restraint have high vagal tone; infants who cry to visual or auditory stimulation have lower vagal tone (Fox, 1989).

The modest stability of variation in irritability over the first 2 years could be due to the fact that the incentives for crying change with age. Irritability in a 2-month-old is due, in large measure, to a low threshold of responsivity to the discomfort of cold, hunger, loud noises, and bright lights. Irritability in a 9-month-old is influenced in a more important way by threshold of reaction to unfamiliarity (Hebb, 1946). Irritability in a 1-year-old is influenced by a vulnerability to separation distress and prior conditioning experiences in which certain events have become acquired cues for distress.

By 3 years of age, the reasons for crying are more varied and include frustrations and prior reinforcements for crying. Thus, we should not be surprised that the correlation between irritability at 1 month and crying at 3 years is relatively low. Each of the small number of responses that children can display when distressed—crying, withdrawal, thrashing, or freezing—is preferentially elicited by different incentives and involves different brain circuits.

As might be expected, extremely irritable and nonirritable infants elicit different reactions from their mothers. A group of 89 lower-class infants were observed in the first 2 weeks of life on the Brazelton Neonatal Behavioral Assessment Scale. One group of 15 infants were extremely irritable and another group of 15 were minimally irritable; these groups represented the top and bottom 17% of the sample. These infants and their mothers were observed at home monthly over the first 6 months. The mothers of the highly irritable, compared with the minimally irritable, infants had less physical contact with their children but soothed them more frequently during the first few months. The mothers of nonirritable infants were more constant in their soothing overtures over time. However, the two groups of mothers became increasingly similar in their responsiveness as time passed. By 6 months, the two groups experienced similar maternal behaviors, and there were few differences between the infant groups in their behavior (Van den Boom & Hoeksma, 1994).

### *Smiling in Infancy*

Crying during the opening months is more salient and more frequent than smiling and, in addition, has an analogue in the distress calls of primates. Smiling has no obvious analogue in most animals; perhaps that is why fewer investigators have probed individual differences in infant smiling, even though variation in this response appears to be heritable (Freedman & Keller, 1963; Repucci, 1968). Frequent smiling to adults does not appear until about 3 months of age and may be impaired by damage to posterior sites in the right hemisphere (Reilly, Stiles, Larsen, & Trauner, 1995). Differences in smiling appear to be stable from 3 months to the end of the 1st year. In one study, variation in smiles to moderately discrepant events at 4 months predicted smiling following success on a cognitive test at 27 months of age, and variation in smiling is more stable over this period than variation in attentiveness, crying, or vocalization (Kagan, 1971).

Over half of a large sample of 4-month-olds never smiled to visual, auditory, and olfactory stimuli, while 10% smiled three or more times to the same incentives. Although three smiles may seem to be a small number in an absolute sense, it represented the 90th percentile of the distribution. When these high smiling infants were matched with infants of the same sex and level of motor arousal and irritability who did not smile at all, the former group had significantly lower sitting diastolic blood pressure when they were 21 months old. This result suggests that frequent smiling at 4 months is associated with low sympathetic tone in the cardiovascular system, an idea supported by the fact that 2-week-olds who showed high levels of heart rate variability to stimulation were frequent smilers at 4 months (S. Fish & Fish, 1995). Four-month-old infants who showed low levels of motor activity and crying to stimulation—called low reactive infants—smiled more frequently at 4, 14, and 21 months as well as at 11 years of age, compared with infants who showed high levels of motor activity and crying—called high reactive. The low reactive-high smiling children had low baseline heart rates when they were 11 years old (Kagan & Snidman, 2004). Thus, frequent smiling to nonsocial stimuli may reflect a special temperamental quality.

### *Activity in Infancy*

The popular temperamental trait called activity level changes its referential meaning between infancy and 3 years of age. Hence, it is not surprising that there is not much preservation of variation in activity level from infancy to the toddler years (Dunn & Kendrick, 1981; Feiring & Lewis, 1980; Matheny, 1983). One study assessed activity in 112 healthy, middle-class newborns using a pressure transducer mattress that distinguished activity during crying from activity during nondistress periods. Fifty of the 112 infants were assessed again when they were between 4 and 8 years of age. Activity in the older children was monitored for 24 hours using an ambulatory microcomputer along with a parental questionnaire. There was only a modest correlation between the vigor of activity during the newborn period and vigorous activity during the day in the older children ( $r = .29$ ). Further, there was no correlation between day and night activity in older children and no relation between newborn activity and parental ratings of activity in older children (Korner et al., 1985). The independence of day and night activity implies that a concept of general activity is not useful.

Activity level in monozygotic (MZ) and dizygotic (DZ) twins, assessed at 14, 20, and 24 months, was moderately stable and heritable (Saudino & Cherny, 2001). The stability coefficient from 14 to 24 months was only .23 and the heritability value .20 (see Saudino & Eaton, 1991, for a similar result with a smaller sample of twins, and Goldsmith & Gottesman, 1981). Matheny (1983) also reported very modest stability of activity in a laboratory from 6 to 24 months but a more robust heritability coefficient. Apparently, a general activity construct that does not stipulate age, context of assessment, or time of day is probably not theoretically useful.

### Attentional Processes

The discoveries of cognitive neuroscience have penetrated the study of temperament and led investigators to examine variation in the distribution of attention. Rothbart, Derryberry, and Posner (1994) describe three aspects of attention that might turn out to have a temperamental contribution.

Infants differ in the rapidity and consistency with which they orient to a moving object or a sound in the periphery. The posterior attention network is especially involved in directing an infant's attention to sensory stimuli. It is believed that the posterior attentional network involves portions of the parietal cortex, thalamus, and superior colliculus and activity in these sites is modulated by noradrenergic axons from the locus ceruleus.

The anterior attentional network involves parts of the prefrontal cortex, anterior cingulate cortex, and the supplementary motor area. This network participates more in effortful control of behavior and the inhibition of activity to distracting or irrelevant stimuli, as well as in the effortful search for specific targets. It is believed that dopaminergic inputs from the ventral tegmental area and the basal ganglia modulate this network.

Finally, Posner and Petersen (1990) posit a vigilance system that mediates maintenance of an alert state over a prolonged duration. Preliminary evidence implicates the role of the right lateral midfrontal cortex as important, which, like the posterior system, is influenced by noradrenergic axons from the locus ceruleus.

Observations of children at 1, 2, and 3.5 years of age revealed stability of inattentiveness from 2 to 3.5 years of age (Ruff, Lawson, Parinello, & Weissberg, 1990). Distractability in a laboratory playroom—flitting from one toy to another—in a sample of 3.5-year-old children showed a modest association with teacher ratings of hyperactivity at 6 to 8 years of age (Carlson, Jacobvitz, &

Sroufe, 1995; Riese, 1988). A longitudinal study of variation in attentiveness, indexed by duration of fixation time to human faces or forms, revealed no stability from 4 months to 13 or 27 months, and only modest stability from 13 to 27 months ( $r = .2$ ), and parental education predicted attentiveness for girls but not boys in the 2nd year (Kagan, 1971). Further, variation in infant attentiveness was not related to the child's IQ or reading ability at 10 years of age (Kagan, Lapidus, & Moore, 1978). Because the psychological bases for attentiveness to an event change from attention to discrepancy at 4 months to the activation of cognitive structures in the 2nd year, we should not expect much preservation of long or short periods of attentiveness to new events.

In sum, irritability, smiling, activity, and attention are probably influenced by temperamental biases and each is usually assessed in parental questionnaires for temperament (see Goldsmith & Rothbart, 1991).

### TEMPERAMENTS IN OLDER CHILDREN

The most popular temperamental qualities in children older than age 2 bear some resemblance to those studied in infants, even though new characteristics emerge after the first birthday. Bates (1989) summarizes some of these qualities. The concept of *negative emotionality* refers to the display of distress, fear, and anger and is similar in sense meaning to one of the three major adult temperaments proposed by Buss and Plomin (1984). A second factor is *difficultness*, a derivative of the Thomas and Chess category that refers to irritability, a vulnerability to stress, and a demanding posture with adults. Bates (1980) acknowledges that this quality is, in part, a construction on the part of the parent. A third, *adaptability to novelty*, describes a child's tendency to approach unfamiliar events and situations. *Reactivity*, a fourth category, is close in meaning to Rothbart's (1989) definition, and *activity* is a fifth temperamental factor. *Attention regulation*, which refers to the tendency to shift attention when distracted by external stimulation, resembles Rothbart's (1989) infant quality of soothability. And Bates (1989) suggests that *sociability and positive reactivity* comprise important temperaments. Finally, Eisenberg et al. (2003) argue that the variation among school-age children in the ability to regulate emotion and relevant behaviors represents important traits that might have a temperamental origin. This regulation can be voluntary or involuntary, and can be influenced by the quality of parental emotional reactions

toward the child (Eisenberg & Spinrad, 2004). These categories may turn out to be stable, but at the present time the evidence is most extensive for the reaction to unfamiliar events and situations. We now summarize this evidence.

### **Reaction to Unfamiliarity**

Two temperamental categories studied extensively refer to a child's reaction to an unfamiliar person, object, event, or context, whether affective restraint, caution, or avoidance, on the one hand, or a spontaneous approach, on the other. The reaction to an unfamiliar event depends on whether it is perceived as a threat, the ease with which it is assimilated, and the availability of an appropriate response. All 1-year-olds reach toward a new toy after playing with a different one because the new object poses no threat, is assimilated at once, and a relevant action is available. However, not all 1-year-olds reach toward a stranger who has extended a hand because this event is not assimilated quickly, and the child is uncertain as to what response to display. Thus, children, like adults, live in a corridor bordered on one side by the appeal of new experiences and, on the other side, by fear of the unfamiliar.

There are three good reasons for an interest in the reaction to unfamiliarity. The relevant behaviors are moderately stable, easily quantified, and the intraspecific variation in these behaviors is present in almost every species studied, including mice, rats, wolves, dogs, cows, monkeys, birds, and fish. For example, the reactions to novel objects among infant monkeys reared either with a female dog or a fur-covered plastic toy were assessed regularly in the laboratory. The behavioral variation in the reaction to novelty during the 3rd year was more clearly a function of the animal's early temperamental bias to remain close to or distant from its surrogate object (the dog or the toy) than to the different conditions of rearing (Mason & Capitanio, 1988).

There is preservation of a timid compared with a nontimid reaction to unfamiliarity when behavior or questionnaire data comprise the evidence (Stevenson-Hinde & Shouldice, 1996). A group of over 1800 Canadian children were rated for fearfulness, prosocial behavior, and restlessness by different teachers from kindergarten through grade six. Most children rated as very high or low in fearfulness when they were in kindergarten were given a similar rating when they were

in the sixth grade (Cote, Tremblay, Nagin, Zoccolillo, & Vitaro, 2002; see also Rimm-Kaufman et al., 2002). A longitudinal study of non-European infants adopted by Dutch parents confirms the preservation of a bias for shy and/or anxious behavior. Young children who had been described by their adopted mothers as shy and prone to a dysphoric mood in the 2nd year were most likely to show internalizing traits when they were 7 years old. Neither the family's social class, nor the mother's early sensitivity with the infant predicted these qualities at age 7 (Stams, Juffer, & van Ijzendoorn, 2002).

The heritability of inhibited or uninhibited behavior to unfamiliarity, based on behavioral observations of a large sample of monozygotic and dizygotic twins observed at 14, 20, 24, and 36 months approached .5 (Kagan & Saudino, 2001). Inhibited children remained close to their mother and avoided playing with both toys and peers, while uninhibited children showed the complementary behaviors. Heritability estimates were over .90 when the sample was restricted to children who were extremely inhibited or uninhibited in a play session consisting of four children (DiLalla, Kagan, & Reznick, 1994). However, only 10% of the children were consistently shy and inhibited at all four ages from 14 to 36 months (Kagan & Saudino, 2001).

Longitudinal data from the Berkeley Guidance Study reveals that boys described by their mothers as very shy in late childhood had distinct traits when they were over 40 years old. The adults who had been shy married, became parents, and established a career later than their less shy peers. Very shy girls, on the other hand, married at normative times but, unlike their less shy peers, did not develop a career, terminated a job when they married or had a child, and conformed to the traditional sex-role norms for that era in American history (Caspi, Elder, & Bem, 1988).

Longitudinal observations of a large group of New Zealand children affirm the preservation of a shy profile. Over 1,000 3-year-olds were rated on a variety of characteristics following a 1-hour interaction in a laboratory setting. About 15% were rated as shy and subdued, and 30% as sociable and spontaneous. When these same subjects were 18 years old, they filled out a personality questionnaire. The adolescents who had been shy at 3 years of age described themselves as cautious, minimally aggressive, and likely to avoid dangerous situations (Caspi & Silva, 1995).

Not all shy, timid, 2- or 3-year-olds become excessively shy adolescents because parents, teachers, and peers have encouraged bolder behavior, and because the shy, inhibited children try to develop a more relaxed, sociable profile. Those who are unsuccessful may have had a different set of experiences. Rubin and colleagues (2002) found that 2-year-olds who were inhibited in the laboratory setting were only likely to preserve that style if they had intrusive, hypercritical mothers. The shy 2-year-olds were less likely to remain reticent if their mothers discouraged shyness (Rubin, Burgess, & Hastings, 2002). The change from shy to sociable behavior is of course more likely in cultures, like our own, that favor the latter as an ideal. This is less likely in Asian cultures which favor a quiet, less bold child (Kerr, Lambert, & Bem, 1996; Rickman & Davidson, 1994).

There is an intriguing relation between season of conception and observer ratings of shyness in both American and New Zealand samples. The preschool children in a large American longitudinal cohort, the National Longitudinal Sample of Youth (NLSY), were rated on shyness by trained home visitors on two different occasions. The 15% of the sample who were rated as very shy on both occasions, separated by 2 years, were most likely to be conceived during the period from late July to late September. Thus, the brain would be completing its basic organization during the period of September to November when the amount of daylight is decreasing most rapidly. The New Zealand children who were rated as shy were most likely to be conceived in January and February. Because New Zealand is in the Southern Hemisphere, daylight begins to decrease during these 2 months. Thus, both groups of fetuses who became shy children spent the first 4 months of their gestation at a time of decreasing daylight (Gortmaker, Kagan, Caspi, & Silva, 1997). The decrease in daylight is accompanied by increases in level of melatonin but decreases in serotonin in the pregnant mother. It is possible that these biochemical changes affect the brains of those embryos who are genetically disposed to develop shyness and increases the probability of that behavioral outcome. Nature can act in surprising ways.

We noted a modest positive relation between infant irritability and a shy profile in the older child. However, as with irritability, a shy posture with children or adults can have different antecedents and, therefore, different meanings. A 4-year-old in a social setting can play alone because (a) uncertainty is generated over the unfamiliarity of the setting, (b) the child feels concern over being evaluated by others, (c) the child prefers to play alone, or (d) the child has experienced traumatic, fear-arousing encounters with other children and has developed a conditioned avoidance to peers. An investigator who codes only "time playing apart from other children" could have etiologically heterogeneous groups with similar scores. On the other hand, if the investigator codes several variables—time playing alone, time staring at peers, talking, smiling, and reaction to overtures from others—it will be easier to parse the isolated children into separate groups, only some of whom possess a temperamental bias to be shy. Every class of behavior is ambiguous as to its antecedent conditions.

The research of Rubin and his colleagues, which relies on behavioral observations, is exemplary. Rubin (1993) makes a distinction between the child who plays alone but who shows signs of anxiety (called reticent) and the equally solitary child who is actively engaged in activities but who does not show signs of uncertainty (called solitary-passive). Both types are stable over time, but the former more often stares at peers and resembles the behaviorally inhibited child (Coplan, Rubin, Fox, Calkins, & Stewart, 1994). *Social reticence* is characterized by an absence of social interaction with others, especially staring at peers while being unoccupied. Other children who also play alone explore objects or engage in constructive behaviors and these children are called *solitary-passive* (Rubin, 1982). Preschool children who are solitary-passive show neither signs of anxiety nor do they display internalizing or externalizing symptoms (Rubin, Coplan, Fox, & Calkins, 1995). Further, 2-year-olds who were able—or motivated—to tolerate a two-minute delay before engaging in an interesting activity (because the examiner made that request) and, in addition, were behaviorally inhibited were most likely to be reticent with peers when they were 4 years old (Henderson, Marshall, Fox, & Rubin, 2004).

Asendorpf (1991) also finds shy behavior to be stable over time, although more intelligent children show a greater decrease in shyness over time compared with their less intelligent peers (Asendorpf, 1994). Shy, reticent behavior with strangers was stable in a group of 99 German children observed in varied settings from the preschool years through the third grade ( $r = .6$ ; Asendorpf, 1990). Asendorpf agrees with Rubin that a child can be shy because of the unfamiliarity of the situation, a concern over evaluation of task competence by

Asendorpf (1991) also finds shy behavior to be stable over time, although more intelligent children show a greater decrease in shyness over time compared with their less intelligent peers (Asendorpf, 1994). Shy, reticent behavior with strangers was stable in a group of 99 German children observed in varied settings from the preschool years through the third grade ( $r = .6$ ; Asendorpf, 1990). Asendorpf agrees with Rubin that a child can be shy because of the unfamiliarity of the situation, a concern over evaluation of task competence by

another, or anxiety over peer rejection (Asendorpf, 1989, 1991, 1993). Buss (1986) argues that some shy school-age children display fearful behaviors to the unfamiliar during the first 2 years of life, while others do not display this trait until they are 3 or 4 years of age.

A similar conclusion emerged from a study of 212 Swedish children followed over a 6-year interval. Psychologists rated the children's behavior in the 1st and 2nd years and annually until 6 years of age. (In addition, mothers rated their infants four times during the 1st year, twice during the 2nd year, and annually until they were 6 years old.) The children who were exceptionally shy or sociable (15% at each end of the distribution) preserved their style from the second to the 6th year of life. The stability was greater for girls than for boys and smaller in magnitude when the whole sample was treated as if sociability were a continuum (Kerr, Lambert, Stattin, & Klackenberglarsson, 1994).

A second group of Swedish investigators followed 144 firstborn children from 16 months through the 4th year of life, a 2-year interval. Some children were attending day care and some were raised only at home. Shy behavior with an unfamiliar adult, based on observations at home, was stable from 28 to 40 months ( $r = .4$ ) but not from 16 to 40 months, and there was no effect of day care attendance on shyness (Broberg, Lamb, & Hwang, 1990). "The increased contact with strange adults that followed from enrollment in out of home care did not affect children's inhibition at 28 and 40 months of age, which suggests that inhibition in the 1st year of life is best viewed as a fairly stable dimension that is not systematically affected by ordinary life changes like those implicit in the initiation of out of home care" (p. 1161). The fact that the children attending day care were not more sociable than those at home with their mothers surprised the authors and will surprise some developmental psychologists.

Alternatively, placement in day care before the age of 2 years apparently influences behavioral inhibition in a middle-class sample. Infants who displayed a combination of high motor activity and distress to unfamiliar auditory and visual stimuli, a profile that predicts behavioral inhibition at age 2, were less reticent with unfamiliar peers at age 4 if they had been placed in out-of-home day care than if they had remained at home with their mothers (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001). An infant's temperament interacts with rearing conditions. In addition, children placed in different types of surrogate care outside the home who

were rated by observers as low in self-control showed larger increases in cortisol secretion from morning to afternoon than most other children (Dettling, Gunnar, & Donzella, 1999; Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Watamura, Sebanc, & Gunnar, 2002). A similar result was found for infant boys in surrogate care who were rated as shy or anxious (Tout, de Haan, Campbell, & Gunnar, 1998).

## INHIBITED VERSUS UNINHIBITED CHILDREN

Kagan and Snidman (2004) regard shyness with strangers, whether peers or adults, as only one feature of a broader temperamental category called inhibition to the unfamiliar (Arcus, 1991; Kagan, 1994). Inhibited children react to different types of unfamiliarity with an initial avoidance, distress, or subdued affect when they reach the maturational stage when discrepancies elicit uncertainty, usually 7 to 9 months in humans. The comparable ages in other species are 2 to 3 months in monkeys, 30 to 35 days in cats, and 5 to 7 days in ducklings (Kagan, 1994). The source of the unfamiliarity can be people, animals, situations, objects, or dynamic events. An inhibited child might, with experience, learn to control an initial avoidance of strangers and, therefore, not appear shy, but still retain an avoidant style to unfamiliar challenges or places or be prone to a serious, dour mood. An inhibited temperament assumes that a child can display an avoidant style in any one of a number of contexts. Membership in this temperamental category is not defined by only one class of behavior, like shyness with an unfamiliar peer. Hence, children who are not particularly shy might have an inhibited temperament.

The complementary category, called uninhibited to the unfamiliar, is characterized by a sociable, affectively spontaneous reaction to unfamiliar people, situations, and events. As with the inhibited child, the category refers to an envelope of profiles whose form changes with development.

Shy or sociable behavior in a specific class of situation can be the product of different biologies and past histories. The independence of an entity (in this case a child) from its functions (behavior in a particular situation) was a major node of disagreement between Whitehead and Russell. Russell (1940) believed that the two ideas were independent, whereas Whitehead insisted that they were a unity. In the statement "Lions stalk gazelles" Russell would have argued that the predicate

*stalk* was applicable to a variety of animals and could be treated as an independent function. Whitehead (1928) would have claimed that lions stalk in a particular way that is different from that of hyenas; therefore, no scholar should posit separate classes of agents and functions that can be combined in any way. We side with Whitehead, as do all who believe that the motives, emotional moods, and postures of an agent who "gives an order to another" are different if the agent is a 3-year-old talking to a peer, a burglar with a victim, an army officer with a private, or a parent with an adolescent. The behavior of temperamentally inhibited children in unfamiliar social situations is not exactly like the profile of those who acquired their shy, timid demeanor through experience alone. The former group displays fewer spontaneous smiles and greater muscle tension. Thus, we should not treat the predicate "is shy" as a quality separable from the child's life history, physiology, and the context of observation. This suggestion applies to all predicates referring to psychological dispositions.

Inhibited and uninhibited profiles appear to be heritable. Identical twins are more similar in the display of shy, timid behavior during childhood than are fraternal twins (Emde et al., 1992; Matheny, 1983, 1990), thus matching data on adults (Davis, Luce, & Kraus, 1994). The Institute of Behavioral Genetics at the University of Colorado has studied a large number of same-sex twin pairs at 14 and 21 months. The heritability coefficients for inhibited and uninhibited behavior, based on direct observations were between .5 and .6 (Kagan & Saudino, 2001). But readers should be aware of the fact that the heritability equations that produce the estimates are vulnerable to the critique of assuming additivity of genes and environment, ignoring epistasis, and failing to measure the environmental factors directly to compute the interaction between genes and experience.

### **The Biological Bases for Reaction to Unfamiliarity**

The brain states created by unfamiliarity, classical conditioning, evolutionarily significant stimuli, and anticipation of the future involve different neural circuits. This claim rests, in part, on evidence from animal studies (Treit et al., 1993a, 1993b) and the fact that the most probable profile of responses is different for these four incentives. An unfamiliar event, for example, a person with a mask, typically produces cessation of activity in a 2-year-old child. This response is mediated

by a circuit involving the amygdala and the ventral periaqueductal gray. However, acquiring a classically conditioned rise in heart rate does not require the central gray, but the amygdala and its projections to the hypothalamus and the sympathetic chain. A startle reaction to a looming object or loud sound need not involve the amygdala. Classically conditioned avoidance of specific tastes, but not odors, can be acquired in anesthetized rats, suggesting that the conditioned avoidance of tastes may be biologically different from learned avoidance to novel sights (Rattoni, Forthman, Sanchez, Perez, & Garcia, 1988). Unfortunately, scientists do not know the circuits that mediate the conscious reports of anxiety over a future threat or challenge. We do know that children and adults can report feeling anxious without any accompanying peripheral physiological changes. In light of this evidence, it seems reasonable to reject the idea of a single fear state and to assume, until data prove otherwise, that discrepancy, classical conditioning, biologically significant events, anticipation of future unpleasantness, as well as separation from a target of attachment create different physiological and psychological states. It is reassuring that physiologists also reject the idea of a unitary state of physiological stress: Hemorrhage, hypotension, and hypoglycemia produce different profiles of secretory release (Sapolsky, 1992).

Each brain, or peripheral, site that participates in a circuit that produces a behavioral or biological reaction has a different responsibility. For example, a child's bodily freezing to the sudden entrance of a stranger wearing a mask requires a sensory cortex to register the features of the person, a parahippocampal region to detect the stranger's discrepant features, and an amygdala to provoke the neurons of the central gray to produce the immobility. Scientists emphasize the contribution of the amygdala because it is the most immediate origin of projections to the structures that produce the immobility. But a child with no sensory cortex could not perceive the person and therefore would not freeze. If the variable of interest had been the perception of the unfamiliar person, rather than the immobility, scientists would emphasize the significance of the sensory cortex.

Scientists are biased to attribute causal status to the structure or process that is the immediate origin of a set of observations. The ancients believed that the emotions of love and anger originated in the heart because a perception of a racing heart always preceded the emotional experience. Suppose that available technology permitted psychologists to quantify moment-to-moment changes in

a number of neurotransmitters and modulators during the presentation of visual and auditory stimuli to young infants and they discovered that variation in norepinephrine secretion from the locus ceruleus predicted variation in inhibited behavior in the 2nd year of life. Under these conditions, the scientists might have argued that the responsivity of the locus ceruleus was the basis for the temperamental biases. The dependent variable selected influences, in a serious way, the brain sites or physiologies awarded causal status. A painful event evokes activity in the amygdala and the HPA. Scientists who measure fMRI activity in the amygdala will emphasize the significance of this structure while those who quantified increases in cortisol would award more importance to the HPA axis. No temperamental bias is located in a particular brain structure. All a scientist can say is that a particular structure is relevant.

One obstacle to progress in understanding temperamental vulnerabilities to variation in avoidance of the unfamiliar is the assumption that there is only one basic fear state with variation in intensity. An infant monkey's distress calls to separation from the mother, a quail chick's immobility to restriction of movement, an increase in heart rate or blood pressure to a conditioned stimulus that had been paired with shock, and flight from a novel object are sometimes regarded as indexes of the same basic fear state. These theoretical discussions of fear ignore the variation in species, incentive event, and specific response quantified and assume that the same emotional state is generated in each of the above instances. This assumption is likely to be incorrect.

Other psychologists (Panksepp, 1990) claim that separation of a mammalian infant from its mother elicits a fear state. Separation, unlike unfamiliarity or a conditioned stimulus that signals pain, produces distress vocalizations, not freezing, defensive aggression, or flight. A kitten faced with an unfamiliar event often shows arching of the back mediated by the central gray. A kitten separated from its mother displays different behaviors. Thus, it is probably an error to use the distress that accompanies separation as a model for fear. This is not to say that the state created by separation is not interesting or of theoretical importance, but this state is probably not the best probe for understanding fear to threat, a conditioned cue, or to novelty. It is of interest that post-traumatic stress disorder usually follows events that are dangerous, such as earthquakes, or those that engender a combination of fear and guilt; for example, witnessing an atrocity (Pynoos et al., 1987). That is one reason why there is a low correlation between the occurrence of dis-

tress to separation at home, or in the laboratory, and cries of fear to discrepant events in 1-year-olds and why a temperamental vulnerability to a fear reaction to discrepancy and a child's attachment classification are only modestly related (Kagan, 1994). One implication of these facts is that the generalizations about fear or anxiety based on separation from caretakers, whether in monkeys or children, should not be applied uncritically to the reactions displayed to unfamiliarity, threat, or conditioned cues for aversive events.

The concept of a basic fear circuit is too ambitious. The meaning of "fear state" is different when the defining referent is (a) a self-report, (b) a change in behavior, or (c) an increased activity in a neural circuit. If this suggestion is valid, we will need different theoretical constructs for fear depending upon which referent is used. Even if a particular brain structure were involved in all of the above phenomena, that fact would be insufficient to assume that the states, which were identical for complex events and shared a single feature, were essentially similar. Although all mammals are capable of internal fertilization, there is extraordinary diversity among them in other systems.

Finally, there is the possibility that, as with parental reports and behavioral observations, the description of the brain events that contribute to a psychological state of fear and the verbal descriptions of an agent are incommensurable—one cannot replace one set of sentences with the other without changing the intended meaning.

### **The Functions of the Amygdala**

Observations of 4-month-old infants exposed to visual, auditory, and olfactory stimulation point to the possible physiological bases for the inhibited and uninhibited temperamental profiles that emerge after the first birthday. The early infant behaviors that are predictive of these two categories can be understood if we assume that some infants are born with a low threshold of excitability in the amygdala and its projections to the ventral striatum, hypothalamus, cingulate, frontal cortex, central gray, and medulla.

The amygdala consists of many neuronal collections each with a distinct pattern of connectivity, neurochemistry, and functions. Each collection projects to at least 15 different sites, and receives inputs from about the same number of regions, resulting in about 600 known amygdalar connections (Petrovich, Canteras, & Swanson, 2001; Stefanacci & Amaral, 2002). Although a simplification, most anatomists conceptualize the amygdala

as composed of three basic areas: (1) the basolateral, (2) the corticomedial, and (3) the central areas. The basolateral area, which transmits its information to the central nucleus, receives rich thalamic and cortical inputs from many external sensory origins, and some input from the viscera, and is reciprocally connected to cortex, hippocampus, hypothalamus, basal ganglia, brain stem, and the bed nucleus. The behavioral reactions of flight or attack are mediated primarily by projections from the basolateral nucleus to the ventromedial striatum and ventral pallidum (Fudge, Kunishio, Walsh, Richard, & Haber, 2002).

The corticomedial nucleus receives primarily olfactory and taste information and projects to the hippocampus, thalamus, hypothalamus, and central nucleus. The central nucleus, like the basolateral, receives input from taste, vision, audition, and the viscera, but most important, from the basolateral and corticomedial areas.

Further, the central area is the origin of a large number of projections to the bed nucleus, cortex, basal forebrain, hypothalamus, brain stem, and autonomic nervous system. Projections from the central nucleus are more responsible for internal, bodily changes that include secretion of hormones, reactivity to the autonomic nervous system, and subtle alterations in posture and muscle tone. Some investigators have suggested that the central nucleus is activated primarily by acute, punctate events to produce a transient reaction. More continuously stressful conditions activate the bed nucleus of the stria terminalis to create a more chronic state. The level of CRH in the central nucleus is correlated with an animal's reactivity to a phasic event; CRH level in the bed nucleus is more clearly correlated with reactivity to a chronic stressor (Walker, Toufexis, & Davis, 2003). This difference suggests a contrast between an acute state of vigilance produced by seeing a snake or a spider with a chronic state of worry over the future. The central nucleus is needed for the acute state, while the bed nucleus maintains the prolonged state of uncertainty to a longer lasting threat. However, this rule has exceptions (Fendt, Enders, & Apfelbach, 2003).

### ***Fear or Surprise***

There is disagreement over the events most likely to activate the amygdala and the psychological states that follow. The central issue is whether the amygdala reacts primarily to imminently threatening events to produce states of fear or to unfamiliar ones to produce states of surprise. Dangerous events should create distinctly different states in brain, and, subsequently, in mind than

unfamiliar ones because not all unfamiliar events pose a threat and some threats are not novel. A female Diana monkey issues a distinct vocalization to the unexpected alarm call of a male leopard. However, she does not vocalize to the same male leopard call if it occurs a second time a few minutes later, even though the leopard remains a threat because the call is no longer a discrepant and therefore not a surprise. This monkey would have vocalized if the second sound had been an eagle's shriek (Seyfarth & Cheney, 2003). The monkey vocalized when the potentially dangerous auditory event was unexpected but not when the same sign of a dangerous event was anticipated. Earlier writers have suggested that mammals show signs of fear to unfamiliar events (Hebb, 1946; Valentine, 1930), and animals with a lesioned amygdala fail to avoid unfamiliar animals or objects. That is why infant monkeys with lesions of the amygdala who had been permanently separated from their mother when they were 6 months of age did not preferentially choose to approach the mother rather than an unfamiliar animal (Bauman, Lavenex, Mason, Capitanio, & Amaral, 2004). The lesioned animals showed no preference because they did not experience the state of uncertainty usually provoked by an unfamiliar adult animal.

Scientists began to focus on the amygdala's contribution to fear rather than surprise after Brown, Kalish, and Farber (1951) reported that the magnitude of an animal's body startle to a loud acoustic probe was enhanced when a light that had been previously paired with electric shock was presented to a rat just before the loud acoustic stimulus. These investigators assumed that rats should be afraid of a light that signaled electric shock, and therefore concluded that the larger startles reflected a state of fear. This assumption was followed by the elegant research of LeDoux (2000), Davis et al. (1994), and others, indicating that the thalamus and the amygdala were necessary for the acquisition of a conditioned reaction of body immobility, potentiated startle, or autonomic reactivity to a neutral stimulus that had signaled an electric shock. Soon a large majority of scientists had concluded that the conditioned stimulus created a state of fear in the animal. This inference was attractive because the concept of fear played an important theoretical role in the middle of the twentieth century when psychoanalytic theory was popular. Fear seemed closely related to anxiety, and Freud had made anxiety the central culprit in neuroses. In addition, the *Diagnostic Statistical Manual* of the American Psychiatric Association had made the anxiety disorders a major mental illness category. This evidence persuaded

Ohman and Mineka (2001, 2003) to suggest that the amygdala reacts primarily to signs of danger rather than to unfamiliarity. They argued that all animals inherit a fear module (located in the amygdala) that reacts, without conscious awareness and free of cognitive control, to events that pose a threat to the integrity of the body. Snakes are presumed to be a classic example of such an event. There are serious problems with this position.

First, the behavioral reactions of most monkeys, chimpanzees, and human infants to a snake are no different from their reaction to discrepant events that are harmless, like a tortoise or seaweed (Marks, 1987). Monkeys born and reared in a laboratory, and therefore protected from contact with live snakes, showed a longer period of motor inhibition to the presentation of a snake, whether alive or an artifact, than to blue masking tape. However that restraint only occurred on the first testing session. During later sessions, the animals showed no more restraint to the snake than to the masking tape. Moreover, a majority of animals failed to show any difference in withdrawal behavior to the snake, compared to the harmless masking tape (Nelson, Shelton, & Kalin, 2003). If snakes were a biologically potent incentive for a fear state, motor restraint should not have habituated so quickly and the majority of monkeys, rather than just 30%, should have shown a withdrawal reaction.

School-age children from a Dakota Indian tribe in Manitoba asked to recall the single most frightening event of their earlier years, most often named either a large domestic animal, like a bull or horse, that had frightened them or a ghost or witch-like figure they believed carried the children away if they disobeyed. Very few children named snakes, even though snakes are common in this area (Wallis, 1954). A critical fact is that select neurons in the amygdala as well as in the bed nucleus, hippocampus, and brain stem respond reliably to discrepant events, whether or not they are harmful (Wilson & Rolls, 1993). Further, the reactivity of these neurons habituates often rapidly as the event loses its unfamiliarity (LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998). Adults in an fMRI scanner looking at faces with neutral expressions showed greater amygdalar activation to new, compared with familiar faces, even though no face had a fearful, or threatening expression (Schwartz, Wright, Shin, Kagan, & Rauch, 2003), as did adults who had shown characteristic avoidance of unfamiliarity during childhood (Schwartz et al., 2003).

Thus, the evidence implies that the amygdala reacts primarily to unfamiliar events, rather than to events that are threatening; unless, the animal knows the event is dangerous. A basic property of the amygdala is a prepared-

ness to receive information from the parahippocampal region indicating that an event that captured attention is deviant from the agent's stored representations. Surprise is a possible name for the psychological state created by such experiences (Whalen, 1998). It is less clear what name(s) is most appropriate for the brain state. But the brain and emergent psychological states that define surprise, following exposure to an unfamiliar event, are different from those that represent a state of fear to the imminent possibility of harm. It is important to differentiate between an unfamiliar event and an unexpected change in the sensory surround (e.g., a sudden loud sound), because the latter need not activate the reciprocal connections between the parahippocampal region and the amygdala.

## **HIGH AND LOW REACTIVITY TO UNFAMILIARITY**

It is assumed, but not yet proven, that 4-month-old infants who show high levels of vigorous motor activity, a great deal of muscle tension, and frequent irritability to a standard laboratory battery composed of visual, auditory, and olfactory stimulation possess low thresholds of excitability in the basolateral and central areas of the amygdala and their projections. These infants, who represent about 20% of an unselected healthy Caucasian sample, are called high reactive. A complementary group who showed low levels of motor arousal and minimal irritability to the same battery, about 40% of the sample, are assumed to have higher amygdalar thresholds to stimulation and are called low reactive. The two patterns of reaction to unfamiliar events are less clear in much younger infants because the connectivity between the amygdala and sites mediating motor activity and distress are not yet mature (Weber, Watts, & Richardson, 2003). However, as noted earlier, the amygdala is part of a circuit that includes the thalamus, sensory and association cortex, and parahippocampal region that are also activated by unfamiliar events. Although the amygdala is the proximal origin of the motor activity in crying, it remains possible that the variation in behavior might be due, in part, to variation in the excitability of another structure in this circuit that primes the amygdala.

### **Childhood Derivatives of High and Low Reactivity**

Kagan and colleagues observed a large number of children at 14 and 21 months who had been high- or low-reactive infants at 4 months. The laboratory batteries at

14 and 21 months consisted of a variety of procedures designed to elicit uncertainty, including intrusion into the child's personal space (placing electrodes on the body or a blood pressure cuff on the arm), exposure to unfamiliar objects (robots, toy animals, or papier-mâché puppets), and encounters with unfamiliar people who behaved in an atypical way or wore a novel costume. A child who cried to any one of these events or did not approach any of the unfamiliar objects when requested to do so was coded as fearful for that episode. High-reactive infants were significantly more fearful at 14 and 21 months than were low-reactive infants. About one-third of the high-reactives were highly fearful at both 14 and 21 months, and only 3% showed minimal fear at the two ages. By contrast, one-third of the low-reactives were minimally fearful at the same two ages and only 4% showed high fear. It is of interest that the remaining children showed intermediate levels of fearfulness (Kagan, 1994).

Support for the claim that these two groups of infants, defined by a combination of motor arousal and crying to stimulation, represent qualitative categories that should not be placed on a continuum of arousal comes from the fact that when the duration of crying to the 4-month battery was either zero (the infant did not cry at all) or longer than 8 seconds, the correlation between degree of motor activity at 4 months and fearfulness at 14 months was close to zero for each of the two cry groups ( $r = .13$  for the subjects who did not cry at all, and  $r = .10$  for those who cried more than 8 seconds). Conversely, when the infants were divided into groups with motor scores that were low ( $<40$ ) or high ( $>50$ ), the correlation between duration of crying at 4 months and fear at 14 months was also low ( $r = .25$  for those with low motor behavior;  $r = .08$  for those with high motor scores). Thus, once an infant had passed the criteria for motor arousal and crying that defined high reactivity, additional motor activity or crying (in that category) had minimal consequences for how fearful the child would become later.

When the high- and low-reactive infants were evaluated at 4.5 years of age, the former group was much more subdued and talked and smiled less frequently during a 1-hour laboratory assessment with an unfamiliar female examiner. By contrast, the low-reactive children were spontaneous; they asked questions, commented on the procedures, and smiled and laughed more often. The differences between the two groups in smiling were more dramatic than the differences in talking. The three

low-reactive boys who smiled the most (more than 50 times) had been the most relaxed infants when they were 4 months old (Kagan, 1997).

A small proportion of high-reactives talked and smiled frequently during the examination at 4 years. Although their environmental histories probably influenced this profile, it is of interest that during the original assessment at 4 months these children smiled more often than the majority of high-reactive infants who were more subdued at 4.5 years. In addition, the spontaneous high-reactives had a lower and more variable heart rate when they were 14 months old, implying that this small group of high-reactives may have possessed a special temperamental quality.

The fact that spontaneous conversation with a stranger is a sensitive sign of uncertainty after 3 or 4 years of age is supported by a different sample of children classified as inhibited or uninhibited at 21 or 31 months and observed again at 5, 7, and 13 years of age. Infrequent talking to an unfamiliar examiner was the best correlate of the original classification of an inhibited temperament at all three ages. It is possible that the small number of children with elective mutism represent extremely inhibited children (Black, 1992).

Restraint on spontaneous conversation in an unfamiliar social situation seems to be analogous to freezing to a novel event in animals. Both responses are mediated by the fibers of the central gray that are innervated by projections from the amygdala. But restraint on spontaneous speech is not a sensitive measure of uncertainty to the unfamiliar until after the third birthday. There was no significant relation between spontaneous vocalization in the 1st and 2nd year and spontaneous speech with an adult at 4 years of age. Although both variables refer to vocal sounds, the responses are different in meaning. Absence of vocalization in the 1st year reflects low affective arousal; restraint on speech at 4 years reflects anticipatory anxiety. One-year-old children are not old enough to be concerned with the examiner's evaluation of them or to anticipate the laboratory procedures that might be administered.

The high- and low-reactive 4.5-year-old children also differed in their social behavior with two other unfamiliar children of the same age and sex when trios of children were observed in a laboratory playroom for a half hour. Almost 66% of the low-reactive but fewer than 10% of the high-reactive children were outgoing and sociable with the unfamiliar children. By contrast, 40% of the high-reactives were avoidant and quiet compared

with only 10% of the low-reactives. Although there was significant preservation of inhibited or uninhibited temperamental styles from 4 months to 4.5 years, these data also imply that environmental factors affect each child's phenotype.

The 4-year-old children who had been high reactive were also more intimidated by the examiner. In one episode, the female examiner asked the older child to perform some actions that would be prohibited by most parents. For example, she opened a photo album containing pictures of herself, took out a large color photograph, and, as she handed it to the child, said, "This is my favorite picture; tear up my favorite picture." More low- than high-reactives either asked her why they should perform that act or, in the case of five children, refused to do so. Moreover, their resistance was not accompanied by any obvious signs of anxiety; they simply appeared to be less afraid of disobeying the requests of an authority figure when that request required them to violate a norm they had acquired. Almost all the high-reactives were reluctant to disobey and, after a 5- to 10-second delay, tore a small corner from the photograph.

Parents of high-reactive infants who became inhibited preschoolers reported that their children were more sensitive to criticism and cried, had a tantrum, or became subdued when chastised. On the face of it, this response does not follow from the hypothesis that high-reactive-inhibited children react to unfamiliarity with uncertainty. Parental criticism is not an unfamiliar event; a person dressed in a clown costume is discrepant. This relation can be understood, however, if we assume that a child older than 3 or 4 years is continually generating representations of the present and immediate future. If an event, like a chastisement, is unexpected, it resembles a discrepant event. Because the amygdala and its circuits are excited by discrepancy, the child might react with crying, withdrawal, or a tantrum. It is possible that adolescents and adults who were high-reactive-inhibited children are more easily threatened by encounters with beliefs, opinions, or philosophical premises that are not in accord with their firm beliefs.

### **Influence of Experience**

Although physiological products of genes make a modest contribution to the inhibited and uninhibited behavioral profiles, they share power with experience. Over one-third of high-reactive infants were not exceptionally fearful or shy in the 2nd year; a small number were fear-

less. Home observations on 50 high- and 50 low-reactive firstborn infants indicated that a mother's actions with the infant affected the probability that a high-reactive child would become inhibited. A nurturing parent who consistently protected her high-reactive infant from all minor stresses made it more, rather than less, difficult for that child to control an initial urge to retreat from strangers and unfamiliar events. Equally accepting mothers who set firm limits for their children, making mundane age-appropriate demands for cleanliness or conformity, helped their high-reactive infants overcome their fearfulness (Arcus, 1991).

The role of experience is illustrated by the variability in each temperamental category. We examined the variability in behavior with the examiner at 4.5 years within two very different groups: high-reactive girls who showed high fear at 14 months ( $N = 16$ ) and low-reactive girls who showed low fear at 14 months ( $N = 28$ ). Although the former, as expected, had significantly fewer spontaneous comments and smiles compared with the latter, the variation within each group was large. For example, although one-third of the high-reactive, fearful girls had fewer than 10 spontaneous comments, one-third had more than 50 comments. One-third displayed fewer than 5 smiles, but one-third had more than 30 smiles. Within the low-reactive, low-fear girls, one-third had fewer than 27 comments and fewer than 21 smiles, but one-third had more than 70 comments and more than 35 smiles. It is fair to suggest that this broad range of outcomes at 4.5 years within these classes of children is due, in part, to differential experience. The envelope of developmental trajectories for each temperamental group is not fixed in a rigid way (Kagan & Snidman, 2004).

Another sample of infants, classified as high reactive or aroused, was observed at 9, 14, 24, and 48 months (Fox et al., 2001). About one-half of the high reactives retained an inhibited persona through 2 years of age, and one-third preserved this profile through the fourth birthday. However, the child's gender and form of rearing influenced the retention or loss of an inhibited persona. High-reactive boys preserved their inhibition more than girls, and those who were placed in day care during the early years were less likely to preserve behavioral inhibition than those raised only at home. Fox et al. (2001) speculated that placement in day care probably influences the preservation of behavioral inhibition because exposure to unfamiliar peers and settings, and freedom from possible overprotection at home, might

allow these children to learn coping strategies to unfamiliarity. Rubin, Cheah, and Fox (2001) coded maternal behavior while 4-year-old inhibited children were asked to build a block tower with their mothers. Mothers who were oversolicitous and excessively responsive to their child's crying were most likely to have children who were reticent when playing with peers.

A sample of 164 of the children in Kagan's sample were evaluated when they were 7.5 years old. Data from maternal reports, teacher descriptions and observations revealed that 26% of the total sample had anxious symptoms. This group of 42 anxious children was compared with 107 control children without anxious symptoms. The 7-year-olds who had been high-reactive infants were most likely to possess anxious symptoms; 45% of high-reactives, but only 15% of low-reactives received this classification. Moreover, the high-reactives with anxious symptoms were most likely to have screamed in fear during the 21-month assessment when a person dressed in a clown costume entered a room where they had been playing. About 20% of the sample of high-reactives were consistently inhibited at four ages: 14 and 21 months, as well as 4.5 and 7.5 years. Not one high-reactive infant was consistently uninhibited across all four evaluations (Kagan & Snidman, 2004).

These children were evaluated again when they were between 10 and 12 years of age. About one-third of the high- and low-reactives displayed a style of social behavior with the examiner that was in accord with their earlier infant temperament, while only 16% showed behaviors that were inconsistent with their infant temperament. More high-reactives were quiet, spoke in a soft voice, sat stiffly in the chair, and often looked away from the examiner. By contrast, more low-reactives were relaxed and talked and smiled frequently with the examiner. The number of spontaneous comments with the examiner at age 11 was a particularly sensitive sign of early temperament. High-reactives preserved a serious facial expression from 14 months to 11 years, while the low-reactives smiled and laughed frequently at every assessment. When the children filled out Q-sorts to describe themselves, the low-reactives were more likely than the high-reactives to report that they were "happy most of the time." Forty percent of the high-reactives retained an inhibited profile from 4.5 to 11 years of age, and 70% of the low-reactives retained an uninhibited profile across this same period. Further, 50% of low-reactives, compared with 13% of high-reactives, were described by their mother as extremely

sociable and extraverted, although the children's descriptions of their own behavior did not correlate highly with their contemporary behavior with the examiner or with the mothers' descriptions. It is important to note that the 4-month temperamental category was a better predictor of behavior at age 11 than the child's fearfulness at 14 or 21 months.

### Biological Assessments

Four biological measures gathered on these subjects at age 11 were regarded as indirect signs of amygdalar activity, even though many brain sites participate in each biological reaction.

#### *EEG Asymmetry*

One measure was an asymmetry in EEG activation that favors the left or the right hemisphere, where desynchronization of alpha frequencies is the index of activation. The left frontal area is usually more active than the right when individuals are relaxed and in a happy mood, but the right is more active than the left when the individual is in a state of uncertainty, fear, or anxiety (Davidson, 2003a, 2003b; Fox, 1991, 1994). The results from a number of studies suggest that children and adults who show right frontal activation in the EEG are more likely to react to a discrepant event, unfamiliar situation or new challenge with greater dysphoria and/or an anxious avoidant response. Individuals who show left frontal activation show the complementary pattern of a more relaxed, happy mood and an eagerness to engage new experiences or challenges (Davidson, Ekman, & Saron, 1994; Schmidt & Fox, 1994; Tomarken, Davidson, & Henriques, 1990). A similar relation was observed in infants. Ten-month-old infants showed left frontal activation to a smiling, but not to a crying, adult, but they were more likely to show right frontal activation to the approach of a stranger (Fox & Davidson, 1987) and to a temporary separation from the mother (Davidson & Fox, 1989; Fox & Davidson, 1988). Further, the smiles of infants are usually accompanied by left frontal activation, while behavioral signs of fear are accompanied by right frontal activation (Fox & Davidson, 1987). Moreover, the tendency to show right frontal activation to temporary separation from the mother is a stable trait in the 2nd year (Fox, Bell, & Jones, 1992). Both socially reticent and solitary-passive children—using Rubin's definitions—show right frontal activation. But only the

reticent group shows low alpha power across the entire scalp, suggesting a higher level of cortical arousal, and perhaps a hypervigilant mood.

When confronted with a stressful or unexpected incentive, like temporary maternal absence, young children show greater EEG activation on the right, compared with the left, frontal area (Dawson, Panagiotides, Klinger, & Hill, 1992). Thus, it is of interest that inhibited, compared with uninhibited, children showed greater activation in the right frontal area under resting conditions (Davidson, 1994a, 1994b). High-reactive infants showed greater activation of the right frontal area when tested during the 1st and 2nd years; low-reactive infants showed greater activation of the left frontal area (Fox, Calkins, & Bell 1994). Because neural activity in the amygdala is transmitted to the frontal lobe, by the nucleus basalis, it is possible that greater desynchronization of alpha frequencies on the right frontal lobe reflect greater activity in the right amygdala (Kapp, Supple, & Whalen, 1994; Lloyd & Kling, 1991). The distribution of receptors for CRH and/or the level of CRH may contribute to the asymmetry of activation. Monkeys who showed a stable and extreme right frontal activation across a 4-year interval had high CRH levels (Kalin et al., 2000). Further, rhesus monkeys who combined high cortisol levels with high fear to unfamiliarity were most likely to show right frontal activation (Kalin et al., 1998). And 6-month-old infants with high cortisol levels were biased to show right frontal activation (Buss et al., 2003).

The 11-year-old children who had been high-reactive infants had greater activation in the right than in the left hemisphere at parietal sites. The high-reactives who, in addition, had been highly fearful in the 2nd year were more likely than low-reactives to be right hemisphere active at frontal sites as well. Further, the low-reactive, 11-year-old boys who described themselves as "happy most of the time" had greater left frontal activation than low-reactive boys who did not report a chronically happy mood.

The earlier research of Fox, Rubin, and their colleagues, which was an incentive for the work by Kagan's laboratory, along with recent evidence from Fox's laboratory, affirms a relation between direction of asymmetry of activation and a temperamental bias for inhibited or uninhibited behavior. For example, Fox et al. (1995) studied 48 children who were seen at 2 years of age and later at age 4. At age 2, the children were observed in settings designed to elicit behavioral inhibition, includ-

ing an encounter with an unfamiliar adult and a novel object. The children returned to the laboratory at 4 years of age for a peer play session. Each child was placed in a quartet of four unfamiliar children of the same sex. Each quartet consisted of one behaviorally inhibited child, one uninhibited child, and two children whose inhibition scores were close to the mean based on their behavior at 2 years of age. The children were observed during free play with peers and during a set of standard tasks using Rubin's coding criteria (Rubin, 2000). This scale allows identification of children who are socially reticent (isolated, staring, unoccupied, and displaying long latencies before they speak) and socially competent children who initiate play and often smile and talk.

Measures of EEG were recorded several weeks earlier. Children showing right frontal activation were more likely to be reticent than those who displayed left frontal activation. Maternal ratings of the child's shyness were correlated with both their play behavior and direction of activation. Of great interest is the fact that the very sociable children who showed right frontal activation were described by their mothers as displaying behaviors classified as externalizing (i.e., disobedience and mild aggression). But the reticent 4-year-olds who were also right frontal active were described as displaying internalizing problems (anxious, tense, and extremely shy). Thus, among children who showed right frontal activation, typical behavior at home was a function of their temperament. And inhibited 7-year-olds showed a more obvious increase in the level of right frontal activation to the challenge of preparing a speech than uninhibited children (Schmidt, Fox, Schulkin, & Gold, 1999).

Perhaps, the most relevant work from the Fox laboratory is based on a longitudinal study of a large group of infants who were classified at 4 months (using a battery similar to the one used by the Kagan group) into high-reactive (14% of the group), low-reactive (15% of the group), and infants who displayed high motor activity, vocalization, and smiling, but minimal distress (9%; we might call these children aroused). The high-reactives were most likely to show right frontal activation at 9 months while the aroused children were more likely to show left frontal activation. In addition, the high-reactives had less alpha power at both left and right frontal sites, implying higher cortical arousal.

These children were observed again at 4 and 7 years of age as they played in groups of 4 unfamiliar children of the same sex. Children who had been high-reactive as

infants and had shown right frontal activation at 9 months were reticent with peers at 4 years of age; a similar result emerged at 7 years (Polak, Fox, Henderson, & Rubin, 2004). The high-reactives with right frontal activation at 9 months were not only reticent but also were described by their teachers as having internalizing features. The aroused infants who displayed left frontal activation had a complementary set of traits.

#### ***Wave 5 in the Brain Stem Auditory Evoked Potential (BAEP)***

The biological measure that best separated the high- from the low-reactives at age 11 was the magnitude of the brain stem evoked potential from the inferior colliculus, the fifth structure in the auditory chain. The waveform generated by the colliculus, called wave 5, occurs within 6 ms of the onset of sound. Amygdalar activity enhances the excitability of the inferior colliculus through projections to the locus ceruleus and the central gray, which synapse on the colliculus. This anatomical fact means that children with a more excitable amygdala should have a larger wave 5 to a series of clicks. This expectation was affirmed for high-reactives had larger wave 5 values than low-reactives (Kagan & Snidman, 2004). The high-reactives who had been inhibited with unfamiliar peers at 4.5 years of age had larger wave 5 values than the high-reactives who had been more sociable. Further, the 15% of the sample who smiled infrequently at every assessment had higher wave 5 values than those who smiled frequently.

#### ***Event-Related Potential***

A third variable that separated high- and low-reactives was the event-related potential (ERP) to unfamiliar scenes. The amygdala sends projections to the locus ceruleus, ventral tegmentum, and basal nucleus of Meynert, which in turn project to cortical pyramidal neurons that mediate the magnitude of the ERP. Children with a more excitable amygdala, therefore, might show larger P300 or N400 to discrepant events. Again, the data affirmed expectation, for high-reactives showed larger N400s to ecologically invalid scenes (e.g., a child's head on an animal's body) than low-reactives. Further, high-reactives with the largest magnitude waveforms to discrepancy at age 11 had more intense symptoms of anxiety or depression 4 years later and showed shallower habituation of the N400 waveform to a different set of discrepant scenes (Kagan & Snidman, 2004).

The P300 and N400 waveforms represent brain activity involving the relation between an incentive event and existing representations. Earlier waveforms in the ERP that occur between 100 and 200 ms reveal different relations to behavior. Fox and colleagues studied a waveform called mismatch negativity (MMN) which occurs to a novel tone inserted in a series of identical ones. The MMN, which occurs with a latency of 200 to 250 ms, is generated by neurons in the primary auditory cortex. Children in two independent samples classified as inhibited showed a smaller MMN to the infrequent auditory stimulus than did controls (Bar-Haim et al., 2003). In addition, 9-month-olds classified as high reactive at 4 months showed a smaller positive waveform to a discrepant auditory stimulus than others (Marshall, Hardin, & Fox, 2004). These two results appear to be inconsistent with the fact that high-reactives at 11 years of age showed larger negative waveforms to discrepant scenes. However, the discrepant scenes shown to the 11-year-olds were meaningful and probably activated the parahippocampal area and its reciprocal connections to the basolateral nucleus of the amygdala. A large negative waveform to an unfamiliar scene (e.g., a chair with one leg) does not have the same significance as the mismatch negativity waveform to a deviant tone because the latter need not involve the amygdala.

Most school-age children show a longer response latency on trials following those on which they made an error—a psychological trait called reflectivity. It is of interest, therefore, that 7-year-olds rated as high on shyness and inhibitory control (based on Rothbart's CBQ) displayed a larger waveform, called error related negativity, on trials in which they made an error, as well as a longer response time on the subsequent trial (Henderson, 2002).

#### ***Sympathetic Activity***

Activity in the sympathetic nervous system also reflects amygdalar activity because the latter structure projects to the sympathetic nervous system. A spectral analysis of supine heart rate revealed that more high- than low-reactives had more power in the low frequency spectrum, which reflects both sympathetic and parasympathetic activity, and less power in the high frequency band, which reflects vagal or parasympathetic activity. The combination of greater power in the low frequency band and a high resting heart rate was characteristic of one of every three high-reactives (compared with only one of five low-reactives). By

contrast, one of every two low-reactives, but only one of sixteen high-reactives, displayed greater power in the higher frequency band and had a low heart rate. Not surprisingly, more children with high vagal tone smiled more often during the 2nd year and described themselves as “chronically happy” at age 11.

Further, more high- than low-reactive infants had higher fetal heart rates (over 140 bpm) a few weeks before birth, and higher 2-week postnatal sleeping heart rates while being held erect, but not when supine. Spectral analysis of the infants’ sleeping heart rates revealed that the high-reactive, compared with the low-reactive, infants had greater power in the low-frequency band (between .02 and .10 Hz) when held erect, suggesting greater sympathetic reactivity (Snidman, Kagan, Rioridan, & Shannon, 1995). A longitudinal study of 31 pregnant mothers and their fetuses revealed that fetuses with high heart rates had less frequent positive affect at 6 months of age (DiPietro, 1995). A variable heart rate in infancy, reflecting less sympathetic and more vagal tone, is linked to a tendency to approach unfamiliarity (Richards & Cameron, 1989), unfamiliar people (Fox, 1989), and facial expressions of smiling and laughter (Stifter, Fox, & Porges, 1989). Finally, 5- and 7-year-old inhibited, compared with uninhibited, children showed greater pupillary dilation, greater cardiac acceleration, and larger changes in blood pressure to cognitive stressors (Kagan, 1994).

The children Rubin classified as socially reticent displayed less vagal and higher sympathetic tone in the cardiovascular system than the solitary-passive or sociable groups. However, the solitary-passive children who had high baseline heart rates were more inhibited at 2 years than those with low heart rates (Henderson et al., 2004). Further, over the course of the laboratory observation at 4 years of age, the children with higher heart rates began to resemble reticent children as the tasks became more structured. Finally, Schmidt, Fox, and Schulkin (1999) reported that behaviorally inhibited (but not control) 7-year-olds displayed increases in heart rate and decreases in heart rate variability to emotional challenges—signs of less vagal tone.

About one of every four high-reactives and one of every four low-reactives preserved their expected behavioral as well as biological profiles, while only one of twenty children classified as high- or low-reactive at 4 months developed a combination of behavior and biology that was characteristic of the complementary category. Only 10% of high-reactives were fearful in the

second year and, in addition, had high values on all four biological variables, but no low-reactive developed these features. These results are remarkably similar to those reported by Fox and his colleagues who followed three temperamental groups first classified at 4 months of age in a battery similar to the one employed in this study.

However, it is important to appreciate that none of the biological variables has the same meaning or significance across individuals with different temperaments. The meaning of left frontal activation in the EEG profiles of the 11-year-olds in the Kagan and Snidman cohort provides an example. The low-reactives who were described by their mother as extremely sociable and outgoing, smiled frequently with the examiner, and had low levels of cortical arousal (as indexed by the beta to alpha ratio) showed extreme left frontal activation. But the high reactives who were described as shy and timid, smiled infrequently with the examiner, and had high cortical arousal were equally likely to show extreme left frontal activation. This fact suggests that left frontal activation does not have the same meaning in youth with different temperaments.

It is likely that this result can be generalized. No measure, whether questionnaire reply, behavior, or biology, has a universal meaning across all individuals. This claim is supported by information on some of the 11-year-olds who were assessed at age 15 years. Six high-reactive boys were extremely subdued and inhibited during a long interview with an examiner conducted in the home. The remaining 17 high-reactive boys were far less restrained. Right frontal activation, high sympathetic tone, and a high ratio of beta to alpha power, along with a large ERP to discrepant scenes at age 11 predicted the extreme inhibition in the six boys who were subdued. But low-reactive 15-year-old girls who showed the opposite traits of garrulousness and sociability during the interview also showed high sympathetic tone and a high ratio of beta to alpha power. Once again, the theoretical significance of a biological variable depended on the type of individual on whom it was measured.

Despite this possibility, most studies of humans—children, college students, or aging adults—treat their samples as if they were relatively homogeneous; gender is the usual exception. This decision is surprising. No behavioral biologist would gather data on a random sample of dogs of different breeds or macaque monkeys from different strains because they know that the strains would react in different ways to an incentive. Hence, psychologists should gather some information on the bi-

ology of their subjects. Some candidates include height, weight, body type, eye color, and, if possible, heart rate, blood pressure, cortisol level, EEG asymmetry and ERP waveforms to varied incentives.

### ***Facial Skeleton***

High and low reactivities differed in physical features, a fact supporting the belief that they belong to different categories. Infants classified as high reactive at 4 months had narrower faces (the ratio of the width of the face at the bizygomatic—high cheekbone—to the length of the face) when they were 14 months old compared with children classified as low reactive (Arcus & Kagan, 1995). The fact that facial skeleton differentiated the two temperamental groups implies the influence of a set of genes that affects features as diverse as the growth of facial bone, ease of arousal in infancy, smiling, and avoidance of unfamiliar events. It is of interest that inbred mouse strains like A/JAX that are susceptible to inhibition of palatal shelf growth following pharmacological doses of glucocorticoids during gestation are more fearful in an open field than strains like C57 BL/6 that are less susceptible to the influence of this steroid on the growth of facial bone (W. Thompson, 1953; B. Walker & Fraser, 1957). This fact implies that the genes that influence the growth of facial bone in response to glucocorticoids are correlated with those that monitor avoidance of novelty.

Second, 11-year-old high-reatives were a little more likely than low-reatives to possess light blue eyes and a small body size (24% of high-reatives, but only 7% of low-reatives had both features). The relation of eye-color and body size to infant temperament in Caucasian children may surprise some readers, but will be less surprising to those who know about the changes in physical characteristics that accompany domestication of wolves, foxes, mink, and cattle. The most extensive work, conducted at a field station in Siberian Russia, was initiated by D. Belyaev and carried on by his colleague, L. N. Trut, after Belyaev's death (Trut, 1999). These investigators selectively bred tame male silver fox with tame females for over 40 years. The wild form, which is not tame, has hairs that are black at the base and silver-white at the outer edge, stiff, erect ears and a tail that turns down. However, the offspring of many generations of breeding tame with tame animals displayed a number of physical features that accompanied the increased tameness and minimal fear of humans. The tame animals developed

white spots on their coat that were free of melanin pigmentation, floppy rather than stiff ears, an upturned tail and a broader face. These physical features are derivatives of neural crest cells. In addition, the offspring of the tame matings had lower levels of cortisol and higher levels of serotonin metabolites and brain dopamine (Trut, 1999). If a minimal fear of unfamiliar adults is associated with distinct physical features in a fox we should not be surprised to find that high- and low-reactive children differ in eye color and body size. It is possible that the genes that mediate the time of migration of the neural crest cells, and perhaps molecular features of these cells, are pleiotropic and contribute to a cluster of physical and behavioral features. Nature works in unexpected ways.

Finally, it is worth noting that extreme values on behavioral or biological variables often separated high- and low-reatives when mean scores did not. There were many occasions when the correlations among variables were low across the whole sample, but the children with values at either extreme were very different. For example, 10% of high-reatives, but not one low-reactive, had a *z*-score equal to or greater than .5 on the four differentiating biological variables; every one of these seven children showed distinct behaviors at 4 months of age that were indicative of high arousal. Persistent aggression is also characteristic of a small group of children. A longitudinal study of boys from different laboratories revealed that only 4% of a very large sample showed persistent aggression across the childhood years (Brody et al., 2003). Male vervet monkeys who are at either extreme on behavioral measures of impulsivity had a lower social rank than a large number of animals whose scores were in the middle of the distribution (Fairbanks, 2001). Many psychologists place great faith in the informativeness of mean values; any other parameter carries the stain of being less than perfect. This bias is irrational. Because nonlinear functions are common in psychology, current statistical procedures that rely on the mean often fail to reveal important relations. The reluctance to acknowledge the utility of examining extreme groups that might be qualitatively different from the rest of the sample is slowing progress in many domains of psychology.

### **Temperaments Constrain**

Despite the predicted relation between the infant classifications of high and low reactivity and the behavior

and biological profiles at age 11, only one-third of the children in the high- and low-reactive groups actualized a behavioral and biological profile that was in accord with expectation. However, very few children showed the profile of the complementary group, a result confirmed by Fox, Rubin, and their colleagues. Most children displayed behavioral and biological patterns characteristic of randomly selected middle-class Caucasian children. Apparently, many high-reactives had learned to cope with their earlier tendency to avoid unfamiliar people and situations and were able to develop a persona that was not obviously shy or timid. Thus, the prediction that a high-reactive infant would not become a sociable, exuberant child with left frontal activation, a small wave 5, and high vagal tone can be made with much greater confidence than the prediction that this child would become a subdued, timid adolescent with high levels of arousal in cortical, brain stem, and autonomic targets. Similarly, the prediction that a low-reactive will not become an extremely shy 11-year-old with high biological arousal is more certain than the prediction that this child will be exuberant and show low biological arousal. Each temperament constrains acquisition of the features of the complementary category. Hidden beneath the common observation that the behaviors and moods of children change from infancy to adolescence is the persistence of temperamental biases that prevent some from attaining a particular psychological profile.

A temperamental bias eliminates many more outcomes than it determines and is like the basic form of the song of a particular species of bird. The animal's genome constrains the basic architecture of the song but does not determine all of its features, for the adult song depends on exposure to songs of conspecifics and the opportunity to hear its own vocal sounds. The constraining power of initial conditions, whether biological or environmental, finds an analogy in a stone rolling down a steep mountain over a 5-minute interval. An observer will be able to eliminate a great many final locations after each 10 seconds of descent, but it is not until the final second that she will be able to predict where the stone will come to rest. When the high promises of the genome project are met and parents can request the complete genomic analysis of their newborn, an expert will be better able to tell parents what the infant will not become than to inform them about the characteristics their infant will possess 2 decades later.

## TEMPERAMENT AND ATTACHMENT

There is a lively controversy surrounding the contribution of inhibited or uninhibited temperaments to a child's reactions in the Ainsworth Strange Situation and, therefore, to the classifications of secure or insecure attachment (Connell & Thompson, 1986). The Strange Situation is an unfamiliar setting; therefore, inhibited children should react with greater uncertainty, when either left alone or with a stranger. As a result, more of these children should be difficult to soothe when the mother returns and they are likely to be classified as type C resistant and insecurely attached.

Infants who were classified type C at 14 months were behaviorally inhibited at 2 years, suggesting that the temperamental bias to be inhibited is contributing to their behavior in the Strange Situation (Calkins & Fox, 1992). Ten percent of Dutch infants assessed in the Strange Situation with their hired caregiver, mother, or father showed an insecure attachment to all three adults, implying a temperamental contribution to their behavior in the laboratory (Goossens & van IJzendoorn, 1990). One group of authors, reflecting on these facts, wrote, "Temperament does play a role in Strange Situation behavior through its effects on the quality and intensity of the infant's separation distress. Infants who are high on fearfulness are likely to react more negatively to the separation episodes" (Thompson, Connell, & Bridges, 1988, p. 1109).

A meta-analysis of data from seven different samples ( $N = 498$ ) revealed that the infant's behavior in the laboratory prior to the mother leaving the child predicted better than chance the child's subsequent behavior and the attachment classification. Infants classified as type C showed more crying and resistance to their mother during episode 2, an episode that occurred prior to any separation (Sagi, van IJzendoorn, & Koren-Karie, 1991; but see Fox, 1995).

Fox, Kimmerly, and Schaefer (1991) performed a meta-analysis on studies that examined the concordance of attachment classifications (based on the Strange Situation) to the mother and the father in separate assessments. Infants classified as Type A, B, or C (avoidant, secure, or resistant) to one parent were more likely than chance to be classified in the same way when they were tested with the other parent. This concordance implies a temperamental influence on behavior in the Strange Situation, as well as the possibility that both the mother and the father behave similarly with the infant.

Further support for the role of temperament is found in an independent study of 9- and 13-month-old infants. A temperamental quality called *proneness to distress*, together with the mother's personality, were the best predictors of an insecure attachment in the child. Specifically, infants who were prone to distress and, in addition, had mothers with high scores on a personality trait called *constraint*—these women were rigid, had traditional views, and avoided risks—were more likely to be insecurely attached. There was no effect of the maternal personality trait alone. Distressed infants reared by a mother who was low on constraint were more likely to be securely attached. Among low-distress infants, however, there was no relation between this maternal personality trait and security of child attachment. Variation in maternal behavior seems to be more important for infants who are vulnerable to distress than it is for those who are minimally fretful and irritable (Mangelsdorf, Gunnar, Kestenbaum, Lang, & Andreas, 1990). Thus, as Van den Boom and Hoeksma (1994) argued, both temperament and family experience act together to influence a child's behavior in the Strange Situation.

The investigators who believe that temperament makes a minimal contribution to the attachment classifications have most often relied on maternal questionnaires to measure the child's temperament. A review of many studies suggests that, for most samples, children described by their mothers as irritable at home were more likely to be classified as insecurely attached in the laboratory. One group of authors suggested that although temperament was not the only influence on the attachment classification, "the empirical overlap between these behavioral domains is greater than might have been anticipated" (Vaughn et al., 1992, p. 469).

## PSYCHOPATHOLOGY AND TEMPERAMENT

It is likely that temperamental biases contribute to psychopathology. Children and adults differ in their psychological and physiological reactions to an unfamiliar event, even when the event is unusually stressful such as an earthquake, divorce, kidnapping, or witnessing a mass shooting (North, Smith, & Spitznagel, 1994).

The extraordinary variation in the development of symptoms of stress following a trauma is probably influenced by temperament. Usually less than 40% of children react to a traumatic event with anxiety or fear. For

example, only 10 of 40 school children who were kidnapped and terrorized for 2 days developed post-traumatic stress disorder (Terr, 1979). During the winter of 1984, a sniper fired at a group of children on the playground of a Los Angeles elementary school. One child was killed, 13 were injured, and a siege followed. Clinicians interviewed the children 1 month later to determine who was experiencing extreme levels of anxiety. Thirty-eight percent were judged anxious, but an equal proportion, 39%, seemed completely free of any unusual level of anxiety. The important fact is that the children who were anxious 1 month after the trauma were those who had shown an inhibited temperament prior to the school violence (Pynoos et al., 1987).

A group of fourth and fifth grade children living in south Florida had been assessed for the presence of an anxious mood over a year before Hurricane Andrew struck the area. The 11% of the children who were still distressed 7 months after the storm were those who had been anxious prior to the hurricane (La Greca, Silverman, & Wassastein, 1998). Similarly, young British children less than 5 years old who became fearful after being taken from their homes during the bombing of London during World War II had been extremely fearful before the bombing raids began (John, 1941). Thus, a temperamental bias favoring a fearful reaction to novelty or threat renders children vulnerable to an extreme reaction to trauma.

The stress associated with entering school for the first time was only associated with an increase in respiratory illness in children who had shown both sympathetic reactivity prior to the beginning of the school year (measured by an increase in heart rate and arterial blood pressure to challenge) and, in addition, had been exposed to stressful experiences at home. Children of the same age and social class who showed low sympathetic reactivity showed no increased rate of respiratory illness, even though they may have lived in a highly stressful home environment (Boyce & Jemerin, 1990).

One team of investigators took advantage of the fact that an earthquake occurred in Northern California (the Loma Prieta earthquake of 1989) in the middle of a study of 20 young children who were entering kindergarten. Six children showed an increase in respiratory illness after the earthquake; five showed a decline. Variation in the change in the helper-suppressor cell ratios and pokeweed mitogen response predicted the children who showed the increase in respiratory illness. The children who showed an up-regulation of the two immune

parameters following school entry had a significant increase in respiratory illness after the earthquake. This fact suggests that the children who perceived kindergarten entrance as stressful (indexed by the change in immune reaction) became most vulnerable to respiratory infections following the earthquake (Boyce et al., 1993). Even though the differences between adults who had an easy or difficult temperament at age 3 years were small, Chess and Thomas (1984) suggested that easy children were better-adjusted adults; Werner (1993) reports a similar result.

It is not clear whether the modulatory processes associated with temperament act directly by (a) blunting the limbic system's initial reaction to the stressor, (b) shortening the duration of the stressful reaction, or (c) acting indirectly through inhibitory processes to mute a consciously experienced stress reaction that is no less intense physiologically than it is in the majority of children. All three mechanisms are possible, and each has relevance for the development of psychopathology.

Epidemiological studies in varied Western countries agree that between 1% and 5% of children have simple or social phobias. The range for the looser diagnostic concept of anxiety disorder is larger—5% to 26%—suggesting that the clinical judgment of whether the symptom is disabling enough to be called a disorder is unreliable (Klein & Last, 1989). No more than one-third of preschool children who are very inhibited will be diagnosed with an anxiety disorder 10 years later. This means that most children grow toward health. Although this knowledge represents a major advance compared with the information available 100 years ago, it is, in an absolute sense, only a modest beginning.

There is consensus that some children inherit a physiological vulnerability that renders them especially susceptible to developing one of the many states of anxiety or depression. About 20% to 30% of first-degree relatives of children with an anxiety disorder had a similar symptom, compared with only 10% of controls (Weissman, 1984).

Although the absolute risk is low, children who were high-reactive infants are at a greater risk than most for developing social phobia in adolescence or adulthood. The established lifetime prevalence of social phobia in Americans and Europeans ranges between 5% and 15% (Merikangas, Avenevoli, Acharyva, Zhang, & Angst, 2002). The 3-month prevalence of any anxiety disorder in a large sample of North Carolina youth from 9 to 16

years of age was between 2% and 3% (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003). However, Schwartz, Snidman, and Kagan (1999) reported that 61% of a sample of 13-year-old adolescents who had been inhibited in the 2nd year of life had developed symptoms of social phobia. One half of a sample of 30, 15-year-olds who had been high reactive at 4 months had serious signs of anxiety over social interaction or unfamiliar situations, and three high-reactive girls, but not one low-reactive girl, had been diagnosed with clinical depression (Kagan & Snidman, 2004). However, most high-reactives are likely to find an adaptive adult niche that will protect them from dealing frequently with unfamiliar people on an unpredictable schedule. Fortunately, many vocations and life roles permit this protection while simultaneously awarding dignity, challenge, and financial security to those with this personality trait. Most humans experience uncertainty over one or more of their symbolic features as a result of their life histories. The usual nodes of uncertainty center on acceptability to others, attractiveness, status, wealth, ability, power, and virtue. The high- and-low reactive temperamental biases amplify or mute the intensity of the felt uncertainty. High-reactives experience this emotion more acutely than most; low-reactives experience it less intensely.

The risk categories for low-reactives are failure to conform to community norms because of less uncertainty over criticism or the consequences of risky decisions. This trait is the best predictor of adult psychiatric problems in contemporary North American and European samples because it is correlated with academic failure. Several studies reveal that an extremely uninhibited profile in early childhood is predictive of extreme levels of aggressive behavior during adolescence. For example, 6% of a large sample of lower-class boys were persistently, and seriously, asocial from their second to their 8th year. The best predictor of this small group was a lack of fear to the discrepancy of suddenly hearing the sounds of a gorilla while the child was playing in the laboratory (Shaw, Gilliom, Ingoldsby, & Nagin, 2003). It is of interest that, compared with controls, criminals show less, and social phobics more, amygdalar activity (as measured by fMRI) to neutral faces that function as conditioned stimuli for a painful unconditioned stimulus (Veit et al., 2002). A low-reactive boy raised by a family that did not socialize aggressive behavior effectively who played in a neighborhood containing peer

temptations for crime is probably at a slightly higher than average risk for a delinquent career (Farrington, 2000). But far less risk accompanies a low-reactive boy in a well-integrated family without pathology that socialized aggression effectively—this boy is likely to be popular with peers.

Although every child and adult has the capacity for anticipating unpleasant events, the intensity and chronicity of the accompanying bodily feelings are muted in many persons, and therefore the state does not interfere with the performance of everyday tasks. Only, a small proportion experience feelings, which accompany the unwanted anticipations, with great intensity or regularity to a degree that they compromise their ability to deal with daily responsibilities. These are the individuals who are regarded as having an anxiety disorder. Because the majority of these patients have never experienced the events they fear, or if they had, the frequency of encounter was low, theory predicts that their anxious state should have extinguished over time. Because it does not we must ask why. There are several possible reasons.

When psychoanalytic theories were popular a half-century ago, it was assumed that some life histories could create a chronic feeling of guilt over violations of moral standards. One consequent of the guilt was the expectation of harm or loss as a symbolic punishment for the ethical lapse. Because the guilt was chronic, the anxiety persisted. Although this interpretation of chronic anxiety had intuitive appeal earlier, it is less attractive today because of a secular decrease in the frequency and intensity of guilt over sexual and aggressive behavior, yet no decrease in the prevalence of anxiety disorders.

A second mechanism that relies on classical conditioning assumes that the individual had experienced intense distress during an encounter with the feared event; therefore its mental representations persisted. Some anxiety disorders could have been acquired by a Pavlovian mechanism. This might be especially true for some phobias, but it cannot explain all of the anxiety disorders unless we make thought a conditioned stimulus. Americans who avoid public encounters with strangers are afraid of being evaluated in an undesirable way; they are not afraid of strangers *qua* strangers. They wish to avoid what they imagine to be a critical evaluation by others because of prior experiences in which they felt an unpleasant tension when with strangers. Thus, the thought of entering an unfamiliar social situation provoked the feeling of anxiety.

The hypothesis of inherited physiological profiles acting as a diathesis for an anxiety disorder is an attractive explanatory candidate. These physiological conditions, which are the bases for temperaments, participate in three different explanatory schemes that probably involve the orbitofrontal prefrontal cortex (OBPFC). Activity in the OBPFC is an important origin of an individual's feeling tone. One part of this area receives sensory information from the viscera, as well as external sources related to eating behavior. The OBPFC also receives input from the amygdala and sends its synthesis of information to an area in the OBPFC called the ventromedial prefrontal cortex, which is the origin of projections to the hypothalamus and brain stem (Price, 1999). This arrangement implies that frequent or intense somatic sensations could be due either to an excitable amygdala, an excitable OBPFC, or an active ventromedial prefrontal cortex. If the neural activity pierces consciousness, the person will experience a change in feeling tone and will be motivated to interpret it. The detected change in feeling tone can be interpreted as fear, anxiety, guilt, or excitement, or as a temporary compromise in bodily function. The child or adult who interprets the change in feeling as implying a threatening event can become very anxious. However, the individual could focus on the bodily sensations and fail to impose an interpretation that implied fear or anxiety—a process more common in China than in Europe and North America (Lee & Kleinman, 1997).

The most parsimonious hypothesis is that there is only one diathesis—a neurochemistry that lowers the threshold of excitability of a brain circuit that when activated leads to somatic sensations and a change in feeling tone. The individual's history determines which target will be feared. A much more reasonable hypothesis is that several brain profiles underlie the various anxiety disorders. This view argues that a person with a particular physiological diathesis might develop a blood phobia, while another with a different physiology will develop social phobia.

Moreover, each visceral target—heart, muscle, gut, labyrinth—that sends afferent information to the brain is influenced by a distinct neurochemistry. It is reasonable to assume that genetic features render a particular visceral target more or less reactive and influence the specific events that will be avoided. For example, adolescents with a phobia of blood often report feeling faint when they see large quantities of blood. This fear is

most likely in those who possess a brisk vasovagal reaction, which is accompanied by high vagal tone. One adolescent boy in Kagan's longitudinal sample who had a blood phobia but no other fears had been a low-reactive infant, an uninhibited child, and an adolescent with extremely high vagal tone.

## **ETHNICITY AND TEMPERAMENT**

Differences in temperament among varied ethnic groups remain a delicate issue because of the racial and ethnic strife around the world. Many psychologists, understandably, shy away from studies that might reveal genetically based differences in mood or behavior among populations that have been reproductively isolated for a long time. A team of scientists compared the frequencies of over 100 different alleles for physiological markers in the world's geographically separate human populations by averaging the difference in frequencies to create an index of genetic distance between any pair of populations (Cavalli-Sforza, Menozzi, & Piazza, 1994). As expected, the index of genetic distance was largest when Asians, Africans, and European Caucasians were compared with each other. But even in the Caucasoid Europeans, people from Scandinavia, England, and Northern Europe were genetically different from populations living in Spain, Italy, and the Balkans. In general, the greater the geographical and linguistic distance between any two populations, and, therefore, the greater the reproductive isolation, the greater the genetic distance. It is not unreasonable to assume that some of the alleles have implications for emotions and behavior.

The most consistent evidence relating temperament to geographically separated populations compares Asian with Caucasian infants. Over 30 years ago, Freedman and Freedman (1969) reported that newborn Asian American infants, compared with European Americans, were calmer, less labile, less likely to remove a cloth placed on their face, and more easily consoled when distressed. Nine years later, Kagan, Kearsley, and Zelazo (1978) found that Chinese American infants living in Boston were less active, less vocal, less likely to smile to stimulation, and more inhibited during the 1st year compared with European American infants from Boston.

Caudill and Weinstein (1969) observed Japanese infants to be less easily aroused than European American infants, and Lewis, Ramsay, and Kawakami (1993) found Japanese infants to be less reactive than American

infants (during well-baby examinations) and less likely to cry to inoculation. Five-month-old European American infants showed distress following arm restraint more quickly than did Japanese infants, implying a higher threshold of distress to this incentive in Asian infants (Camras, Oster, Campos, Miyake, & Bradshaw, 1992). Kagan and colleagues administered the battery of visual, auditory, and olfactory stimulations described earlier to 4-month-old infants living in Boston, Dublin, and Beijing. The Caucasian infants from Dublin and Boston were more easily aroused and distressed than the Chinese infants from Beijing (Kagan et al., 1994).

These differences in ease of arousal to unfamiliarity during the 1st year have some parallels in older children. Mothers of 6- to 7-year-old children living in Shanghai described them as less active, less impulsive, more controlled, and more shy than did mothers of children living in the Pacific Northwest (Ahadi, Rothbart, & Ye, 1993). Further, the parents of school-age Thai children, compared with those of European American children, were more concerned over low energy, low motivation, somatic problems, and forgetfulness, whereas the parents of European American children reported more concern with disobedience, aggression, and hyperactivity (Weisz et al., 1987, 1988).

It is relevant that Asian American adult psychiatric patients require a lower dose of psychotropic drugs than European American patients (Lin, Poland, & Lesser, 1986), implying that Asian populations may be at a lower level of limbic arousal. There is, in addition, greater genetic diversity in many loci determining blood groups and proteins among Caucasians than among Asians. Europeans and Asians have been reproductively isolated for over 30,000 years—over 1000 generations. It requires only 15 to 20 generations of selective breeding to produce obviously different behavioral profiles in many animal species (Mills & Faure, 1991). Perhaps, scientists should consider the ethnic composition of their samples when the psychological variables they quantify bear some relation to reactivity and ease of arousal.

The influence of culture has been lost in the excitement over the many significant discoveries in biology. A comparison of European and Asian cultures in the seventeenth and eighteenth centuries, before the West's influence on the latter, illustrates the power of culture. The primary entity in European society is the individual; each person must attain salvation, wealth, status, or happiness on their own. By contrast, the imperative for

Asian youth is to seek harmony with, and become part of, a group—first family and later peers and community. Although children and adolescents can develop either an individualistic or a communal attitude, high- and low-reactives may find the two ethics differentially friendly. High-reactive-inhibited children feel more secure in a social network that sets strict rules for behavior, does not regularly pose demands for excessive risk, and rewards loyalty to the community standards with praise. This type of child is vulnerable to uncertainty in an individualistic society where accomplishment requires entrepreneurial risk, competitive posture, dealing with strangers, and confronting unpredictability.

The low-reactive-uninhibited child is less threatened by such an imperative, enjoys the excitement of risk and meeting strangers, and is more likely to bridle when deviance is punished, whether in the form of extreme talent, lack of civility, or domination of others. Both socialization and temperament contribute to the development of a personality type that conforms to the demands of the local culture.

## TEMPERAMENT AND MORAL AFFECTS

Variation in the intensity of moral emotions might be influenced by temperament. The experience of anxiety, shame, or guilt as an accompaniment to the contemplation or commission of an act that violates personal or community standards is an important source of restraint on those actions. It is likely (as Kant believed) that individuals vary in the intensity of their shame and guilt, although the biology that accounts for this variation may be different from the physiology that represents the foundation for the appearance of the moral emotions in most children. Even though parental practices and attitudes are most influential, temperamental factors might play a small role. The intensity of the experienced moral affects are due to efferents that originate in limbic sites and excite peripheral organs, as well as the quality of afferent activity in the periphery to the medulla, amygdala, and, eventually, frontal cortex.

Damasio (1994) described the case of an adult male who lost, through surgery, the ventromedial surface of his prefrontal cortex. This neural tissue receives afferent information from the amygdala, which, in turn, receives it from the heart, lung, gut, and muscles via a nucleus in the medulla. Without this neuronal surface the individual cannot have the subtle anticipatory feel-

ing of anxiety over risking money on an investment or changing jobs. This patient, who had been an intelligent and successful man prior to the surgery, began to make impulsive decisions after the surgery despite no change in his measured intelligence.

Consider a hypothetical but common situation. A 5-year-old wants a toy that another is enjoying and thinks about seizing it. One of the factors that will influence the probability of a seizure by the envious child is a feeling of anxiety over the possible consequences of the aggressive act. Although socialization in the home will influence the intensity of that feeling, it is reasonable to suggest that children with equivalent socialization experiences will differ in the intensity of the anxiety state because of temperamental factors. This variation is related to the activation of the sympathetic nervous system and the receipt of information from limbic targets by the frontal cortex. For example, low-reactive 1- and 2-year-old infants show less fear to an examiner's criticism than high-reactives. Kochanska (1991, 1993) has shown that shy, timid children raised by mothers who used reasoning in their socialization had a very strict conscience (using a projective measure of conscience). Neither the form of maternal socialization nor the child's shyness, considered alone, predicted variation in the conscience measure.

It is important to emphasize that most children are capable of the moral emotions of anxiety, shame, and guilt. Further, although some children inherit a temperament that favors an exaggerated guilt reaction, such children need not show any pathology later in life. Nor is it likely that most children with a temperament favoring a less intense affective response will become juvenile delinquents. Most parents of these latter children will impose heavier socialization demands on them. Nonetheless, if the environment is permissive of aggression, stealing, and lying, the child with a temperamental bias for a sluggish anxiety/fear reaction is probably at greater risk for aggressive or delinquent behaviors than other children growing up in the same social context (Kochanska, 1995).

The children who had been high-reactive infants should be more vulnerable than others to bouts of guilt because of greater sympathetic activity, and therefore, greater visceral feedback to the amygdala and the OBPF. However, a verbal report of guilt can occur with or without an appropriate change in physiology at the time of the ethical violation. Some children might say they feel guilty, but this confession might not be correlated with a

physiological reaction. Eleven-year-old children were asked in the home setting to rank 20 Q-sort items descriptive of their personality from most to least characteristic. One item was, "I feel bad if one of my parents says that I did something wrong." There was no difference between high- and low-reactives in the mean rank assigned this item (the mean rank was 10), however, high-reactives who ranked this item as more characteristic of self (a rank less than 10) showed a larger number of biological signs of amygdalar reactivity than the low-reactives who rated this item as equally characteristic of self or the high-reactives who did not admit to feeling guilty. The high-reactives who confessed to feeling guilty had a mean standard score greater than .00 across the biological variables that reflected cortical and autonomic arousal. The low-reactives who admitted to equally frequent feelings of guilt had a mean standard score less than .00 (Kagan & Snidman, 2004). The fact that only high-reactives who admitted feeling bad following parental criticism showed signs of cortical and autonomic reactivity suggests that they may be especially vulnerable to bouts of guilt. Most children can be socialized to feel shame or guilt following violation of a standard, but a small proportion are especially vulnerable to these emotions because of their temperament (Kagan & Snidman, 2004).

The mothers of these children ranked 28 statements describing their child from most to least characteristic of their son or daughter. One item referred to the child's behavior when chastised: "is sensitive to punishment." The high- and low-reactive girls differed in the rank the mothers awarded this item, for many more high- than low-reactive girls were described this way. And the high-reactive girls described by their mothers as sensitive to punishment showed greater right parietal activation in the EEG than the high-reactive girls who were less sensitive to punishment.

Low-reactive boys who had high vagal tone represented a special temperamental category. These boys are likely to become group leaders if they grow up in typical American middle-class homes with loving parents who socialize school achievement and the control of aggression. The same boys raised by indifferent parents in large cities may become delinquents. Antisocial adolescents who showed minimal autonomic reactivity to simple stimulation—a lower heart rate and less frequent skin conductance responses—were more likely to continue a criminal career than equally antisocial adolescents who did not become adult criminals (Raine,

Venables, & Williams, 1990; see also, Katz & Gottman, 1994).

It is possible that the small group of criminals who commit violent crimes (probably fewer than 5% of all delinquents and criminals) possess a special temperament. In a longitudinal study of a large New Zealand cohort, the young adults who were violent had been rated at 3 and 5 years of age as low on control of behavior (Henry, Caspi, & Silva, personal communication). A minority of impulsive, minimally fearful 5-year-old boys became adolescent delinquents; only 28% of high-delinquent boys had been rated by their teachers 8 years earlier as highly asocial (Tremblay, Pihl, Vitaro, & Dubkin, 1994). Thus, only a small proportion of asocial adolescents were born with a temperament that placed them at risk for this profile.

## CONCLUSION

The inclusion of biological evidence in studies of temperament and personality is a welcome development. The history of science is rich with examples of the accelerated progress that occurs when two or more previously isolated domains probe common problems with different vocabularies and methods. The fields of biophysics, molecular biology, and radio astronomy are obvious examples. The union of such domains, by providing new information, refines existing terms and eliminates concepts that have outlived their usefulness. This first phase of a collaboration between biology and psychology has led to some new ideas, for example, the realization that the concept of one fear state is not theoretically useful.

As Galen anticipated, children, like animals, inherit different biologies that, in turn, affect the manner in which environmental events influence their psychological growth. Developmental scientists should assume from the beginning that different temperamental types will not react in the same way, behaviorally or biologically, to a given experience and invent constructs that capture that fact.

Psychologists may eventually replace the current constructs, which describe children and their environments (parents, sibling, and school settings) separately, with single synthetic constructs that represent a particular temperamental type growing up in a particular set of contexts. To illustrate, instead of writing about high-

reactive infants, on the one hand, and protective, permissive families, on the other, psychologists might invent a new construct that describes the envelope of possible profiles for the category of child developing in this environment. As environments shape children of varied temperaments into different phenotypes, it will be useful to invent new concepts rather than rely on the language of analysis of variance that describes interactions between the temperamental type of child and a rearing environment.

This suggestion is a special instance of the more general rule that the construct chosen depends on the investigator's purpose. Light can be described as a wave, a particle, or as a source of heat or illumination. It can be useful on some occasions to describe a psychological profile with a construct that defines its current features, biological origins, and experiential history, as we do with the concept of bipolar illness and mathematical genius.

Temperament and history act together to create a psychological barrier between a potentially emotionally charged external event and reaction of the limbic system that renders the event less potent. Fifty years ago, these phenomena would have been called a defense. Although all individuals can learn defenses to protect them from distress to threat, a small proportion of children may inherit a temperament that makes it easier for them to establish these defenses. A child's experiential history determines the meaning imposed on an event; a combination of temperament and history determines both the ease with which the interpretation of an event gains access to varied brain circuits as well as the excitability of those structures.

The return of temperamental constructs will, inevitably, increase scientific interest in affective phenomena and, in so doing, alert psychologists to those events that have their primary effect on feeling tone and emotions rather than on behaviors, especially the emotion families called guilt, shame, fear, anger, pride, anxiety, sadness, excitement, surprise, and joy. Individual variation in the frequency and intensity of those affect states is influenced by temperament and the constructions that children create from their encounters. It is reasonable to be optimistic about the future of developmental psychology if scientists search for the coherent profiles that emerge from biological predispositions and life histories and do not insist on reducing each profile either to the actions of genes or the consequences of experiences. We will then attain a synthesis as fruitful as the one that followed the recognition that

evolution required mutation, recombination, geographical isolation, and a natural selection of those features that were adaptive in particular settings.

## CHAPTER 5

# *Emotional Development: Action, Communication, and Understanding*

CAROLYN SAARNI, JOSEPH J. CAMPOS, LINDA A. CAMRAS, and DAVID WITHERINGTON

### A CONCEPTUAL FRAMEWORK FOR FEELING AND EMOTION 227

#### A Working Definition of Emotion 227

#### Culture, Emotion, and Emotional Development 235

### THE DEVELOPMENT OF EMOTIONAL COMMUNICATION IN EARLY LIFE 239

#### Phase 1 (Prenatal to 6 Weeks): Initial Reactions to Emotion Signals 240

#### Phase 2 (6 Weeks to 9 Months): Pre-Referential Communication 241

#### Phase 3 (9 Months to 18 Months): Behavioral Regulation and Referential Communication 243

#### Phase 4 (18 Months/2 Years and Beyond): The Rise of Other-Conscious Emotions 246

### EMOTIONAL DEVELOPMENT IN CHILDHOOD AND ADOLESCENCE: SOCIAL EFFECTIVENESS AND POSITIVE ADAPTATION 248

#### Social Adjustment and Emotion Regulation 248

#### Emotional Competence 249

#### Social Effectiveness and Skill 1: Awareness of Our Emotions 250

#### Social Effectiveness and Skill 2: Ability to Discern and Understand Others' Emotions 254

#### Social Effectiveness and Skill 3: Use of a Vocabulary of Emotion and Expression 258

#### Social Effectiveness and Skill 4: The Capacity for Empathic and Sympathetic Involvement 262

#### Social Effectiveness and Skill 5: Skill in Differentiating Internal Emotional Experience from External Emotional Expression 266

#### Social Effectiveness and Skill 6: Skill in Adaptive Coping with Aversive Emotions and Distressing Circumstances 271

#### Social Effectiveness and Skill 7: Awareness of Emotion Communication in Relationships 279

#### Social Effectiveness and Skill 8: Capacity for Emotional Self-Efficacy 282

### CONCLUSION 284

### REFERENCES 288

Extraordinary changes have been taking place in the study of emotion in the past 30 years. When the chapter dealing with socioemotional development was published in the fourth edition of this *Handbook* (Campos, Barrett, Lamb, Goldsmith, & Stenberg, 1983), the study of emotion and emotional development was just emerging from decades of neglect. As was noted in that chapter, there were two principal reasons for the neglect. The first was the widespread conviction that emotions were epiphenomenal, and the second was that emotions could not be

measured with specificity. The 1983 chapter described the emergence of a functionalist approach to emotions, and showed how, contrary to prior thought, emotions profoundly affected cognitive, perceptual, social, and self-regulatory processes. It also described the close link between emotion and temperamental dispositions, attachment, and parent-child interactions. It also documented major advances in the measurement of emotion in face, voice, and action. The chapter in the fifth edition of this *Handbook* detailed the elaborations in theory

and research in emotion and emotional development since 1983, and extended the treatment of emotion to include new concerns about emotion competence.

The remarkable surge of investigation on emotion has continued unabated in the past 10 years, and the results of such investigations are dramatically changing our conceptualization of both the nature of emotions and their function in development. Three major themes in recent research stand out: (1) the close link between emotion and action, (2) the social functions of emotion, and (3) the closing of the gap in knowledge about development between infancy and adolescence.

The present chapter reflects these three emphases. First, we describe a recently revived way of conceptualizing emotion—one that traces its roots to the long-ignored work of John Dewey (1894, 1895). Second, we stress children's understanding of emotion, and how children cope with their emotions and the environmental transactions that evoke them. Third, we are concerned with emotional development in preschool and middle childhood, when the significance of emotion is especially broad in scope. The chapter also contains a number of subordinate themes. For instance, we review some of the intriguing research that has been done with infants and toddlers on how they develop systems of emotional communication. In the process, we show how the emotional expressions of others regulate the behavior of infants and children and result in empathic behavior, emotion regulation, and coping. Furthermore, we discuss why action has become so important in contemporary approaches to emotion, and how cultural approaches to emotion are beginning to draw our attention to the importance of emotion communication in development.

## A CONCEPTUAL FRAMEWORK FOR FEELING AND EMOTION

Emotions seem to be most closely linked to what a person is trying to do. One's perception and interpretation of events is never independent of the action that one can perform on them (Adolph, Eppler, & Gibson, 1993; Dewey, 1894, 1895). Indeed, an event can be defined as an opportunity for action. However, not all events generate emotion—only those in which one has a stake in the outcome. Hence, we propose a working definition of emotion that emphasizes action, the preparation for action, and appraisal of the significance or relevance to concerns of

person-environment transactions. This framework includes communication as a central aspect of action.

### A Working Definition of Emotion

*Emotion is thus the person's attempt or readiness to establish, maintain, or change the relation between the person and her or his changing circumstances, on matters of significance to that person* (Campos, Frankel, & Camras, 2004).

The definition may initially appear to be odd because of the absence of any reference to the traditional elements found in the most prevalent definitions of emotion. There is no allusion to feeling, vegetative states, facial indices of internal states, or other intrapersonal criteria. Instead, emotion is determined by the significance of a person-event transaction. Because the definition emphasizes what the person is trying to accomplish, and because it comes from a conception of emotion that stresses the consequences of emotional states, this working definition of emotion is often called a functionalist one (Barrett & Campos, 1987; Campos, Mumme, Kermoian, & Campos, 1994; Frijda, 1986, 1987; Lazarus, 1991).

There are at least four ways by which events become significant. The first is a particularly powerful and pervasive one: goal relevance and its corollaries. Lazarus (1991) specifically links the first step in the generation of emotion to this factor; however, goal relevance ensures the generation only of some kind of affect. To account for whether the affect has a positive or negative hedonic tone and a behavioral valence of approach or withdrawal, Lazarus posits the congruence or incongruence of an event to personal goals: Goal congruent transactions produce positive hedonic tone, and goal incongruent transactions bring about negative tone. To explain how a specific emotion such as fear, anger, or shame comes about, he proposes the factor of ego involvement (this determines the specific nature of the emotion elicited). So, regardless of the specific goal one is working toward, a person who overcomes obstacles to goal attainment is likely to experience happiness or relief. A person who relinquishes a goal experiences sadness, regardless of whether that goal involves physical, social, or psychological loss. A person who encounters obstacles to goal attainment will show frustration or anger. The specific nature of the goal can also affect the experience of a given emotion. Thus, avoidance of threat is linked to fear, wanting to atone is related to

guilt, and the wish to escape the scrutiny of others following a transgression is linked to shame. Table 5.1 lists the factors that Barrett and Campos (1987) proposed for the generation and manifestation of a variety of emotional states. Some of these emotions are called “primordial emotions,” to denote their likely presence in the neonate and their rudimentary appraisal demands; others are called “concurrent state emotions,” to specify their close link to flexible goals and strivings; still others are called “social emotions,” to indicate their origin in social rules backed by emotion communication from significant others. For all of these emotions, goal relevance is typically the most fundamental principle of emotion generation.

Not all emotions are generated by the relation of events to goals. A second way in which emotion can be generated is through the social signals of others, which have powerful capacities to render a person-environment transaction significant (Klinnert, Campos, Sorce, Emde, & Svejda, 1983; McIntosh, Druckman, & Zajonc, 1994). They do so because social signals can generate a contagious emotional response and tendency for action in the perceiver (Hatfield, Cacioppo, & Rapson, 1994). Social signals can also give meaning to a transaction associated with the signal (such as when an infant catches the mother’s fear of dogs and begins to avoid them; e.g., Bowlby, 1972). Finally, social signals play a central, though under-investigated, role in generating emotions such as pride, shame, and guilt through the enduring effects that they can have as accompaniments to the approval and disapproval of others.

A third source of significance comes about through hedonic processes—specifically, when hedonic stimulation is experienced and becomes the object of one’s strivings (Frijda, 1986). Hedonic stimulation refers to the sights, sounds, tastes, smells, and tactile stimulations that intrinsically produce irreducible sensations of pleasure or pain. With pleasurable hedonic experience, we are more likely to want to repeat such experience and thus we approach objects and people. It is the opposite with painful experience. Pleasure and pain are affectogenic in the following way, taken from Frijda (1986): If, after one experiences pleasant stimulation and one wants to repeat the experience, the emotion of desire is generated; similarly, if one experiences pain and wants not to repeat the experience, the emotion of aversion is created. Desire and aversion, with further development, can become the core of much more complex emotional transactions, including envy, jealousy, and rage.

The fourth way that events become significant comes from memory of transactions from the past. Although all emotion theories stress the role of memory in generating affect, we would like to emphasize the importance of past experience for the selection of strategies for responding emotionally. Such a link is best represented in the research on working models in attachment (Bretherton, 1985). For example, as Cassidy (1994) has said, avoidantly attached infants typically have a history of interactions in which their attachment figure has ignored the infant’s social signals such as bids for comfort. When these bids are consistently rejected by the caregiver, the child is predisposed toward muted affect during reunions with the caregiver. The past history of ignoring social bids makes the risk of present rejection too great. By contrast, infants who are classified as ambivalently attached have a history of interaction with a figure who has responded inconsistently to their social signals. When such children are reunited with the attachment figure following separation, they show exaggerated, rather than muted, emotional reactions. Such exaggeration serves the function, in part, of ensuring the parent’s responsiveness and avoiding the parent’s insensitivity. Thus, past experiences determine not only the precise nature of the emotion a child undergoes (as in the case of desire and aversion discussed earlier) but also the manner in which the child responds to, or copes with, contemporary interactions with significant others.

### *Feeling and Emotion*

What is the role in the emotion process of what we call feeling—the irreducible quality of consciousness that accompanies evaluations? The layperson’s conception places feeling at the core of emotion. That conception goes as follows: Events elicit feeling, feeling organizes expressions (or outward signs) of feeling and autonomic and instrumental behavioral reactions designed both to manifest outwardly and, in addition, to deal with the feeling. In development, many theorists (e.g., Lewis & Michalson, 1983; Sroufe, 1979) have proposed that feeling is absent in the young infant and comes about only after the infant has acquired the capacity to distinguish self from other—an accomplishment that begins to be shown by 9 months of age.

The functionalist approach to emotion gives feeling a major role as a facet of emotion, but not as its core. Feelings are not prior in time to other processes in emotion generation, as orthodox conceptualizations require. We propose that the origins of feeling come from four

**TABLE 5.1 Characteristics of Some Emotion Families**

Emotion Family	Goal	Appreciation re Self	Appreciation re Other	Action Tendency	Adaptive Functions	Facial Expression <sup>b</sup>	Physiological Reaction	Vocalic Pattern <sup>f</sup>
Disgust	Avoiding contamination or illness	This stimulus may contaminate me, or cause illness	<sup>a</sup>	Active rejection	Avoid contamination and illness; learn about substances/events/attributes to avoid; alert others re contamination	Brows lowered, nose wrinkled, with widened nasal root; raised cheeks and upper lip	Low heart rate and skin temperature; increased skin resistance <sup>c</sup>	Nasal, slightly tense, "very narrow," but fairly full and powerful voice
Fear	Maintaining integrity of the self (physical or psychological integrity)	This stimulus threatens my integrity	<sup>a</sup>	Flight; active withdrawal	Avoid danger (physical and psychological); learn about events/attributes that are dangerous; alert others re danger	Brows raised and often pulled slightly together; eyes very wide and tense, rigidly fixated on stimulus	High, stable heart rate; low skin temperature; "gasping" respiration <sup>c</sup>	"Narrow," extremely tense, very weak, thin, high voice
Anger	Any end state that the organism currently is invested in achieving	There is an obstacle to my obtaining my goal	<sup>a</sup>	Active forward movement, especially to eliminate obstacles	Attain difficult goals; learn to overcome obstacles and achieve goals; communicate power/dominance	Brows lowered and pulled together; mouth open and square or lips pressed tightly together	High heart rate and skin temperature; facial flushing <sup>c</sup>	"Narrow," medium to very tense, medium to extremely full voice
Sadness	Any end state that the organism currently is invested in achieving	My goal is unattainable	<sup>a</sup>	Disengagement; passive withdrawal	Conserve energy; learn which goals are realizable; encourage nurturance by others	Inner corners of brows moved upward; corners of mouth pulled downward, often with middle of chin pulled upward	Low heart rate; <sup>d</sup> low skin temperature and skin resistance	"Narrow," thin, lax, slow, or halting voice
Shame	Maintaining others' respect and affection; preserving self-esteem	I am bad (self-esteem is perceived to be impaired)	Someone/everyone notices how bad I am	Active or passive withdrawal; avoiding others; hiding of self	Behave appropriately; learn/maintain social standards; communicate submission to others and to others' standards	—	Low heart rate; blushing <sup>e</sup>	"Narrow," moderately lax, thin voice
Guilt	Meeting one's own internalized standards	I have done something contrary to my standards	Someone has been injured by my act	Outward movement; inclination to make reparation, to inform others, and to punish oneself	Behave prosocially; learn/maintain moral and prosocial behavior; communicate contrition/good intentions	—	High heart rate and skin conductance; irregular respiration <sup>e</sup>	"Narrow," tense, moderately full voice
Pride	Maintaining the respect of oneself and others	I am good (I have respect for myself)	Someone/everyone thinks (or will think) I am good	Outward/upward movement; inclination to show/inform others about one's accomplishments	Behave appropriately; learn/maintain social standards; communicate ability to meet standards	—	High heart rate <sup>e</sup>	"Wide," medium tense, full voice

<sup>a</sup>No "appreciation re other" is central to primordial or concurrent-goal emotions; however, particular family members might involve such an appreciation.

<sup>b</sup>These facial movements are adapted from Izard (1979).

<sup>c</sup>These are adapted from Ekman, Levenson, and Friesen (1983).

<sup>d</sup>Ekman et al. (1983) found increased heart rate with sadness; however, decreased heart rate is consistent with our theoretical position on sadness. We think it possible that most subjects in Ekman et al.'s study experienced an agitated grief state rather than a sad "giving-up" state.

<sup>e</sup>These are hypothesized physiological reactions.

<sup>f</sup>These vocalic patterns are adapted from Scherer (1986).

sources, some of which are different from the sources that generate emotion and were delineated earlier (Campos et al., 1994). One of these is the conscious accompaniment to the process of *appraisal*—the determination of how an event impinges on one's goals (Lazarus, 1991). The appreciation of the meaning of an event shows that it *matters* to the individual, and feeling is the registration of this significance. In short, feeling accompanies—not precedes—the registration of events.

The second source of feeling is the consciousness of the activation of goal-oriented central motor commands (efference). Efference, unlike return sensory flow to the brain (afference), has rarely been linked to consciousness in psychological theories, yet efference plays a role in the perception of self-motion as well as in the sense of volition—of willing a body movement to take place (Teuber, 1960). This notion of the importance of efference in generating feeling is consistent with the reasoning of Ekman, Levenson, and Friesen (1983), who discussed the importance of motoric commands to create facial patterns and for bringing about both emotion and feeling. It is also consistent with recent theorizing by Damasio (1994) who stated, “the brain learns to connect the fainter image of an ‘emotional’ body state, without having to reenact it in the body proper” (p. 155). The link between efference and emotion again renders feeling contemporary with emotion generation, not as an antecedent.

The third way feeling can be generated is through the perception of sensations coming from both smooth and striated muscles and from the effects of hormones. Our language is full of references to these internal states such as when we talk of feeling a “cold” fear, being “flushed” in anger, having “butterflies in the stomach,” and so forth. In addition, many cultures literally embody emotion by referring to somatic states that occur when one is in distress or euphoria (Shweder, 1993). The role of feedback seems undeniable in creating aspects of feeling (Laird, 1984), but feeling is again not primary. It follows response generation.

The fourth way that feeling can be generated is through the direct perception of emotional expressions in the face, voice, and gesture of another (Hatfield et al., 1994). This is the phenomenon referred to as *socially induced affect* (McIntosh et al., 1994), which is defined as the generation of a like or complementary feeling state in the other as a result of the perception of social displays in another. This phenomenon is quite context specific. At this time, we do not understand the

circumstances in which expressions by another most directly generate a similar feeling in the perceiver, those which generate an emotional state that is similar in valence but different in quality, those in which an opposite emotional state is elicited, and those in which no feelings are generated at all. Research on the ontogeny and consequences of affect contagion and socially induced affect is sorely lacking, despite exciting work with socially deprived infant monkeys suggesting that no social experience is necessary for social signals to affect behavior in affectively appropriate ways (Kenney, Mason, & Hill, 1979; Sackett, 1966; see also the subsequent section in this chapter on the related process of empathy). Socially induced affect renders feeling simultaneous with the detection of social signals, not prior to them. Such considerations are what have led us to propose that feeling is a facet of the emotion process, but not its core. In addition, because infants can show facial and instrumental behavior patterns of specific emotions very early in life (e.g., Gaensbauer, 1982; Stenberg & Campos, 1990), appraisal, efference, and afference are available to the young infant, and so may affect emotion contagion (Haviland & Lelwica, 1987). We thus find no reason to deny infants younger than 9 months of age the experience of feeling.

### *Facial Expressions and Emotion*

Facial expressions have been hypothesized to play a particularly important role in the emotion process. One historically influential emotion theorist (Tomkins, 1962) virtually equated emotion with facial responding. For preverbal infants, facial expressions have been proposed to have additional importance because they are presumed by some to be the sole means by which emotions can be communicated before the advent of language. Thus, some scholars have proposed a virtually one-to-one correspondence between emotion and facial expression for postneonatal infants (Izard, 2004; Izard, Ackerman, Schoff, & Fine, 2000) and developed coding systems for infant emotions that rest on the identification of prespecified facial configurations. Such an approach to emotion measurement would have considerable appeal because it provides an easy solution to the problem of identifying emotion in infants. However, we believe it is fundamentally flawed on both an empirical and conceptual level. Recent studies have documented numerous examples of nonconcordance between emotion and these prespecified facial expressions. For example, infants on the visual cliff display

clear indications of fear (e.g., refusal to crawl) but do not show prototypic fear expressions. Indeed, they often *smile*! Conversely, infants typically produce the prototypic facial configuration of surprise (involving raised brow and open mouth) as they introduce an object into their mouth for oral exploration (Camras, Lambrecht, & Michel, 1996). Such mismatches do not imply that facial expressions are misleading or irrelevant to infant emotion. As we further argue, we believe that facial expressions serve as critically important components in a larger pattern of information that observers perceive and integrate in making an emotion judgment (see Oster, in press, for a somewhat different but related view of infant emotional facial expressions).

### ***Action Tendencies and the Flexible Manifestation of Emotion***

In the course of studying blind infants, Fraiberg (1971) discovered that many parents of such children showed profound disappointment when they encountered low levels of facial responsiveness and eye contact in their children. The parents seemed to withdraw from their children and to lack the incentive to provide them with physical and social stimulation after noting their children's apparent unresponsiveness. Fraiberg (1971) discovered that although blind infants were indeed relatively unresponsive *facially* during social encounters, they seemed extraordinarily articulate in expressing their emotions and social responses through the actions of their *fingers*. When this responsiveness was pointed out to the parents, they dramatically increased their levels of interaction with the infants; the infants, in turn, were able to maintain their digitally mediated level of social responsiveness.

Fraiberg's observations document an important principle about emotions: Many different responses can be in the service of any given emotion—emotional responses exhibit the property of equipotentiality. To expect, as some theories do (e.g., Ekman et al., 1983; Izard, 1977, 1991; Tomkins, 1962, 1963), a close correspondence between a given response or response pattern (e.g., a facial expression) and a given emotional state is likely to lead to errors of inference. The opposite is also true: The same response can be recruited to express many different emotions. Some years ago, Kagan (1971) put it well. He said that the smile serves many masters. Consider that the action of smiling can be in the service of joy, scorn, nurturance, embarrassment, and other emotions, or stereotyped social greeting. Similarly, the

action of doing nothing can be in the service of sadness (as in depressive withdrawal), fear (as in keeping still to avoid detection), or anger (as in passive aggressiveness). Emotions are best considered as “syndromes”—alternative patterns of behavior, any of which can under the right circumstances specify the emotion (Lazarus & Averill, 1972). It is not possible to identify a priori an operational definition of a given emotion that can be applied in all circumstances, such that knowing the response or response pattern by itself one can predict the emotional state of a person. A discrete emotion thus lacks a gold standard—an ostensive definition. Neither the face, voice, gesture, specific instrumental behavior nor autonomic signatures are likely to have more than a probabilistic relation to an emotional state; even then, context must be taken into account to interpret the meaning of a response (see Camras et al., 2002).

At present, the concept of *affect families* (Barrett & Campos, 1987; Dewey, 1934; Kagan, 1994) is used to convey the notion that each experience of a given emotion such as anger or fear is likely to differ in important ways from other emotional experiences of the same class. Each instance of an emotion differs from another in social signaling, type of behavior shown in context, and pattern of appraisal, yet, so long as the adaptational intent is the same for two different experiences, it can be said that the different instances bear a “family resemblance” to each other. Through such adaptational intents, emotions can be classified and their differential consequences understood (Shaver, Schwartz, Kirson, & O'Connor, 1987), not by similarity in morphology.

### ***Measuring Emotion via Action Tendencies***

The absence of an ostensive criterion for a given emotional state creates serious problems of inference. One attempt to resolve this dilemma has been proposed by Frijda (1986) in his concept of *action tendencies*. Avoidance of threat, for instance, is the action tendency for fear; avoidance of social contact of the scrutinizing other is that for shame; devotion of effort to remove an obstacle is the action tendency for anger, and so on. Table 5.2 lists Frijda's proposed action tendencies and the specific emotions that they denote—a list that he considers incomplete but representative. Note that Frijda's list of action tendencies yields a much larger number of emotions than does reliance on universality of recognition of facial expressions, which usually are limited to fear, sadness, joy, surprise, sadness, disgust, and possibly contempt.

TABLE 5.2 Relational Action Tendencies, Activation Modes, and Inhibitions<sup>a</sup>

Action Tendency	End State	Function	Emotion
Approach	Access	Producing situation permitting consummatory activity	Desire
Avoidance	Own inaccessibility	Protection	Fear
Being with	Contact, interaction	Permitting consummatory activity	Enjoyment, confidence
Attending (opening)	Identification	Orientation	Interest
Rejecting (closing)	Removal of object	Protection	Disgust
Nonattending	No information or contact	Selection	Indifference
Agonistic	Removal of obstruction	Regaining control	Anger
Interrupting	Reorientation	Reorientation	Shock
Dominating	Retained control	Generalized control	Arrogance
Submitting	Deflected pressure	Secondary control	Humility
Deactivation	—	(Recuperation?)	Sorrow
Bound activation	Action tendency's end state	Aim achievement	Effort
Excitement	—	Readiness	Excitement
Free activation	—	Generalized readiness	Joy
Inactivity	—	Recuperation	Contentment
Inhibition	Absence of response	Caution	Anxiety
Surrender	Activation decrease?	Activation decrease or social cohesion?	Laughter, weeping

<sup>a</sup> Adapted from Frijda (1986).

For Frijda, the concept of action tendency in no way refers to a response that can be measured by electromyography or by operational definition of a given response. Rather, action tendency refers to any of a number of flexibly organized phenomena that *serve the function* of, for example, avoiding threat or overcoming an obstacle. In this sense, action tendency is similar to the ethologist's conception of a behavioral system—a conception that replaced notions of fixed action patterns with appreciation of the multiplicity of ways by which an animal can attain an end (Bischof, 1975). The behavioral system for the ethologist, like the concept of a specific emotion, is defined by the function those behaviors serve. How is function measured? The functionalist's answer is: (a) by inference from the organization of behavior, (b) by suppositions about what the person is trying to accomplish, and (c) by noting whether progress toward the inferred goal is proceeding smoothly or with difficulty. The identification of the operation of a discrete emotion is intimately tied in to the context in which the person is found and the types of behavior pattern the person shows in that setting.

Although the task of measuring emotion is much more difficult than initially thought when emotion was re-

stored to its place in scientific study a few years ago, there is a major precedent for measuring the organization of behavior—a precedent that is both intellectually persuasive and highly influential (Sroufe & Waters, 1977). In attachment theory, Bowlby (1969) posited that attachment could be measured by proximity seeking in times of fear or distress. Although proximity seeking can be operationalized by measuring the physical distance of the child from the attachment figure (Coates, Anderson, & Hartup, 1972; L. Cohen & Campos, 1974), such an approach reveals little in the way of stability of individual differences in attachment, nor is it an index that retains its manifestation as the child grows older and shows attachment patterns in a variety of different ways. Attachment theorists (e.g., Ainsworth, Blehar, Waters, & Wall, 1978) have solved this problem of measuring “proximity seeking” by noting first of all whether different behaviors shown by the child in the context of reunion with the caregiver are in the service of proximity-seeking, even though there may be no approach toward the caregiver. There are many alternative ways in which attachment security can be manifested: smiling at the caregiver, making pickup bids, sharing the joy of playing with a toy, and so on. These alternative behavioral strategies are taken as

partial evidence for what Sroufe (1979; Sroufe & Waters, 1977) calls “the organization of behavior.” The organization stems from the similar ends that morphologically quite different behaviors serve. The crucial factors of avoidance and ambivalence in attachment are similarly inferred by judging the many alternative ways that a child can give the parent the “cold shoulder treatment” specifying avoidance, or the “angry yet relieved” expression of ambivalence. In short, we think investigators of emotion can learn useful lessons from the literature on attachment, especially to the extent that both emotion and attachment exhibit the property of equipotentiality of responses.

This approach to measurement of the action tendencies related to attachment needs to be generalized to the study of other emotional states. It should not be thought that such flexibility of behavior organized around an emotion is limited to the older school-age child and the adult. Fraiberg’s (1971) observations of blind infants’ social responsiveness described earlier demonstrate this, and so do 8- to 9-month-old infants tested on the visual cliff, a highly reliable fear elicitor (Scarr & Salapatek, 1970). At that age, infants can manifest fear by literal avoidance of descending onto the glass-covered deep side of the cliff, or they can approach the mother, but in a manner indicative of fear. The infants do this by detouring around the deep side, hitching along the sidewalls of the cliff table until they reach the mother (Campos, Hiatt, Ramsay, Henderson, & Svejda, 1978). Behavioral flexibility is the rule, not the exception, in the manifestation of emotion. Restriction of such flexibility in the interests of measuring one or more responses chosen a priori puts at risk the internal validity of a given study, as well as its external or ecological validity.

### ***Component Systems Approaches to Emotion and its Development: Dynamical Systems and Functionalist Perspectives***

In the previous section on action tendencies, we emphasized how emotions lack a gold standard because various aspects of emotional action—facial, vocal, and gestural signals, or specific instrumental behavior—are flexibly organized depending on context. Just as any emotion action cannot be fully understood independent of context, so *any* component of emotion, whether it be action or action tendency, goals and concerns, physiological patterning, appraisals, experiential feeling states, or social and physical contexts, cannot explain emotion itself independent of the other components that comprise the system and the relations that exist among

the components. For example, an individual may experience road rage only when he is in a hurry (i.e., the impediment has high significance), when he can find no way around the impeding driver, when he appraises the driver as deliberately obstructive, and when the driver resembles his estranged father. As emphasized by the dynamical systems approach, emotion cannot be reduced to any one of these components; specific components themselves do not engender emotion, only the relations among components. Thus, fully capturing the complexity of emotion and its generation requires a view of emotion as *relational*, deriving from the *interactions* of many components (Fogel & Thelen, 1987; M. D. Lewis, 2000; M. D. Lewis & Granic, 1999; Mascolo & Harkins, 1998).

Such a view has immediate implications for our conceptualization of emotional development. Understanding the difference in emotion between a 12-month-old and an 18-month-old extends beyond a simple acknowledgment of differences in how the two appraise events, and must include consideration of those developmental changes that engender such alterations in appraisal: changes in the infant’s goals and concerns as well as the means available to the infant for acting on the world and thus achieving his goals. The source of developmental transformation in emotion thus resides in the *relations* among components that comprise the system (Fogel et al., 1992; Griffin & Mascolo, 1998; Witherington, Campos, & Hertenstein, 2001). As envisioned by dynamical systems approaches, these components influence one another so that the system *self-organizes* into relatively stable patterns that differ across age. By way of contrast, traditional explanations have attributed emotional development to factors that they consider to be external to the emotion system. A classic example of such an approach is evident in Emde, Gaensbauer, and Harmon’s (1976) biobehavioral shift model of emotional development. By their account, the emergence of social smiling around 2 months and the emergence of fear in multiple contexts around 8 months *reflect* overarching neuromaturational change. To quote Emde et al.: “The emergent affect behavior is not the organizer, it merely indicates it” (p. 8). From the standpoint of biobehavioral shifts, emotional development is determined by outside factors (Emde, Kligman, Reich, & Wade, 1978). Most cognitive theories of emotional development follow a similar line of approach by arguing that emotional development is attendant on the development of specific cognitive prerequisites that are considered external to emotion, such as new representational

and memory abilities, the emergence of objective self-awareness, or the emergence of an ability to evaluate behavior against a standard (e.g., Kagan, 1984; M. Lewis, 1998). From a dynamical systems perspective, these factors are intrinsic components of the emotion system in that they become organized in specific configurations during emotion episodes.

When emotion is viewed as self-organization rather than organization from without, it also becomes clear that development may involve components unique to the emotion system such as appraisal. Appraisal, unlike objective self-awareness or recall memory, is an emotion-specific form of cognition, an evaluation of events by an individual's goals and concerns. As such, appraisal is a cognitive-motivational process rather than a purely cognitive one (Barrett & Campos, 1987; Mascolo & Fischer, 1995). The concept of appraisal again highlights the importance of viewing the components of emotion in relation to one another. *Causality* in the emotion system is multiply determined by the relation of many components. Thus, environmental events do not cause the development of emotion independent of an individual's concerns and goals and vice versa. Similarly, evaluations of events do not cause the development of emotion independent of the individual's action repertoire, their goals and concerns, and so on. All of the components that comprise the emotion system thus assume formative significance in understanding stability and transition in emotional development (Fogel et al., 1992).

As an organizational framework, the functionalist approach also provides a useful heuristic for integrating our understanding of the relations that exist among the components of the emotion system. The functionalist approach adopts as its central level of analysis the goal-mediated relation between person and environment and identifies certain commonalities or themes in significant person-environment transactions (Barrett & Campos, 1987; Campos et al., 1994). What any given person is doing in a particular context can be organized by a set of abstracted functional relations—what Lazarus (1991) has termed *core relational themes*—that hold for all potential person-environment transactions, such as “trying to overcome an obstacle to obtain a goal” or “trying to avoid a threat to one's well-being and safety.” We have already discussed these general themes in the context of emotion families and relational action tendencies. To organize the enormous behavioral and contextual variability that characterize the emotion process in real-time person-environment

transactions, the functionalist appeals to those themes involving basic matches/mismatches between an individual's concerns and events in the world (Witherington, 2003). For example, many different concrete events can call forth the emotion of anger: the stubbing of a toe, a traffic jam, or misplacing one's keys. For the functionalist, what unites all of these events is their serving as obstacles to goal attainment. Similarly, many different actions can be in the service of the emotion of anger: striking out at others, stonewalling, or finding an alternate route to work. What unites all of these actions is the function they can serve—the removal of an obstacle.

The functionalist thus adopts an abstract level of explanation for emotion and its development that is grounded in the particularities of a person's real-time encounters with the environment but that extracts from these particulars a set of general functional relations. In this way, the functionalist approach provides an invaluable interpretive framework for understanding the emotion process in all of its complexity (Witherington, 2003). However, the question of how specific emotion actions emerge during specific emotion episodes remains largely unaddressed by the functionalist framework. Dynamic systems approaches to the study of emotional development complement the functionalist approach by attempting to address this question (e.g., Camras, 1992; Fogel et al., 1992; Lewis & Granic, 2000). As earlier described, both the functionalist approach and the dynamic systems approach view emotion as a self-organizing, multicomponential system, the patterning of which is multiply determined such that no one component is any more primary in the emergence of pattern than any other. But whereas the functionalist approach sets its sights on providing a meaningful organizational framework for interpreting person-environment transactions, the dynamic systems approach takes as its charge the explanation of the emotion process at the more specific level of real-time action in context. For example, with respect to smiling, Dickson, Walker, and Fogel (1997) have shown how the fine-grained morphology of infant smiling patterns varies in accordance with the particular form of play in which infants and parents are engaged. When play involved book reading, 12-month-olds predominantly displayed smiles consisting only of lip corner raises, but when parent-infant interactions turned to physical play, infant smiling most characteristically involved opened mouth smiling, and when parents playfully vocalized with their infants,

infant smiling typically included both lip corner raises and contraction of the orbicularis oculi muscles surrounding the eyes (termed the *Duchenne* smile after the nineteenth-century French neurologist). Furthermore, Duchenne and non-Duchenne smiles—smiles not involving orbicularis oculi contraction—may grade into one another, reflecting a quantitative dimension of positive engagement. In a longitudinal sample of 1- to 6-month-olds observed during play with their mothers, Messinger, Fogel, and Dickson (1999) found that non-Duchenne smiles typically preceded in close temporal proximity Duchenne smiles and that this relational correspondence between the two forms did not vary across the age range studied. These findings reveal how intimately involved contextual factors are in the formation of emotion-related actions during real-time parent-infant interactions. Current applications of dynamic systems principles to emotional development, however, are not specific to emotion; rather, the same principles apply to any action-in-context, emotional or otherwise. In the absence of an organizational framework like that provided by the functionalist approach, dynamic systems approaches have yet to offer specific insight into emotion itself as a content domain. Thus, the contribution of dynamic systems approaches to the study of emotional development as *emotional development* remains largely unexplored.

### ***Change in Person-Environment Relations and Emotional Development***

Given the importance of person-environment relations in the generation of emotion, it should come as no surprise that factors that alter the relation of person to environment have important consequences for emotional development (Witherington et al., 2001). In the period of infancy, motor achievements such as visually guided reaching, crawling, and walking fundamentally alter the way infants psychologically engage the world and are widely regarded as important points of transition in cognitive and perceptual development. Treating emotion as a multicomponent system suggests that our investigations of emotional development should target such points of motoric transition as well as pervasive ecological changes, such as entering preschool. Developments in a variety of domains result in changing the relation between the person and the world and thus lead to important changes in emotion.

Considerable evidence supports a link between experience with crawling and emotional development (Berten-

thal & Campos, 1990; Saarni, Mumme, & Campos, 1998). For example, experience with self-produced locomotion, either through crawling or through the use of a walker, gives rise to the phenomenon of wariness of heights (Campos, Bertenthal, & Kermoian, 1992; Campos et al., 1978). Parents also report major increases in their infants' displays of anger and temper tantrums following crawling onset (Campos, Kermoian, & Zumbahlen, 1992). Furthermore, the emergence of crawling affects the whole socioemotional climate in which the infant resides. Parents of crawling infants embark on new forms of emotional communication with their infants (Campos et al., 1992; Zumbahlen & Crawley, 1996). Once infants begin to crawl, parents direct much more positive affect toward their infants in the context of exploration and the discovery of new events and situations. At the same time, parents begin to regard their infants as more sophisticated and intentional, assigning them more responsibility for their actions. This change, coupled with the increased chance for a mobile infant to encounter dangerous situations, produces a substantial increase in parental targeting of fear and anger to their infants once crawling begins.

Like crawling, infant walking has long been regarded as functionally related to infant emotional development (Mahler, Pine, & Bergman, 1975; Spitz, 1965). Work by Biringen, Emde, Campos, and Appelbaum (1995) provides preliminary support for such a relation. Infants and their mothers in the study showed increased tendencies to test each other's wills and engage in open confrontations once the infants began to walk independently. Infants acted more willful and defiant, and mothers viewed their infants in much more emotionally negative terms following walking onset. Evidence, therefore, suggests that motor milestones such as walking and crawling fundamentally alter the infant, her social world, and her relation to that world and in the process reorganize her emotional life and the emotional climate in which she lives.

### **Culture, Emotion, and Emotional Development**

Our attempts to understand how culture affects emotion and emotional development have changed considerably in the past 30 years. In the 1970s and 1980s, researchers were mostly concerned with universals in emotion expression. The search for universals generated impressive evidence on the similarity of recognition of facial expressions by preliterate tribes (Ekman, 1973; Ekman,

Sorenson, & Friesen, 1969), and judges in both Western and non-Western countries (Izard, 1972). In turn, this evidence led to the widespread use of facial expressions as the preferred indices of emotional states, and motivated the “emotion revolution” of the 1970s and 1980s. The apparent universality of *recognition* of facial expression also led to studies on the *elicitation* of facial expression patterns of anger and fear in infants of different cultures (Camras, Oster, Campos, & Bakeman, 2003; Camras, Oster, Campos, Miyake, & Bradshaw, 1992; Camras et al. 1998) and the development of methods of facial expression measurement based on anatomical criteria and judgments of emotion by coders (Izard & Dougherty, 1982; Oster, 1995). Although many criticisms have been leveled at research on universality of recognition (Fridlund, 1994; Russell, 1994, 1995), they have on the whole not proven entirely convincing (Ekman, 1995; Izard, 1995). As a result, the search for universals continues in cross-cultural studies of patterns of appraisal (Mesquita & Frijda, 1992), speculations about child-rearing functions (Trevvarthen, 1988), and attributional biases (Morris & Peng, 1994).

Recently, the study of culture and emotions has broadened considerably beyond the issue of universality to the role of culture in the generation, manifestation, and regulation of emotion (D’Andrade, 1984; Kitayama & Markus, 1994; Lazarus, 1991). Because a complete review of culture and emotion is beyond the scope of this chapter, we will limit ourselves to an illustration of how emotion communication accompanies and helps to inculcate cultural values, affects pre- and perinatal emotionality, determines the types of events to which an infant or child is exposed, and creates the emotional climate in which a person is immersed.

### ***What Is Culture and Does Culture Influence Infants?***

The concept of culture is rarely defined. For our purposes, *culture* refers to a set of traditional, explicit and implicit beliefs, values, actions, and material environments that are transmitted by language, symbol, and behavior in an enduring and interacting group of people. Because of the centrality of symbols, language, and values for culture, most studies of culture and emotion deal with adults, and especially the language of adults (Wierzbicka, 1992). Infants and children with minimal language skills are generally assumed to be beyond the pale of symbolic influence (Winn, Tronick, & Morelli, 1989). However, symbols, language, and values can have

profound direct and indirect effects on the preverbal child. The direct effects result from diet, housing, and the material and physical implements of the culture that are used in child rearing. The indirect effects are largely mediated by two factors: (1) the physical/social context in which the infant is raised, and (2) the exposure of the child to the characteristic behavior patterns and nonverbal communication strategies of members of that culture (Gordon, 1989). So, subtle yet powerful are these direct and indirect effects that the infant can be said to be acculturated beginning at birth and maybe even before (Tronick & Morelli, 1991).

**Parental Practices.** Although the demand for provision and protection of infants and meeting their needs must be universal, the way in which those needs are defined and met varies enormously. One way that culture influences the infant is through the mother’s selection of interventions for regulating social signaling, including the baby’s crying and struggling. For this reason, swaddling methods have received a great deal of attention from anthropologists. They have discussed how in Middle Eastern societies swaddling facilitates sleep and transport (Whiting, 1981), soothes the child, and permits the mother to work nearby in kibbutzim (Bloch, 1966), maximizes proximity between mother and child, facilitates responsiveness to the child’s social signals, such as in the Navaho nation (Chisholm, 1983, 1989), and brings about desirable habituation and autonomic regulation in response to stimuli in noisy environments (Landers, 1989). In the United States, by contrast, swaddling has been unpopular largely because it restricts freedom of movement (Lipton, Steinschneider, & Richmond, 1965) and possibly produces undesired yet distinctive effects on the formation of characteristic emotional dispositions (Mead, 1954), some of which, such as passivity, are not valued in the United States (Chisholm, 1989).

Another cultural variation in parenting practice evident even in the neonatal period is that of co-sleeping. Co-sleeping has been proposed as a socialization mechanism that fosters attachment throughout life by creating a powerful motivation to remain close to the parent (Abbott, 1992). Although sleeping in separate beds and separate rooms is the norm in the United States, data collected in eastern Kentucky exemplifies the widespread regional variation that can occur in co-sleeping (Abbott, 1992). Co-sleeping occurred across all social

classes in eastern Kentucky, but was less common among the college educated. Interview data suggested that co-sleeping did facilitate greater interdependence in the family and fostered close emotional ties early in life. Findings such as these contradict widespread beliefs that the effects of co-sleeping are uniformly negative (see discussion in Morelli, Rogoff, Oppenheim, & Goldsmith, 1992).

Physical activity and infant positioning are other examples of parenting practices related to emotional development and showing considerable variation across cultures. Compared to Americans, Gusii infants are exposed to more light tossing and vigorous handling. Provision of such vigorous stimulation has been proposed to explain how Gusii infants overcome fear by 3 to 4 months of age (Keefer, Dixon, Tronick, & Brazelton, 1991).

A traumatic influence with potentially long-lasting consequences for the newborn is circumcision. Circumcision is a painful procedure often conducted without anesthesia or analgesia. It may well form the nucleus of disturbing and enduring memories for pain. Moreover, cultural variations exist in the circumcision procedure: What was at one time a religious ceremony conducted in an intimate family gathering has become routine medical practice involving medical personnel with the family excluded. The emotional climate provided to the infant during the circumcision ritual in the home (the bris) is vastly different from that provided on a plastic restraint board in a hospital nursery and may also influence the infant's memories for pain. In addition, in religious ceremonies, the circumcised newborn is often given small amounts of sweetened water to drink. Such oral stimulation may help soothe the infant's pain reactions, in the same manner that Blass and Ciaramitaro (1994) have reported that sucrose does for other painful procedures.

**The Significance of Exposure to Events.** Culture determines the types of events to which the child is exposed. Emotional reactions are determined not only by transactions taking place in the present but also by the history of prior encounters with similar events in the past. It is as if an adaptation level of experience is built up, and depending on the discrepancy of an event from that adaptation level, the child will show intense, moderate, or weak emotional reactions.

This principle of *adaptation level* is well exemplified in the literature on culture and attachment patterns. In

the attachment literature, there is evidence that infants from northern Germany show a preponderance of apparent avoidant patterns of attachment (Grossmann, Grossmann, Huber, & Wartner, 1981). By contrast, in Japan, there is a preponderance of apparently ambivalent and hard-to-soothe infants (Miyake, Chen, & Campos, 1985). In the kibbutzim in Israel, still another pattern of behavior is shown: Infants are extremely upset by the entry of strangers in the attachment testing situation.

What accounts for such different patterns of behavior (Sagi, Lamb, Lewkowicz, Shoham, Dvir, & Estes, 1985)? Why do children in three different areas of the world react to the same events in such dramatically different ways? One interpretation is that the value system of different cultures affects what events infants are exposed to and thus to what events they become emotionally responsive. In northern Germany, for example, infants are frequently left alone outside of stores or supermarkets or in the home while the mother steps out briefly. The pattern of exposure (the adaptation level) to being alone renders maternal separations in attachment testing not a very great departure from that to which the infant is accustomed. As a result, infants with such a background may show little or no upset on a brief maternal separation and have little reason to give a strong response to the mother on reunion. Not surprisingly, 49% of infants tested in the Ainsworth Strange Situation in Germany show the "A" pattern of not directing much attention to the reentry of the mother.

In Japan, there is a very different value system—one in which the mother desires very close proximity to her child. In Japan, babysitting is rare, and when it occurs, it is usually done by the grandparents. Accordingly, Japanese infants have very few experiences with separation from the mother. As a result, when the mother leaves the infant alone or with a stranger in the attachment test, the separation is extremely discrepant from the infant's past experience. As a result, the infant shows considerable upset, and it is thus no surprise that the infant is hard to console after experiencing intense distress on separation. The difficulty in consoling the child results in classifying the child as a "C" infant.

In the kibbutzim in Israel, security measures and the history of unexpected terrorist attacks make for a strong form of xenophobia. Strangers are looked on askance, and they are typically not allowed to approach infants. Because infants are very sensitive to the emotional communication of significant others by 12 months of age,

they have become sensitized to be wary of strangers themselves. As a result, when a stranger enters the room and initiates contact or approach to the child, the infant is set to become intensely fearful. Interestingly, in urban Israel, where the xenophobia is usually much less evident, infants do not show such intense negative reactions to strangers. The adaptation level of the kind of reaction that significant others typically give to the infants determines the intensity level of their negative responses. Much xenophobia in caregivers results in high levels of stranger distress; less xenophobia results in considerably lower levels. In sum, the value system of each culture (expectations of independence in northern Germany, desire for extreme proximity in Japan, and the need to protect the community in Israeli kibbutzim) leads to different levels of experience against which new experiences are compared. The culture thus determines both exposure to events and the context for differential emotional reactions.

Other examples of how exposure and values interact to influence emotional-expressive behavior can be found in patterns of eye contact: It is usually encouraged in Western culture, where looking into a baby's eyes forms "a window into the soul." However, in certain African societies, eye contact is generally discouraged. Certain tribes believe that eye contact allows another person to cast an "evil eye" on the infant. As a result, infants are often kept in dark corners of the living hut, and held in a manner that minimizes the chance of eye contact. The end result for the infant is a cool, subdued demeanor (LeVine et al., 1994).

Still another instance of culture determining what an infant is exposed to stems from the work with the Efe in central Africa on multiple mothering (e.g., Tronick, Morelli, & Ivey, 1992). Because maternal mortality is extremely high among the Efe, the culture attempts to compensate for the negative consequences of maternal loss by fostering multiple caregiving. Infants are thus often passed from one person to another, and the infant becomes accustomed to being handled by more than one caregiver. As a result, the loss of the mother becomes much less traumatic for Efe infants than for infants elsewhere.

**Culture and Emotional Climate.** Emotional climate refers to the characteristic patterning and intensity of verbal and nonverbal emotional communication that is within earshot and eyeshot of an audience. Cultures often differ in such emotional cli-

mates. In some cultures, loudness and extremes of gesticulation are encouraged or tolerated; in others, quiet and peaceful expression is the expectation. Such emotional climate may influence the emotional reaction of infants, children, and adults quite profoundly (Briggs, 1970).

Consider that vocal expression of affect is very pervasive and quite closely linked to the communication of discrete emotion (Scherer, 1986). It is now well known that the fetus can hear sounds in the womb from the seventh gestational month onward. As a result of the transmission of sounds through the amniotic fluid (DeCasper & Fifer, 1980; DeCasper, Lecanuet, Busnel, Granier-Deferre, & Maugeais, 1994; Fifer & Moon, 1995), the unborn infant can acquire considerable experience about patterns and intensities of vocalic emotional communication. Just as the newborn can identify his or her mother's speech within 3 days of birth, it is possible that the newborn can come into the world with built-in expectations of what the typical emotional climate is in the society in which he or she is born.

In Japan, the emotional climate is one of soft vocalizations, few verbalizations, and much gentle stroking of the infant (Miyake, Campos, Kagan, & Bradshaw, 1986). This pattern of softness and low frequency and volume of speech has been attributed to the rice paper walls of the typical Japanese household, together with the Japanese value for harmony and tranquility in the home. To attain these cultural goals of harmony, mothers are charged with the responsibility of keeping volume of communication low and to keep the infant's crying to a minimum. Thus, Japanese mothers communicate with their infants much more by touch and less by vocalization than do American mothers.

Emotional climate is thus a crucial means by which culture affects emotion. It is known that in cultures differing emotional climates have important effects on children. Thus, parental quarreling and fighting can result in infants and children of that family becoming maladjusted and insecure (Davies & Cummings, 1994).

In concluding this discussion of culture and emotion, the emphasis in this chapter should be clear: Emotions are relational and functional (in that they serve a purpose), they are embedded in social communicative relations, they are flexibly responsive to context, and they link our actions with our goals. Consistent with the preceding material on culture and emotional development and with a functionalist approach, in the remaining sections of the

chapter we take a systems approach to emotional communication as *multichannel* (or multibehavioral), which includes facial expression, vocal quality, gesture, touch, eye contact, interpersonal distance, and so forth (Schefflen, 1974). With increased exposure and experience, young children's emotional-expressive behavior begins to resemble the normative emotional communicative patterns, as prescribed by the culture in which they live. Social referencing, which is reviewed in the next section, is a key interactive process for facilitating this learning of emotional meaningfulness.

In addition, a systems approach to communication is very useful for understanding the kinds of emotional-social phenomena that develop in the preschool and elementary school years, which are discussed in later sections. These phenomena include self presentation strategies, empathy-mediated prosocial behavior, emotion management, and coping strategies, among others. Systems communication theorists (e.g., Watzlawick, Beavin, & Jackson, 1967) emphasize further that what may be most important about communication is its involvement in the *regulation* of relationships, and their notion of *metacommunication* describes this regulatory function: A message, conveyed by nonverbal behavior, communicates how the content of what is said should be understood. In short, communication about communication is intended to influence us, and such communications are typically emotion laden. We turn next to a discussion of the early development of emotional communication, emphasizing social referencing, not only because it is a particularly well-investigated emotional communication process, but also because it illustrates this metacommunicative function of relationship regulation.

## THE DEVELOPMENT OF EMOTIONAL COMMUNICATION IN EARLY LIFE

In previous sections, we have discussed the evocation of emotions in response to alterations in some significant aspect of the infant's relations in the environment. We now discuss how emotions provide signals indicating such a relational change and how such signals thereby can produce an effect on the infant.

It proves surprisingly difficult to study emotional communication in early life. The difficulty stems from a point made over 30 years ago by John Smith (1977) in

his studies of avian communication. He distinguished between the message and the meaning of a communicative signal. According to Smith, "message" refers to the invariant information encoded in the environmental display that comprises a signal, while the "meaning" of the message refers to the signal's predictive value about the behavior of the communicator within a particular situational context.

Put another way, the message is that which can be physically described in the action of a communicator—what can be put on a photograph or an audiotape. The meaning is what the message forecasts about the future behavior of the communicator—whose smile can predict approach, scornful rejection, manifestations of pity, or a simple farewell. The point in Smith's distinction that is so crucial for the study of communication between parent and infant is that one cannot predict meaning from a message with very much accuracy.

Smith emphasized that messages are interpreted in their context for many reasons. These contextual factors can change the meaning of a message, further weakening the apparent close relation between message and meaning we so often take for granted. Sometimes, features of the context enter into the perception of the message, and cause the impact of messages on recipients to be very different than what one would expect. Take the mother smiling at her infant as an example. That smile (a message), has a different meaning and will have a differential impact on the infant, depending on whether the mother smiles when the infant is distressed (which can imply misattunement by the mother with the infant's state) or if the mother smiles while the infant is playing with the mother, which would be an expectable part of a social transaction. Because our research methods involve manipulating the message, they are often not suited to identifying what the meaning is for the child to the extent that there is a cleavage between message and meaning. To maximize the chances that we are studying meaning in emotional communication, we therefore consider emotion communication to have occurred only when a manipulation is shown to have an emotional impact. Studies that only address discrimination of the display by infants (i.e., habituation studies) will not be emphasized here.

In brief, we consider emotional communication to occur whenever one person exhibits emotional behavior and another person witnesses and is affected by that emotional behavior. We look for three components in a thorough study of emotional communication: (1) on the

input side, registration of the emotion signal by the perceiver, and (2) on the output side, a valenced response to that signal manifested in the recipient's own expressive or instrumental activity, and (3) in between, some degree of appraisal of the input such that the appraisal may change both the significance of the input and the nature of the emotional response. Registration refers to the perception of an expression of emotion (or some component of that expression) and includes the ability to distinguish among expressions of different emotions. (Habituation and preferential looking studies focus on the registration of emotion signals.) A valenced response is one that can be reasonably interpreted as reflecting the content of the internal appraisal and motivation processes on the part of the infant such as approach or avoidance, smiling or frowning. Valenced responses, whether expressive or instrumental, can be diffuse (oriented at no particular event in the world) or targeted at some specific object in the world or at one's own actions. We also emphasize that we use the term *appraisal* broadly without implying the necessary involvement of higher-order cognitive processes. As we review empirical findings, one concern that we raise is about the rush that sometimes exists to attribute to the infant understandings of meanings when these three criteria have not been met.

We delineate four phases of increasingly complex emotional communication between an adult and the infant. Phase 1 (prenatal to 6 weeks) describes the infant's initial valenced reactions to emotion signals. Phase 2 (6 weeks to 7 to 9 months) covers the developmental period preceding the advent of referentiality (i.e., understanding that a communicative signal may refer to some external aspect of the environment). Phase 3 (9 months to 18 months/2 years) focuses on the development of referential emotion communication, behavioral regulation (i.e., where the expressive and instrumental behaviors of the child are affected by the other's emotional expressions), and retention of the emotion signal's impact over progressively longer durations. Phase 4 (18 months/2 years and beyond) is marked by the development of what the literature calls self-conscious emotions, but which, following Watson (personal communication, April 1999), we call "other-conscious emotions" because they depend on the child's detecting the expressive and instrumental reactions of others to his or her own behaviors. We also hypothesize that during this period, marked improvements take place in the child's comprehension of the different "meanings" carried out by different negative emotional messages such as fear versus anger.

### **Phase 1 (Prenatal to 6 Weeks): Initial Reactions to Emotion Signals**

In the neonatal period that extends from birth to 4 to 6 weeks, rudimentary valenced responses to emotional messages clearly exist as evidenced by two findings. First, as a consequence of prenatal exposure, newborns respond to the valence of speech prosody produced in their mother's native language but not in nonmaternal languages (Mastropieri & Turkewitz, 1999). Second, newborns appear capable of responding with cries and negative facial expressions to the cries of another neonate (Dondi, Simion, & Caltran, 1999).

#### ***Neonates' Responsiveness to Emotion Prosody***

Because the newborns' behavioral repertoire is extremely limited, garnering evidence for the infant's responsiveness to emotional expression presents a major challenge to researchers. In an ingenious study, Mastropieri and Turkewitz (1999) examined neonates' eye widening in reaction to speech produced in either the mother's native language or in a novel language using neutral, happy, sad, or angry prosody. Increased eye widening was found in response to happy prosody, but only for speech produced in the maternal language. This pattern of results suggest that early discrimination of vocalic emotion is not an innate capacity, but instead appears to be based on prenatal experience with a specific language. Furthermore, there is as yet no evidence for discrimination beyond the distinction between positive and neutral or negative vocalic emotion.

**Neonatal Crying Contagion.** Although to date no one has demonstrated discrimination among vocalic expressions of different discrete negative emotions (e.g., anger, sadness, fear), there is strong evidence for a valenced response to crying. The contagious crying phenomenon has been documented repeatedly, and constitutes a remarkable demonstration of the presence of emotional communication in the neonatal period (e.g., Martin & Clark, 1982; Sagi & Hoffman, 1976; Simner, 1971). Newborns tend to cry in response to the cries of another newborn, though not those of an older infant, a chimpanzee, or white noise. In a methodologically rigorous replication of earlier studies, Dondi et al. (1999) found that neonates decreased their rate of sucking and also showed increased facial distress to cries of unfamiliar infants. Because their expressions of distress were demonstrated in a different modality than the dis-

tress stimulus itself (viz., the cry of the other neonate), newborns apparently may not have been merely mimicking the vocal stimulus, but rather truly reacting to the meaning of the cry of the other child. Interestingly, Martin and Clark (1982) reported two fascinating phenomena: (1) that recordings of the babies' own cries resulted in some reduction of their own cries, and (2) that the neonatal crying contagion dropped out by 5 months of age. Both phenomena pose challenges for future research because they require replication and, if replicated, careful study of the processes involved in each.

### **Phase 2 (6 Weeks to 9 Months): Pre-Referential Communication**

During this period, the infant can engage in synchronous dyadic interaction with the caregiver. This phenomenon indicates some limited ability to apprehend the caregiver's emotional valence, understand when the caregiver is targeting her or his emotion toward the infant, and then align her or his own emotional valence and behavior to be congruent with that exhibited by the caregiver. Two other phenomena appear to be well established about emotional communication in this time period. First, infants respond differentially to the valence of mothers' vocal contours (Fernald, 1993). Second, infants discriminate facial expressions as stimulus patterns but show no convincing evidence of comprehending their specific emotion meanings. Some investigators have obtained data that they interpret as demonstrating more substantial communication competencies—a relatively full comprehension of the rich emotional messages generated by the caregiver. While these interpretations are plausible, the research paradigms employed are not suitable to yield the unambiguous inferences that have been drawn from them.

### ***Evidence for Rudimentary Emotional Exchange and Its Constituents***

As in the previous period, the strongest evidence of infants' responsiveness to emotional signals comes from studies using acoustic stimuli. The responsiveness to vocalic communication markedly exceeds that evidenced in the neonatal period, exhibiting differentially valenced responses to the valence of adults' emotional signals. For example, in a study noteworthy for its methodological rigor and conceptual richness, Fernald (1993) presented 5-month-old infants with acoustic stimuli specifying prohibition or encouragement of ap-

proach. She reported that 5-month-olds smiled more in response to infant-directed messages specifying "approval" than to messages specifying "prohibition" irrespective of whether the message was produced in English or in an unfamiliar language (German or Italian). Negative affect was more likely to occur in response to prohibitions. Fernald's investigation offers a strong demonstration that by 5 months of age, infants are able to discriminate the emotional valence of acoustic messages and to transform differential message content into congruent behavioral reactions that are either appropriately positive or negative. The issue of whether infants can respond at this age to more specific emotional meanings (e.g., fear versus anger) at this age has not been addressed.

A number of other studies investigate infants' differentially valenced responses in dyadic setting. Numerous investigations (e.g., Cohn & Tronick, 1988; Feldman, Greenbaum, & Yirmiya, 1999; Field, Healy, Goldstein, & Guthertz, 1990; Jaffe, Beebe, Feldstein, Crown, & Jasnow, 2001; Moore & Calkins, 2004) have demonstrated what many call "interactional synchrony," but which we conservatively call "expressive coincidence"—contingencies in the timing of positive or negative expressions during face-to-face interactions between mothers and infants even younger than 3 months of age. More specific "matching" (what we prefer to call "co-occurrence") in the level of positive or negative affect has also been shown (Feldman et al., 1999; Tronick & Cohn, 1989; Weinberg, Tronick, Cohn, & Olson, 1999).

Many of these studies claim to have demonstrated a process of direct and unmediated emotion contagion (Haviland & Lelwica, 1987; Stern, 1985; Trevarthen & Hubley, 1978). However, in our own view, what appears to be direct mutual mirroring between mother and child may instead result from the operation of two other powerful and rudimentary determinants of emotion—contingency and agency (or lack thereof). Lewis and his colleagues (e.g., Lewis, Hitchcock, & Sullivan, 2004), following the pioneering work of J. S. Watson (1972), have unequivocally shown that infants as young as 2 months of age smile when their actions produce a contingent effect on the world and evidence distress when a previously operative contingency fails. Studies of affective synchrony may sometimes confound contingency and its failure with direct affective matching. Thus when contingent reciprocal smiling takes place, it might produce similar emotional

responses in mother and baby. However, such shared emotion need not depend on either direct contagion or (alternatively) on the infant's in-depth comprehension of the emotional meaning of the smile. A simpler explanation is that the infant smiles contingently at the mother not because the baby sees a smile, but because the baby notices a contingent reaction that happens to be a smile.

In some of the broadest claims in this literature, researchers propose that processes of synchrony and matching may contribute to the development of emotion regulation (Feldman et al., 1999; Moore, Cohn, & Campbell, 2001) and attachment (Jaffe et al., 2001). For example, mothers' positive emotion signals may induce a more positive response in their infants and may also contribute to the development of a secure attachment relationship. This conclusion has obvious intuitive and emotional appeal, in that it reflects the notion that emotional bonds are built on shared evaluations and experiences. However, we think it critically important to also emphasize that not all maternal smiles directed at the infant are positive in their impact: Maternal responses must be context sensitive rather than always synchronous. For example, Stern (1974) reports that if the infant is attempting to terminate an interaction and the mother continues to force her smiling presence into the infant's visual field (effectively making a demand that the infant suppress her or his negative affect and return the smile), then such maternal insensitivity may result in interactional failure. The same may be said if the mother's first response to the infant's crying is to smile, rather than to present the infant first with sympathy, which the mother then transforms into a smile, paced with the infant (Holodinski & Friedlmeier, in press). If such failures are chronic, they may contribute to the etiology of psychopathology (Gergely & Watson, 1996, 1999; Holodinski & Freidlmeier, in press).

The still-face paradigm provides another interesting context in which to appreciate the ambiguities of studying emotion communication in young infants. In the still-face procedure, normal face-to-face infant-adult interaction is disrupted by an episode in which the adult ceases all movement and thus fails to respond to the infant's signals. The still-face effect rests primarily on the cessation of facial rather than vocal signals (Striano & Bertin, 2004). Furthermore, differential effects of positive versus negative or neutral expressions also have been reported. Rochat, Striano, and Blatt (2002) showed that 2-month-old infants maintained their smiling and gazing if the experimenter posed a smile rather than a

neutral or sad expression. This finding suggests that infants' affinity/preference for happy expressions can overcome the negative emotional impact of contingency disruption that normally occurs in the still-face procedure, although the effect of the smile is not strong. Alternatively, infants may find the happy still-face to be less discrepant from their normal experience because they are exposed to smiles more often than neutral or sad expressions in the course of their day-to-day social interactions. Interestingly, Rochat et al. (2002) found that 4- and 6-month-old infants responded equivalently to still-face disruptions involving happy, neutral, or sad expressions. However, in a study that manipulated mothers' sequencing of happy or sad expressive behavior during the course of nondisrupted social interaction, D'Entremont and Muir (1999) found that 5-month-old infants smiled more to happy than to sad facial expressions (irrespective of the presence or absence of the voice). Taken together, these findings suggest that older babies perceive differences among emotional expressions but their common response to happy and sad still-face poses may have been determined by the disruption of contingency that was equivalent across the expression conditions. This again illustrates the important point that emotion communication, including the impact of the signal on the recipient, will depend in part on contextual features—in this case, the maintenance and disruption of previously learned contingencies. The flow of contingencies may be as or more important in determining the infant's emotional responses than the flow of emotional contents between persons.

### *Weaknesses in the Evidence for Discrimination of Discrete Emotional Signals*

The evidence reviewed earlier considered infants' discrimination of and responsiveness to the valence of emotional signals. Another substantial body of research has focused on characterizing infants' abilities in this age range to discriminate among discrete emotional signals. Much of this research has employed experimental procedures (i.e., habituation and preferential looking procedures), originally designed to investigate the discrimination of one display from a second, when those two displays differ in only one dimension or feature, for example, in pitch, hue, size, numerosity, and so forth. In our view, the application of these techniques to the problem of differential perception of emotional signals is problematic. The expressive stimuli presented in these studies involve a complex set of features and these studies fail to isolate those aspects of the stimuli to

which infants are attending and responding. For example, using a habituation procedure that employed several models showing variations of each emotional expression, Serrano, Iglesias, and Loeches (1992, 1995) claim infants in this age period distinguish between and respond differentially to static facial expressions of happiness, sadness, anger, and fear on the basis of their emotion-defining features. However, the Serrano et al. studies, like many others, make these claims without systematically isolating *which* stimulus features infants attend to and influence their behavior.

Similar problems exist with studies claiming to demonstrate that infants in this age range distinguish among multimodal expressions of emotion. For example, Montague and Walker-Andrews (2002) employed a familiar infant game (peek-a-boo), reporting that 4-month-old infants distinguish between facial and vocal displays of happiness, sadness, anger, and fear. Yet, it is hard to identify in this study the specific determinants of infants' differential responses, whether the stimulus or the violation of some contingent relation that the infant has come to expect, is the basis for their findings.

The problem of attributing to the infant a rich participation in emotional exchange is not restricted to discrimination studies using static displays of emotions but extends as well to studies of dynamic emotion stimuli. Investigations utilizing the intermodal preference method (involving preferential looking toward a facial expression that corresponds to an emotion vocalization) have reported that 14-week-olds can match facial and vocal expressions for happiness, sadness, and anger when they are displayed by their mothers (although not when they are displayed by unfamiliar persons; Kahana-Kalman & Walker-Andrews, 2001; Montague & Walker-Andrews, 2002). Walker-Andrews (1997) has argued that intermodal matching constitutes evidence for some understanding of affective meaning and has labeled this phenomenon emotion *recognition*. However, because intermodal matching may involve simple associative mechanisms, we prefer to interpret these results as evidence for discrimination of one multimodal affective signal pattern from another, but we are skeptical that these studies get at the issue of the infant's recognition of emotion meaning. As with studies involving only facial or only vocal emotion signals, these studies do not tell us what the physical basis for the infant's discriminative responding in multimodal displays, much less the emotional meaning of the displays (in Smith's terms, as discussed previously).

Studies purporting to demonstrate in postneonatal infants contagion not of crying but of quite specific emotions also are subject to overinterpretation. For example, in a study of 10-week-old infants, Haviland and Lelwica (1987) reported that babies mirrored happy and angry facial expressions in response to their mothers' facial and vocal displays, and exhibited nonspecific mouthing movements in response to sad displays. While all these findings are intriguing, we think it an overinterpretation to claim (as do Haviland and Lelwica) that emotion contagion occurred in this study. In our view, to distinguish emotion contagion from the superficial imitation of facial actions, infants must be observed to display clear indicators of the emotion in a form that differs from the observed stimulus. The strong evidence needed to support such broad attributions has not been presented in any study to date.

### **Phase 3 (9 Months to 18 Months): Behavioral Regulation and Referential Communication**

The infant undergoes a major set of cognitive, social, emotional, agentic, and perceptual changes in the age period that we are about to review. These changes have marked impact on the emotional communication of the infant. The most significant change for our purposes is the emergence of the infant's ability to engage in referential gestural communication (i.e., what it is that the mother is emoting about). Prior to 8 to 10 months, infants typically do not show any reliable tendency to follow the gaze or pointing gesture of the parent. By 9 months, infants begin to show such referential understanding, which becomes progressively more specific with the child's advancing age, and culminates in the baby being able to identify the approximate coordinates of where the experimenter or mother is looking or pointing (Bakeman & Adamson, 1984; Campos et al., 2000; Mumme, Bushnell, DiCorcia, & Lariviere, in press). The implications of this new ability is that the infant becomes capable of engaging in what has been called a "two-person communication about a third event," becomes able to link quite precisely the target of the mother's or experimenter's pointing and gaze, and increasingly becomes able to retain the emotional impact of prior emotional messages (i.e., shows affective memory).

During this period, the infant also becomes able to draw another person's attention to events of significance to herself (i.e., the infant shows affective sharing). In addition, the infant becomes increasingly able to retain the affective impact of prior emotional signals (i.e.,

shows affective memory). The changes shown by the infant during this age period enable her to imbue environmental events with affective meaning as imposed by parents' or others' emotional messages. In some cases, these emotion messages may even alter the valence of infants' reactions to events. However, during this age period, the infant may still show major deficiencies in processing certain aspects of the emotion message (e.g., the specific negative emotion indicated by a negatively valenced signal). As such deficiencies are overcome, the infant is prepared for a fourth stage in development of emotional communication.

#### ***Onset of Emotional Communication Involving Environmental Objects***

Two studies clearly document how the infant by 8.5 months of age becomes capable of reacting to the social signals of the mother directed at a third event. In one study (Boccia & Campos, 1989), the infant's reaction to strangers was markedly affected by whether the mother posed a stern or cheery greeting and facial expression when a stranger walked into the room. In the second study (Svedja, 1981), the mother's vocalization of the baby's name followed by a nonsense phrase ("tat fobble") resulted in cessation of the infant's approach to a toy that was significantly longer when the vocalization was uttered in a fearful or angry manner than when it was uttered joyfully. These studies demonstrate that referential communication occurs in infants as young as 8.5 months of age for facial and vocal expressions combined and for vocal expressions produced alone. Regarding responses to facial expressions produced alone, while several studies have demonstrated regulatory effects in 12-month-olds (e.g., Camras & Sachs, 1991; Gunnar & Stone, 1984; Klinnert, 1984; Zarbatany & Lamb, 1985), none has investigated infants at younger ages. In addition, no studies to date have examined behavioral regulation in response to emotion signals produced in either modality by babies younger than 8.5 months of age. Thus, the precise age of onset for behavioral regulation with respect to environmental objects or events is not currently known.

#### ***Effects of Emotional Communication in Older Infants***

In contrast to younger infants, there has been considerable research on older (10- to 14-month-old) infants' behavioral regulation in response to emotion signals. In an early and powerful demonstration of this phenomenon, Sorce, Emde, Campos, and Klinnert (1985) showed that

12-month-old infants referenced their mother (i.e., looked toward her) when they reached a mid-level drop-off on the visual cliff and most proceeded to cross if she displayed a facial expression of happiness or interest but not of sadness, anger, or fear. The mid-level drop-off induced a state of uncertainty in the infants and they therefore sought information from their mother to help them determine whether to proceed across the cliff. Through their actions, infants demonstrated that they did more than merely register their mothers' emotion signals; they displayed a valenced response reflecting an attempt to maintain or change their relation to the environment.

#### ***Primacy of Facial versus Vocal Signals***

A current controversy among investigators of behavioral regulation centers on the relative effectiveness of emotion signals produced in different modalities (e.g., facial versus vocal). Because it is virtually impossible to ensure that signal intensity is equated across modalities, attempts to make direct comparisons between facial and vocal expressions may be misleading. Furthermore, the fact that vocal signals can be inescapably imposed on the infant more readily than facial signals may create a false impression that vocal expressions are more effective behavioral regulators. In reality, this differential effectiveness may sometimes be attributable to the differential registration of the signal by the infant. Empirical studies of facial versus vocal signaling have produced mixed results. Mumme, Fernald, and Herrera (1996) found that facial but not vocal expressions influenced infants' behavioral reaction toward a toy, and Vaish and Striano (2004) found that infants responded more readily on the visual cliff to maternal positive vocal signals than to smiling. However, as cited earlier, other investigations show that infants do indeed alter their behavior in response to facial expressions produced without accompanying vocalizations. Some inconsistencies across studies may be due to differences in the emotions that are examined and in the nature of the regulatory response observed (e.g., behavior toward the mother versus toward the target object, response to the first delivery of the signal versus later trials). Thus, further research is necessary to identify both the signal and the situational parameters that determine the specific effects of both facial and vocal signals of emotion on infants' behavior. In addition, modalities other than facial expression and vocalization should be examined. For example, in a recent study, Hertenstein and Campos (2001) showed that

infants respond to maternal tactile behaviors that might be interpreted as indicating a negative emotional response (i.e., gently squeezing the abdomen as the infant reached toward a toy).

### *Referential Specificity*

Referential specificity constitutes the notion that infants understand that an emotional expression is uniquely directed toward the object of the expresser's attention rather than to other objects in the environment or to no particular object at all. Without referential specificity, infants may misinterpret emotion signals, for example, linking mother's disgust display directed, say, at an insect, to a nontargeted object, or even to the infant herself. Thus, referential specificity requires the infant to identify more precisely the object of an emotion signal and respond in an appropriately selective manner. Several recent studies (e.g., Hertenstein & Campos, 2004; Moses, Baldwin, Rosinsky, & Tidball, 2001; Mumme & Fernald, 2003; Phillips, Wellman, & Spelke, 2002; Rapacholi, 1998) have investigated referential specificity by comparing infants' responses to targeted versus nontargeted objects. Such studies have found evidence for referential specificity in infants as young as 12 months of age. Referentially specific responding implies that the infant's behavior reflects more than merely the general induction of emotion that might affect behavior with respect to all objects and events encountered in the environment. Nonetheless, a generalized emotional reaction and more specific referential responding are not mutually exclusive processes. Indeed, a number of studies have analyzed infants' own emotional expressions in response to the adult's emotion signals and produced evidence for an alteration of the infant's own expressions of emotion as well as the child's instrumental, voluntary behaviors (e.g., Boccia & Campos, 1989; Mumme & Fernald, 2003). However, these effects are inconsistently found (e.g., Hertenstein & Campos, 2004) and the factors that determine whether or not infants' own emotional expressions are altered have yet to be determined.

### *Affect Specificity*

Affect specificity refers to the infant's ability to make qualitative distinctions among emotions of the same valence (e.g., distinguish anger from fear). Most studies of behavioral regulation have compared reactions to positive versus negative emotional expressions (typically happiness versus fear or disgust). The accumulated evi-

dence leaves little doubt that infants respond to the meaning of these signals at the level of their positive or negative emotional valence. However, in contrast to referential specificity, the issue of affect specificity has received relatively little attention.

Regarding distinctions among the negative emotions, Sorce et al. (1985) have attempted to systematically compare fear, anger, and sadness expressions in the same experimental procedure. In their study, almost no infants crossed the modified visual cliff when mothers displayed an expression of fear or anger, while approximately a third of the babies did proceed to cross in response to the sad expression. Although these findings suggest that 12-month-old infants distinguish among different negative emotions, one possible interpretation is that they distinguish on the basis of emotional intensity (i.e., degree of negativity) but do not understand the qualitatively different relational meanings and functional implications of fear versus anger versus sadness.

Another indication that infants in this phase of development may not be differentially responsive to discrete negative emotional signals comes from a study by Bingham, Campos, and Emde (1987). In this study, 13- to 15-month-old infants encountered a doll whose arm appeared to break and fall off when the infant touched it. At the same time, the experimenter uttered the nonsense phrase "Tat fobble" using a facial expression and vocal tone appropriate for one of six basic emotions: fear, sadness, surprise, joy, disgust, or anger. Videotapes of the procedure allowed for manipulation checks of the experimenter's emotion poses and examination of the infant's own expressive and instrumental responses. This study yielded highly significant differentiation of behavior along a hedonic tone dimension, such that negative emotions elicited withdrawal behaviors and positive emotions elicited greater duration of play with the doll than did the negative signals. However, infants did not respond differently in either expression or instrumental behavior to the different negative emotions. This lack of response differentiation took place despite the paradigm affording the opportunity for the infant to respond differently (e.g., showing nurturance to the doll or the experimenter in response to experimenter sadness versus showing avoidance of either the doll or the experimenter in response to anger). The authors concluded that perhaps infants at this age were not yet able to react differentially to emotional signals more specific than positive versus negative. They also cautioned for the need of further research to validate their tentative conclusion about

the lack of differential behavioral regulation by discrete emotion signals.

### ***Retention of Valenced Effects of Emotional Communication***

Another important issue in the study of behavioral regulation is the duration of a signal's effect on the behavior of the infant. If emotional expressions are to play a significant role in social and emotional development, their impact must extend beyond the immediate context of occurrence.

Relatively few studies have examined the enduring effects of emotion communication. However, not surprisingly, these have found the period of effectiveness to increase with infant age. For example, Svejda's study (1981; summarized in Campos, Thein, & Owen, 2003) of vocal communication provided evidence of carryover effects across trials separated by 1-minute delays for 8.5-month-old infants. Examining older infants, Hertenstein and Campos (2004) found that 11-month-olds showed differential behavioral regulation (i.e., referential specificity) when the delay between exposure to the signal and the infant's opportunity to respond was 3 minutes but not when it was extended to 60 minutes. In contrast, the effectiveness of the emotion signal was retained across a 1-hour delay in 14-month-old babies. One study of behavioral regulation has also provided suggestive data indicating that there may be systematic individual differences in infants' retention of emotion signals. In an investigation of 10- and 15-month-olds, Bradshaw (1986; Campos et al., 2003) found behavioral effects across a 25-minute delay period for only a subset of participants.

### ***The Development of Affective Sharing by the Infant***

While studies of behavioral regulation have largely focused on infants' responses to adults' affective expressions, emotion communication is a bidirectional process in which both parties in a dyadic interaction may generate as well as receive emotion signals. Evidence for infants' deliberate targeting of their own emotional expressions can be found for babies as young as 7 months of age. In a study of infants' responses to arm restraint, Stenberg and Campos (1990) found that infants at this age directed their negative expressive responses toward their mothers rather than toward the site of the frustration (i.e., their restrained hands). In a further investigation of the phenomenon, Conrad (1994; Campos et al., 2003) studied the consequences of infants encountering a display of a monkey clashing cym-

bals while the mother was located some distance away. She reported that 11.5-month-old infants (but not 9-month-old infants) directed emotional expression toward their mothers more often when their mothers were facing toward the infant rather than facing away. Likewise, Jones, Collins, and Hong (1991) found that 10-month-old infants produced "anticipatory smiles" (i.e., smiles that were followed by looks toward their mother) more often when mothers were attending to their play rather than reading a magazine. Similar results also were obtained by Striano and Rochat (2000) and Venezia, Messinger, Thorpe, and Mundy (2004) for 10-month-old infants using a different emotion induction procedure. Results of these studies converge to suggest that intentional affect sharing by infants emerges at around the same time as their understanding of referential specificity in the emotion communications of others. Beyond this, infants appear to be attempting to influence the recipient by "bringing affective events to her attention."

### **Phase 4 (18 Months/2 Years and Beyond): The Rise of Other-Conscious Emotions**

In the next phase of the development of emotional communication, we believe that two significant changes take place in the infant's reactions to emotional signals from others. One is the establishment of differential expressive and instrumental behavioral responses to different emotion signals of the same valence (e.g., anger versus fear). The second is a major change in the infant's construal of the two-person communication about a third event leading to what are commonly called the "self-conscious" emotions (e.g., shame, guilt, pride), but which, the reader will recall, we prefer to call "other-conscious" emotions to note the importance of the emotional reactions of others in their generation. In contrast to the previous age periods, we acknowledge that our description of this phase includes considerable—albeit grounded—speculation. Therefore, several of our proposals regarding Phase 4 remain to be confirmed empirically.

### ***Affect Specificity Revisited***

To date, strong evidence demonstrating infants' abilities to make qualitative distinctions among emotions of the same valence is lacking. Nonetheless, in an exploratory study involving a small number of participants, E. Anderson (1994) observed a tendency for infants in this age range to respond differentially when an experimenter gazed at an unfamiliar food item while verbaliz-

ing “Look at that” using sad, angry, disgusted, fearful, or happy vocalizations and facial expressions. For example, 18-month-old female infants tended to give the item to the experimenter in response to a sad emotion message but tended to pick it up and eat it in response to a happy message.

Beyond such preliminary data, a survey of the infant literature suggests that by 18 months of age infants may indeed understand the specific meanings and implications of some negative emotions. Infants’ affect vocabulary develops rapidly around this age (Dunn, Bretherton, & Munn, 1987) and includes words for several negative emotions (e.g., scary, yucky, mad). Furthermore, Zahn-Waxler and Radke-Yarrow (1990) found that by 2 years of age many infants show appropriate empathic/sympathetic responses to other persons’ expressions of distress. In a study involving experimenter-produced expressions of disgust, Rapacholi (1998) showed that 18-month-old infants produced an emotionally appropriate response (i.e., avoiding the disgust-targeted food item when choosing a food item for the experimenter). However, data produced in all these studies are subject to possible interpretations that do not involve the necessary imputation of affect specificity in the infant’s understanding of the emotion message. Therefore, this issue remains an important challenge in the area of emotion communication.

### *The Development of Other-Conscious Emotions*

The fourth phase in the development of emotional communication also involves the generation of complex emotions that may require, for their generation, the integration of a number of higher-order cognitive, perceptual, and retentive capacities. These emotions include embarrassment, shame, guilt, and pride. According to Michael Lewis (e.g., Lewis, 1993) these emotions begin to develop between 15 and 18 months, and are in part the consequences of the development of self-recognition as indexed by the “rouge” task. In this well-known paradigm, an infant in this developmental phase will detect and respond appropriately to the sight of a dot of rouge surreptitiously placed on her nose and viewed only in a mirror reflection. Successful performance on the rouge/mirror self-recognition task is taken to indicate the origins of a reflective self that in turn permits the emergence of self-conscious emotions (see Lewis & Brooks-Gunn, 1979; Lewis & Ramsay, 2004). Lewis has called these emotions “self-conscious” because of the link between mirror self-recognition and other indices of self-development, on the one hand, and the onset of

these emotions, on the other hand. As indicated earlier, we prefer to designate them as other-conscious emotions because they rest on the child’s detecting other persons’ reactions to the child or her behavior.

We believe that emotional communication plays a necessary role in the development of these emotions. Indeed, as noted earlier, the emotions of embarrassment, guilt, shame, and pride may come about as a result of the emerging appreciation by the child of the meaning of the communication by others of anger, sadness, fear, contempt, and other emotions. In other words, the child must first perceive these emotions in others, differentiate them one from the other, know to whom these emotions are being targeted, and have a sense of responsibility by the child in the elicitation of these emotions in others. We also believe that some of these emotions, particularly anger and contempt, are likely to be part of the elicitation of some complex emotions (especially shame), but not of others (particularly guilt).

More specifically, we propose that embarrassment and shame come about when the infant conducts an action toward a third event in the world (including toward himself, considered as an object) and that action elicits certain negative emotional signals such as scorn/disgust, anger, sadness, and general disapproval. By way of contrast, we propose that guilt occurs when the infant becomes aware that his or her actions produce emotions in another person that take the form of sadness, pain/suffering, disappointment, fear, and other variants of these emotion families. Thus, the set of emotion signals that produce shame and guilt are overlapping but not identical. For example, if another person shows fear in response to the infant’s action, guilt is more likely to be produced than shame because the emotions that produce shame are emotions that typically lower the power and status of the child in the eyes of the other. Fear is not usually relevant to such status reduction. In sum, discrete emotions may be necessary, and the infant may need clearly to distinguish their different meanings, in order for the more complex emotions of shame, guilt, and pride to form.

If this reasoning is supported by empirical data (and we know of none relevant to the point at this writing), the child must begin to differentiate negative emotions from one another as a necessary prerequisite for generating two related but quite different emotions of shame and guilt. Indeed, the general action tendencies linked to shame (attempts to discontinue social intercourse) and guilt (attempts to engage in reparation of damage to another, which damage has been created by one’s

actions) require that the emotional signaling to which the shamed or guilty person is subjected be different. Another person's fear has no bearing on discontinuance of one's interaction with that person; another person's scorn or anger does. By contrast, when a person reacts with scorn or anger directed at a child who has done something damaging to another, the offending party is not likely to experience or to express guilt. Guilt is a response to the suffering of another presumably caused by one's self; scorn and anger are not indicators of suffering (Campos, Thein, & Owen, 2003).

Furthermore, we believe that the same emotion message (e.g., sadness) may generate different self-conscious emotions depending on the context in which it occurs. For instance, sadness may elicit guilt when it is expressed after a child engages in a disapproved action but may elicit shame when it is directed to the child herself. Anger may not elicit guilt when it is expressed after a child engages in a hurtful action.

In conclusion, our focus has been on early development in illustrating the theoretical perspective taken in this essay. In the next section, we turn to an extended discussion of recent empirical research undertaken with preschoolers, school-age children, and adolescents. Much of the recent research with these older children and youth embeds emotional experience in social interaction, whether the focus is on socialization of emotional expression norms or on emotion knowledge as applied to social effectiveness. There is also a greater emphasis on the development of the self as related to emotional development, and we address this link in our discussion of self-conscious emotions as well as in our discussion of adolescent "true self" development. Finally, we once again examine emotion regulation research in this older age group relative to temperament influence and the development of coping strategies. Throughout the next section, we also suggest topics for further research, which are also highlighted in our conclusion.

#### **EMOTIONAL DEVELOPMENT IN CHILDHOOD AND ADOLESCENCE: SOCIAL EFFECTIVENESS AND POSITIVE ADAPTATION**

Noteworthy in recent research has been the greater emphasis given to how children's and youth's emotional development is manifest in their social competence. Although appraisal processes and the regulation of emotion continue to garner much scientific attention, our

emphasis on the functional nature of emotional experience is especially relevant to how *social goals* are the fulcrum around which a great deal of emotion is elicited, experienced, and expressed.

Social psychologists have long examined the question of what constitutes well-being or positive adaptation, and a review of that literature is not appropriate here (for a brief review, see Diener & Lucas, 2000); however, what that research does consider is the extent to which social effectiveness and well-being are personality traits or dependent on the situation a person finds her- or himself in, especially if there has been a sudden change. The research on children's emotion regulation suggests that to some extent a proneness to negative emotion, which may function much like a temperamental disposition, may be related to social adjustment (for reviews, see Eisenberg & Morris, 2002; Swanson, Hemphill, & Smart, 2004). As an illustration of such research that attempts to tease apart the influences on children's resilience and adjustment, we consider a recent longitudinal study by Eisenberg and colleagues (Eisenberg et al., 2004).

#### **Social Adjustment and Emotion Regulation**

Eisenberg and her colleagues (2004) differentiate between *effortful* control—the ability to voluntarily inhibit or activate behavior—and *reactive* control—the relatively inflexible tendency to be either overly inhibited or impulsive. Although both types of control have their roots in children's temperament, the former construct is considered by Eisenberg and her colleagues as pivotal to their definition of *effortful emotion regulation* (Eisenberg & Spinrad, 2004), whereas the latter construct, reactive control, is less accessible to voluntary control and is linked to temperamental reactivity. Reactive control is also more often linked to problems of adjustment when this characteristic is particularly pronounced in the individual child, in large part due to its involuntary nature. Eisenberg and colleagues cite Block and Kremen's theorizing (Block & Kremen, 1996), which stipulates that most of us would like to operate with as little control as possible and with only as much control as necessary. When these are adaptively functioning and in balance, then the individual is operating in an ego-resilient fashion. However, the individual can be prone to excessive control and thus be maladaptively inhibited or prone to insufficient control and similarly maladaptively impulsive. If these less adaptive tendencies are elicited when faced with taxing stressors,

then Block and Kremen suggest that the individual is not responding with resilience.

Eisenberg et al. (2004) examined how effortful control and reactive undercontrol were related to children's internalizing and externalizing problems over a 2-year period. Both parents' and teachers' ratings of the children's behavior were obtained, and the children themselves were observed doing a puzzle that required sustained effort to solve. The sample ranged from 4.5 to 8 years old, and they were reassessed 2 years later. The results were very complex, indicating that there is no simple path between emotion-laden qualities such as effortful control and reactive control to subsequent social adjustment. The clearest outcome was that impulsivity and insufficient effortful control were directly predictive of externalizing problems, and this relationship was even stronger if the children were rated by their teachers as high in dispositional anger. Proneness to sadness did not moderate this relationship, but as the authors point out, such externalizing children often do experience sadness due to peer rejection. The latter is understood to be a situational response of sadness as opposed to a "dispositional" proneness to sadness.

A recent study undertaken with toddlers (Lawson & Ruff, 2004) used constructs similar to the Eisenberg et al. research. The results also indicated that negative emotionality and ability to sustain attention predicted later behavioral outcomes. More specifically, maternal ratings of emotional lability and proneness to irritability at age 2, defined by the authors as their index of "negative emotionality," and trained observers' ratings of attentiveness during frustrating play episodes with the mother combined to predict cognitive function (IQ) and problem behavior ratings (maternal ratings) at age 3.5 years. Their results indicated that when young children have both risk factors, low attentiveness and proneness to negative emotionality, at a young age, they are likely to obtain both lower IQ scores and be rated as significantly demonstrating more problem behavior. The authors refer to this as the "double hazard" of combined risk factors for both concurrent and predicted outcomes. Those children who showed both high levels of negative emotionality and low attentiveness showed a decline in IQ from age 2 to age 3.5, possibly due to the cumulative effects of this double hazard. Children who were prone to negative emotionality but had high attentiveness appeared to be protected against this deleterious outcome (especially for behavior problems). Interestingly, Gumora and Arsenio (2002) found with a considerably older group of children (sixth to eighth graders) that grade point average could be

predicted by the young adolescents' emotion regulation and mood-related disposition toward academic activities: Those adolescents who reported more negative affect regarding ordinary academic routines obtained lower grade point averages, even when cognitive ability was controlled for. Lawson and Ruff do caution that both attention and emotionality consist of a variety of components: "Attention includes persistence, intensity, and flexibility; negative emotionality can refer to fear, anger (irritability), or sadness" (p. 164). They note that further research is needed to tease apart these respective components for us to have a complex understanding of how negative emotionality and attention processes work together in children's development.

Other studies undertaken by Eisenberg and her colleagues with preschoolers (e.g., Eisenberg et al., 1997; Fabes, Hanish, Martin, & Eisenberg, 2002) suggest a continuity that may start relatively early in life (e.g., the Lawson and Ruff research), continue through the preschool years, and as the most recent Eisenberg study described earlier and the Gumora and Arsenio study suggest, may continue through the elementary school years and extend into middle school as well. Indeed, in a longitudinal study Valiente et al. (2003) found that when attention shifting and focusing and children's persistence at a puzzle task were aggregated, they predicted a reduced level of externalizing behavior over time: This effect was most pronounced for children prone to negative emotionality. These authors suggested that negative emotionality may be a moderator of the linkages between attentional processes (which they subsumed under the construct of effortful control) and externalizing behavior. Such research, albeit complex, does indicate that developmental psychologists have provided the *preliminary* data needed to inform public policy about early intervention, which may include parent guidance as well as appropriately structured preschool education for addressing the needs of children who are faced with the "double hazard" of low attentiveness and proneness to negative emotionality at a young age.

### Emotional Competence

Another way to conceptualize children's emotional development relative to their overall psychological adjustment or well-being is to examine their level of functioning according to the degree to which they access the various skills characteristic of emotional competence. Similar to such constructs as *well-being*,

TABLE 5.3 Skills of Emotional Competence

1. Awareness of one's emotional state, including the possibility that one is experiencing multiple emotions, and at even more mature levels, awareness that one might also not be consciously aware of one's emotions due to unconscious dynamics or selective inattention.
2. Skill in discerning others' emotions, based on situational and expressive cues that have some degree of cultural consensus as to their emotional meaning.
3. Skill in using the vocabulary of emotion and expression terms commonly available in one's subculture and at more mature levels skill in acquiring cultural scripts that link emotion with social roles.
4. Capacity for empathic and sympathetic involvement in others' emotional experiences.
5. Skill in understanding that inner emotional state need not correspond to outer expression, both in oneself and in others, and at more mature levels understanding that one's emotional-expressive behavior may impact on another and to take this into account in one's self-presentation strategies.
6. Skill in adaptive coping with aversive emotions and distressing circumstances by using self-regulatory strategies that ameliorate the intensity or temporal duration of such emotional states (e.g., stress hardness) and by employing effective problem-solving strategies for dealing with problematic situations.
7. Awareness that the structure or nature of relationships is largely defined by how emotions are communicated in the relationship such as by the degree of emotional immediacy or genuineness of expressive display and by the degree of emotional reciprocity or symmetry in the relationship (e.g., mature intimacy is in part defined by mutual or reciprocal sharing of genuine emotions, but a parent-child relationship may have asymmetric sharing of genuine emotions).
8. Capacity for emotional self-efficacy: The individual views her- or himself as feeling, overall, the way he or she wants to feel. Emotional self-efficacy means that one accepts one's emotional experience, whether unique and eccentric or culturally conventional, and this acceptance is in alignment with the individual's beliefs about what constitutes desirable emotional balance. In essence, one is living in accord with one's personal theory of emotion and moral sense, when one demonstrates emotional self-efficacy.

*social adjustment*, and *ego-resilience*, the construct *emotional competence* is a superordinate term that subsumes a number of emotion-related skills. The definition of emotional competence is straightforward: It is the demonstration of self-efficacy in emotion-eliciting social transactions. Elsewhere one of us (Saarni, 1999) has extensively reviewed the developmental contributors to emotional competence; briefly, they include the self or ego identity, a moral sense or character, and a person's developmental history. The components of emotional competence are those skills necessary for self-efficacy in emotion-eliciting social transactions. Table 5.3 summarizes the skills of emotional competence.

The derivation of these eight skills was largely based on a survey of empirical investigations in the field of emotional development, although there is relatively less research that directly addresses the last two skills. However, these last two skills reflect implicit assumptions in many studies on emotional development in Western societies: We live in social-emotional systems (reflected in Skill 7 and see especially the work by Gottman and his colleagues on meta-emotion in family functioning, e.g., Gottman, Katz, & Hooven, 1997) and emotional competence should ultimately address personal integrity—we can discern what works best for us, relative to our values (Skill 8). These skills of emotional competence also reflect a Western cultural bias, which is of concern, and thus caution should be exercised when try-

ing to generalize these skills to non-Western societies (e.g., Mesquita, 2001).

Later, we review a variety of studies that illustrate how each of the skills of emotional competence develops or is manifest, and we emphasize research that focuses on how the emotional competence skill facilitates an individual's effectiveness in relationships. In many cases, as children mature, their enhanced developmental functioning reveals itself in more complex manifestations of a given skill with concomitant advances in how interpersonal exchanges are negotiated.

**Social Effectiveness and Skill 1: Awareness of Our Emotions**

On some very basic level, knowing what we feel clarifies what we want. Theorists who emphasize close links between emotion and motivation readily acknowledge that the intended target or goal is critical for how we understand our subjective experience of emotion (e.g., Lazarus, 1991). Likewise, our emphasis on the functional nature of emotion is consistent with this perspective. By the time children are 2 to 3 years of age, awareness of emotional state is usually empirically examined from the standpoint of how children use emotion labels or descriptive phrases to refer to their subjective feelings. A number of studies have shown that young children spontaneously talk about their own affective states as well as about others' emotions (e.g., Bloom,

1998; Harris, 1997). The conversations between these young children and their family members also imply that they have expectancies for how they *will* feel as well as memories for how they *did* feel. Young children's conceptualization about their own subjective emotional experience encompasses the past, present, and future, and it is most reliably elicited in familiar interpersonal contexts. These everyday sorts of emotion-related communicative exchanges imply to young children that their emotions are part of a whole scenario of events, behaviors, and other people (see also Thompson, Chapter 2, this *Handbook*, this volume). In short, emotional experience is contextualized.

Furthermore, research with young children has shown that they construe their emotions as directed at something or someone as opposed to what elicited or caused the emotional response (Harris, 1995). For example, consistent with an earlier section, when children verbally describe their emotional reactions, they include the target of their feeling in their statements (e.g., mad *at* you, scared *of* snakes, happy *about* the party). They are less likely to talk about the causes of their emotional reactions (e.g., a conflict over a toy that led to one child feeling treated unfairly and thus becoming angry). However, when young children talk about experiencing pain, they do include the cause of pain, saying that they would feel pain on being pricked by a pin, but they would not say that they feel pain *about* pins.

Levine (1995) examined more thoroughly how younger children construed beliefs about the causes of anger and sadness in hypothetical vignettes. Her sample consisted of 5- to 6-year-olds, and she found that for anger they focused both on the aversiveness of the outcome and on the need to have the desired goal reinstated. For sadness, the children more often mentioned the loss felt by the protagonist and the impossibility or futility of having the goal reinstated. Interestingly, Levine used the same event for both anger and sadness stories, but she varied the attributions surrounding goal outcome. Her vignettes featured a child who could not go out to play because of an injury. In one version, the child had to stay inside but did not want to, and in the other version, the child wanted to play outside but helplessly could not. The former elicited attributions of anger and the latter sadness. Her results indicated that children appear to learn (in our culture at least) that their emotions can be explained by the status of their goals—whether the goals are met, violated, endangered, or lost.

Children who know what they feel are more able to negotiate with others when there is a conflict or a need to assert themselves. However, as Gottman, Katz, and Hooven (1997) argue, children are more likely to be effective negotiators when they can “down-regulate” or de-escalate their internal arousal sufficiently that they can attend to the social exchange and respond with useful social compromises to ease the impasse or conflict. Arsenio and Lemerise (2001) take this idea one step further in their model of social information processing, which is integrated with emotion processes such as encoding of affective cues from peers, the affective nature of the relationship a child has with the peer (e.g., hostile versus friendly), and empathic responsiveness. With this model, they suggest that a researcher can examine more effectively how and why children respond to some peer interactions with aggression and to others with social competence.

By early adolescence, well-functioning youth have the confidence to disclose their emotions and opinions to others, thereby revealing a “true self” to others in so far as they choose to express what their genuine emotions are, despite negative interpersonal consequences. Relevant research has been undertaken by Harter and her colleagues on adolescents' perceptions of their true self and under what conditions they present a dissembled self to others (Harter, 1999; Harter & Lee, 1989; Harter, Waters, Whitesell, & Dastelic, 1998). In addition, an early study (Saarni, 1988) found that some preadolescents recognized that although negative social consequences could occur if they revealed their genuine emotions, nonetheless, they contended that they would indeed express their genuine emotions because the emotions *themselves* were deemed important. With this kind of awareness of one's emotions, we can begin to understand how emotions themselves begin to constitute a part of a developing individual's definition of self (see Harter, 1999). This capacity to be aware of one's self and one's emotional responses is also relevant to the development of self-conscious emotions—pride, shame, guilt, hubris, envy, and embarrassment—and we turn next to a discussion of these emotions and their function in children's experience.

### *Self-Conscious Emotions*

Lewis' work (1993, 1995) on the development of pride, hubris, shame, embarrassment, and guilt constitutes a cognitive appraisal view of how such emotions come about (see also Mascolo & Fischer, 1995). According to

Lewis, these self-conscious emotions require that an objective self has developed: Children can refer to themselves and have conscious awareness of themselves as distinct from others. The cognitive appraisals involved include (a) recognition that there are standards to be met, (b) evaluation of the self's performance relative to these standards, and (c) attribution of responsibility to the self on success or failure in meeting the standard. At around the time children acquire objective self-awareness (15 to 24 months, as measured by self-referential behavior; e.g., Lewis & Brooks-Gunn, 1979), they also become aware of parental standards for behavior, rules that they are expected to follow, and desirable goals for comportment. Children learn about these standards through their family's disciplinary practices, and over the next few years their increasing cognitive sophistication also allows them to gauge the degree to which they have met the standards. The sorts of standards young children learn about are rather simple and concrete, for example, "you should say please if you want something," or "how terrible of you to bite your little sister!" As children become older, their beliefs become more differentiated relative to the standards and rules that they believe they should follow and the goals that they think are worthy. Meeting these standards presumably yields positive emotional experience, both from the experience of mastery and in receiving social approval (e.g., Stipek, 1995).

Children also develop an appraisal of self-agency or responsibility: Have they failed or succeeded at reaching the goal or at living up to the standard, or are they performing according to the rule? Although Lewis does not directly address issues of controllability, Weiner's work certainly informs us of how perception of controllability is directly implied in whether people feel responsible for events (e.g., Weiner & Handel, 1985). Dweck and Leggett (1988) have also contended that if individuals view themselves or their world as modifiable and thus controllable, they will have a different appraisal of such a context (and themselves in it), leading to different emotional sequelae, than those who view themselves and their environments as fixed and static.

Young children may believe they do cause things to happen—that they are in control of events, when they are not, due to their cognitive egocentrism that blurs desire and reality (e.g., Harris, 1989). On a simple level, a 2-year-old may believe and act as though "if I want a cookie, then I should have a cookie." But if that same young child believes that "if I want Mommy to love me,

then I have to be a good girl for her," she may then egocentrically conclude she must have been a "bad girl," when her mother simply expresses negative feelings that are unrelated to her child's behavior. Research by Zahn-Waxler and her associates (Zahn-Waxler, Cole, & Barrett, 1991; Zahn-Waxler, Kochanska, Krupnick, & McKnew, 1990; Zahn-Waxler & Robinson, 1995) suggests that young children (especially girls) growing up with depressed mothers may be particularly at risk for developing excessive "accountability" for their mothers' feelings and mood state. Such children were very careful in their interaction with others, as though others were quite fragile, and their behavior included higher levels of appeasement, apologizing, and suppression of negative emotion than comparable children of nondepressed mothers. Thus, these 2- to 3-year-old children appeared to believe unrealistically that they had control over events and over their mothers' emotional responses and/or were responsible for them.

The last cognitive appraisal that has to develop before self-conscious emotions are experienced is a focus on one's self from an evaluative standpoint such that either the whole self or a particular aspect of the self is considered the focus of the success or failure at living up to the standard, rule, or reaching a goal. Lewis (2000) contends that the more that the whole self is globally assumed to be responsible for the success or failure, the more that either hubris (arrogance) or shame will be felt, respectively. When specific aspects of the self are seen as leading to the success or failure, then pride or guilt will be felt, respectively. The emotional responses of pride and guilt are specific self-attributions as in "my effort paid off" (pride) or "it was my mistake and I'll deal with this fiasco" (guilt). The prideful feelings of accomplishment and pleasure allow the individual to undertake still further challenges; the guilt felt on one's failure at a particular event or in a particular situation allows for interpersonal repair and future improvement (see also Barrett, Zahn-Waxler, & Cole, 1993, for a discussion of "avoiders versus amenders" in toddlerhood, with the "amenders" apparently experiencing guilt rather than shame or embarrassment).

There is also a critical interpersonal context that needs to be taken into account in distinguishing shame and guilt—whether we are observed or alone. We do not need social *exposure* to feel guilt (although it might help), but it is a significant feature in our feeling ashamed and wanting to hide from others' view (e.g., Barrett et al., 1993). Exposure contributes to another

self-conscious emotion, embarrassment, which is not necessarily the same as shame. As an illustration of such research, Lewis and Ramsay (2002) proposed that there are two types of embarrassment, one is simply due to being the object of other's attention (exposure embarrassment) and the other is a more self-evaluative embarrassment that may be linked to shame. They studied 4-year-old children's reactions to a performance task (i.e., yielding success or failure) and a situation designed to emphasize focus on the self (e.g., receiving lavish compliments) and examined the children's cortisol responses after both conditions to see if they differed. The preschoolers who expressed behaviors indicative of shame or of evaluative embarrassment during failure at the task responded with higher cortisol levels, whereas the exposure to attention situation did not result in elevated cortisol responses. They concluded that shame and evaluative embarrassment are more stressful—as evidenced by the higher cortisol secretion—than feeling oneself to be the object of others' focused (and positive) attention.

Differences between shame and guilt have also been extensively studied by Tangney and her colleagues, using self-reported experiences rated according to dimensions devised by the authors (reviewed in Tangney and Fischer, 1995). She found with young adults that personal shame experiences were more often associated with a sense of powerlessness and having less control over the situation as well as feeling exposed to others' judgments. Furthermore, shame-prone individuals were more likely to externalize blame onto some other person or event. Shame experiences were also reliably associated with withdrawal or avoidance of others, whereas guilt was associated with reparation and nonavoidance of others. Fergusson and Stegge (1995) reviewed the attribution literature on the development of guilt and shame, and they argue that not until middle childhood do children more reliably use a causal analysis of events in reporting their emotions.

A somewhat different view of how shame, guilt, and pride develop has been proposed by Barrett (1997). Her emphasis is on *emotion communication* as a necessary component for the development of self-conscious emotions. She attributes the primary significance for the emergence of the self-conscious emotions to the significant relationships in children's lives, most notably, their parents. Her argument is that the standards by which children view their behavior as shameful, guilt-inducing, or prideful would never be internalized if children did

not *care* about the emotion-laden responses of their primary caregivers to their behavior. Thus, for self-conscious emotions to develop, young children would also need to be able to recognize and understand their parents' emotion-laden communicative behavior as directed toward them, and that such instances of parental emotion communication have meaning for the desirability or undesirability of their behavior. This may account for why young children do not demonstrate clear instances of shame, pride, or guilt until the 2nd year of life.

Research on children's self-conscious emotions has received considerable attention in the previous decade: Tangney and Fischer's (1995) volume on self-conscious emotions contains a number of chapters that address developmental issues. Reimer (1996) has sought to integrate research with young children's self-conscious emotions with clinical work on adolescents and adults to examine the development of shame in later childhood and adolescence. The development and functioning of self-conscious emotions clearly needs more attention at all age levels. It would appear that the development of self-conscious emotions are especially relevant to clinical practice, whether it be the treatment of depression that occurs with a greater frequency among female adolescents or the development of effective interventions to facilitate a child's coping with the emotional aftermath of sexual abuse (see Tangney, Burckhardt, & Wagner, 1995, for a review of shame, guilt, and psychopathology).

### *Awareness of Multiple Emotions*

Also relevant to children's and adolescents' social effectiveness and adaptation is their ability to be aware of experiencing multiple emotions or conflicting emotions (as in ambivalence). This development may appear as early as 5 to 6 years of age (Stein, Trabasso, & Liwag, 2000) or not until late childhood (Harter & Whitesell, 1989), depending on the criteria and methods for eliciting such understanding from children. Stein and Trabasso examined 5- to 6-year-olds and determined that at this age children could readily describe people who make them feel good *and* bad or whom they liked *and* did not like. However, Stein and Trabasso cautioned that this did not mean that children simultaneously felt conflicting emotions: Rather they first focused on one situation to which they attached values and attributions, responded emotionally to its impact on them (e.g., "I don't like her because she took my Halloween candy"), and then focused on another situation with its accompanying values and attributions and respond emotionally

to its impact (e.g., “But I like her when she plays with me”). Thus, ambivalence for Stein and Trabasso was viewed as a *sequential* process with different appraisals attached to the different or polarized emotional responses, and they suggested that this process was the same for adults, just much more rapid.

Studies conducted by Harter and Whitesell (1989) and by Donaldson and Westerman (1986) were similarly concerned with children’s cognitive construction of their own emotional experience, particularly when multiple emotions are involved. Harter and Whitesell focused on the cognitive developmental prerequisites for understanding the simultaneity of multiple emotions embedded in a situation or relationship. Not until children had the ability to coordinate multiple attributes of a situation with the dimension of emotional valence (at about 10 years of age) could they make sense of opposite valence emotions (happy and sad) about different targets that co-occur in a situation (e.g., “I’m glad I get to live with my dad, but I’m sad about not being able to live with my mom too”). Young adolescents developed further and could integrate simultaneously opposite valence emotions about the same *target* (e.g., “I love my dad, even though I’m mad at him right now”). Harter and Whitesell acknowledged that what may occur as we cognitively integrate contrasting emotions about the same target is a rapid oscillation between the multiple emotion-eliciting aspects of a relationship or situation.

Harter and Buddin (1987) also pointed out that it is not known whether children might experience simultaneously two (or even more) emotions but can only cognitively construct an explanation about the experience that focuses on one emotion. They also noted that children may in some situations experience only one overwhelming emotion, for example, fear, but as they seek to cope with the scary situation or have to communicate about it to someone else, they begin to cognitively construct a more complex system of appraisals about the emotion-eliciting situation or relationship.

### Summary

This first skill of emotional competence—the ability to be aware of an emotional experience—facilitates children’s problem solving, for knowing how to respond emotionally to a particular eliciting encounter is crucial to deciding on a course of action, especially if a first impulse to action is potentially going to incur some undesirable consequences, and thus be less self-efficacious

in the long term. In terms of social effectiveness, knowing how one’s self tends to react, whether it is with shame or with a conflicted set of emotions leading to ambivalence, is still a source of important information for the developing child or teen to integrate into his or her self-definition, especially knowing that some emotional experiences render one’s self acutely vulnerable in interpersonal situations.

### Social Effectiveness and Skill 2: Ability to Discern and Understand Others’ Emotions

To understand others’ emotions and motives, children need (a) to make sense of others’ expressive behavior and action tendencies, (b) to understand common situational elicitors of emotions, and (c) to comprehend that others have minds, intentions, beliefs, and inner states. There is a fairly substantial research literature on these topics and the reader is referred to reviews in Denham (1999); Dunn (2000); Halberstadt, Denham, and Dunsmore (2001); Harris (2000); Underwood (1999); von Salisch (2001); and Thompson, Easterbrooks, and Padilla-Walker (2003). A variety of studies indicate that children who are more accurate in understanding others’ emotional experience also tend to be more socially competent (see reviews in Halberstadt et al., 2001). These studies typically establish a given child’s social competence either by teachers’ ratings or by peers’ sociometric choices. Then the children’s understanding of emotion terms, of facial expressions, of elicitors of emotion, and so forth are assessed and correlated with the children’s social competence ratings (e.g., Hubbard & Coie, 1994). Other investigators have examined children’s maladaptive social interaction to see whether deficits in their understanding of others’ emotions contribute to their ineffectual social behavior. Specific clinical populations have also been studied for how their understanding of others’ emotional experience may differ from nonclinic samples, for example, autistic children, children who have been abused, and children who have witnessed family violence (for brief reviews, see Saarni, 1999, and Southam-Gerow & Kendall, 2002).

Two studies have considerable potential for broadening research on this topic. In the first study, Barth and Bastiani (1997) investigated children’s biases in labeling the expressions of their classmates’ facial expression photos. Accuracy scores were based on congruence of the judged expression and which expression the class-

mate was intending to produce expressively for the photo. Bias scores were calculated as the proportionate number of times a child used a particular expression label (e.g., sad, happy, mad, surprised, or afraid) relative to the total number of classmate photos that were judged. The children made these ratings at the beginning of the school year and again 5 months later. The children's peer acceptance, based on sociometric ratings, and their general social adjustment, based on teacher ratings, were also assessed.

Noteworthy among their results was that those children who had a bias for "seeing" angry facial expressions (contrary to what the familiar classmate was trying to produce expressively) were also the ones who had less satisfactory peer relations, and their teachers rated their adjustment more often as hostile dependent. This outcome is consistent with research with older children who used a hostile attribution bias in their peer relationships (e.g., Crick & Dodge, 1994). These results may also be linked to Isley and colleagues' research on parent-child expressed affect and the children's subsequent social competence with peers (Isley, O'Neil, Clatfelter, & Parke, 1999). In that study, negative expressed affect by parents toward their children was associated with their children's impaired social functioning with peers. Similarly, Schultz, Izard, and Ackerman (2000) found that parental depression and family instability predicted preschool children's anger attribution bias, which in turn was associated with peer rejection. These children were also rated as aggressive by their teachers.

The second study we describe in some detail was on how rejected children behave when mildly interpersonally stressed. Hubbard (2001) had 7- and 8-year-olds rate their peers for how liked or not-liked they were as well as who starts the most fights. The former sociometric rating yielded a rejection index and the latter an aggression index. She then observed the children in a rigged game with a confederate whom they did not know and who was 1 year older. The children were under pressure to win the game to obtain a prize. Compared to accepted children, the rejected children were more likely to express both facial and verbal anger during the game. They also expressed more happiness, but only when some game maneuver was to their advantage. Interestingly, aggressive children were not necessarily more likely to express anger (or happiness or sadness) than nonaggressive children. This particular finding is also

consistent with that found by Underwood and Hurley (1999). We would like to see research that combines elements of the Barth and Bastiani approach with Hubbard's approach: For example, would rejected children demonstrate a bias in their perception of emotion in others, or are they simply oblivious and insensitive to emotional cues? Why did this game context not elicit anger in children rated by their peers for being likely to start fights? Is this a context in which a potential bias for perceiving anger in others is not elicited?

### ***Understanding Others' Feelings and Cognitive Development***

The ability to understand what others are experiencing emotionally does not develop in isolation from other aspects of emotional development and cognitive development. Emerging insight into others' emotions develops in interaction with increasing awareness of an individual's own emotional experience, with the ability to empathize, and with the ability to conceptualize causes of emotions and their behavioral consequences. The more children learn about how and why people act as they do, the more they can *infer* their emotional state, even if it is not especially obvious or may even be counterintuitive. The studies reviewed show that the growth in emotional development that children show over time is deeply tied to their cognitive development as well. (For a recent review of children's cognitive understanding of emotions, see Harris, 2000.)

**Facial Expressions and Emotion-Eliciting Situations.** We concur with the view espoused by Lewis and Michalson (1985) that facial expressions can have a dual function; they can be *signs*, in which case they bear a one-to-one correspondence to internal emotional state, or they can function as *symbols*, in which case they refer to something else. When facial expressions are symbolic, they are referring to metacommunicative processes (e.g., Wagner & Lee, 1999; Weber & Laux, 1993), for example, placating someone, deterring someone, or presenting oneself in a more favorable light. The dissociation of facial expression from internal emotional experience is taken up in detail in the discussion of Skill 5.

By mid to late childhood, most children recognize and can verbalize that a person's expression may be both a social and an emotional response (e.g., Underwood & Hurley, 1999). Gross and Ballif (1991)

reviewed the early research on children's understanding of emotions in others based on facial expression cues and situational elicitors of emotion. They concluded that as children matured, they became more accurate in their inferences about what others were feeling. The easiest emotions to figure out were positive ones: Smiling faces and situations depicting pleasure and getting what one wants were readily comprehended as associated with happiness. Negative facial expressions depicting sadness, fear, or anger were more difficult for children to decode. However, if paired with a detailed emotion-eliciting situational context, children were much more likely to infer the negative emotion in question.

As children grow older, they combine both facial and situational cues as they attempt to discern and understand the emotional experience of others. Wiggers and van Lieshout (1985) suggested that when there was a contradiction between a facial expression and the emotion-eliciting situation, school-age children were more likely to opt for whichever cue was more clearly presented. An example used by Wiggers and van Lieshout is a scenario depicting a boy with a weak smile about to get a fearsome injection. The situation, in this case, is more definitively portrayed than the boy's facial expression, and as a result, children conclude that the boy is anxious or afraid, despite the attempt at a smile. Children also recognize that others might feel a mixture of feelings about a situation.

The preceding conclusions were largely based on research that was done by having children appraise hypothetical vignettes, photos, and the like. Fabes, Eisenberg, Nyman, and Mischealieu (1991) investigated 3- to 6-year-old children's understanding of others' emotions in naturalistic settings. They found that happy reactions were more often correctly identified (according to adult standards) than negative reactions, thus replicating the general outcome of interview-based research. Fabes et al. also examined children's understanding of the causes of emotions and found that children could more readily identify causes for negative emotions. They interpreted this result as based on the greater intensity of negative emotional states and concluded that children more readily evaluate the causes for goal failure (i.e., any undesired outcome). A developmental difference found by Fabes et al. was that their youngest children tended to attribute causes to wants and needs, but the older children in

kindergarten more often made use of others' personality traits in their construal of what gave rise to the emotional response. This use of personalized information in understanding others' emotional experience is further examined in the next section.

**Taking into Account Unique Information about the Other.** The most relevant studies for more fully describing this feature of understanding others' emotional experience were conducted by Gnepp and Gould (1985) and Gnepp and Chilamkurti (1988) and theoretically elaborated by Gnepp (1989). Gnepp and Gould examined whether children (ages 5 to 10) could use information about a story character's past experience (e.g., being rejected by your best friend) to predict how the character would feel in some new situation (e.g., subsequently meeting the best friend on the playground). Not unexpectedly, the youngest children were more likely to use the current situational information to infer what the character was feeling (e.g., she would be happy at seeing her best friend) and older children were more likely to infer the character's emotional state by taking into account the prior experience (e.g., she would feel sad on seeing her best friend). An interaction also occurred between the hedonic tone (positive/negative) of the emotion and the use of personal information: If the story character experienced a negative *emotion* at Time 1 but encountered a commonly assumed positive *situation* at Time 2, children were more likely to use prior personal history information when inferring how the character would feel at Time 2. Gnepp (1989) suggests that children must first recognize what a person's perspective was at Time 1 and then must apply that inferred perspective from Time 1 to Time 2 to come up with the atypical emotional response.

In an analogous investigation, Gnepp and Chilamkurti (1988) presented stories to elementary school children and adults in which characters' personality traits were systematically described as either desirable or undesirable traits. The story characters then had some experience befall them, and the children were to infer the emotional reaction of the character to this new experience. Older children and adults were more likely to take into account the prior trait information in inferring the emotional response of the character in the new situation. The younger children (6-year-olds) were less consistent in doing so, but a number were able to take personality trait information into account when

inferring how someone might emotionally respond to an emotion-eliciting event, even when the emotional reaction might be atypical for the eliciting event. Lagattuta and her colleagues (Lagattuta, Wellman, & Flavell, 1997), determined that even preschoolers could figure out that the same situation could evoke different emotional responses in story characters if the cues were presented very explicitly (e.g., pictorially showing the story protagonists experiencing atypical emotional reactions).

These investigations show us that by school entry, children are well on their way to superimposing multiple frames of reference onto one another across time intervals to predict or infer other people's emotional responses. In Gnepp's research, a distinction was not made between emotional state and emotional-expressive behavior: The assumption was that children would infer emotional state. Whether children could also infer what sort of expressive behavior would be displayed, and whether it would be congruent with an atypical internal emotional state or with the consensually defined "typical" emotion response to the situation, was not part of the focus of these studies. Little research has since been undertaken on this topic, an omission that we would like to see remedied.

**Social Competence and Discerning Others' Emotional States.** A number of studies indicate that children with emotional problems or who have been abused show deficits in their understanding of links between facial expression and emotion, in producing facial expressions, and in discriminating emotion expressions (e.g., Camras, Grow, & Ribordy, 1983; R. J. Casey, 1996; Pollack, Cicchetti, Hornung, & Reed, 2000; Shipman, Zeman, Penza, & Champion, 2000). The research by Pollack et al. (2000) warrants further description: These investigators found that neglected children had difficulties in discriminating emotions, whereas physically abused children appeared to have a bias to perceive angry facial expressions. Thus, the sorts of early emotion communication experiences that children receive influence how they construct their understanding of others' emotional expressions and emotional states, and as we elaborate under our discussion of Skill 6, this early emotion communication exposure is also linked to their ability to regulate their own emotional arousal with peers and in school (e.g., Gottman et al., 1997).

Do children who are exceptionally socially competent show an enhancement of understanding emotion

and expression linkages? Custrini and Feldman (1989) reported that among girls, but not among boys, degree of social competence greatly influenced their overall accuracy score in encoding and decoding others' emotions. Girls who were below average in social competence scored well below boys, regardless of their social competence level, and the highest scoring children were girls who were above average in social competence. Other research undertaken by Walden and Knieps (1996) suggested that preschoolers who obtained high sociometric peer preferences as play partners were also those who tended to be better at discriminating among emotional facial displays and who tended to demonstrate high spontaneous expressivity (but they did not excel in posed expressions). Another study undertaken by Edwards, Manstead, and McDonald (1984) with somewhat older children demonstrated a similar relation: Children's sociometric rating was positively related to their ability to recognize facial expressions of emotion.

Further support for links between social effectiveness and emotion *knowledge* can be found in research undertaken by Denham, McKinley, Couchoud, and Holt (1990) on preschoolers' peer interaction and in a study on family-peer connections by Cassidy, Parke, Butkovsky, and Braungart (1992). The Denham et al. results showed that children who demonstrated greater knowledge of emotion in the puppet task (especially in understanding anger and fear) were perceived by their peers as more likeable. In the Cassidy et al. (1992) study of kindergarten children, emotion understanding was measured by interviewing the children about identification of emotional facial expressions, how particular emotions were situationally elicited, and what were the social consequences to such emotions. They found that children who demonstrated more complex emotion understanding were more accepted by their peers.

More recent research undertaken by Garner and Estep (2001) examined the relations among preschoolers' emotion knowledge and their social skills. Their results indicated that children's understanding of situational clues to infer what emotions would likely be felt was a negative predictor of children's use of nonconstructive anger reactions with their peers. Their assessment of children's ability to provide explanations for the causes and consequences of others' emotions was a significant predictor of the children's initiating social interaction as well as being chosen as recipients of social bids.

**Problematic Outcomes and Understanding Others' Emotional States.** Discerning and understanding others' emotional experience does not necessarily always contribute to one's skill at emotional communication. Paradoxically, in certain circumstances, some children would be better off tuning out others' emotional behavior. Children who are exposed to and involved in their parents' depressed feelings represent one group who are at risk for an aversive emotion socialization experience, and another group consists of those children exposed to marital conflict accompanied by overt anger. It is unrealistic to assume that children can tune out their parents' negative emotions, but outcomes for children if such experiences are frequent, intense, and started early in life do not bode well. Investigations of how children of chronically depressed parents (for the most part, mothers) develop emotionally has been reviewed by Downey and Coyne (1990) and by Zahn-Waxler and colleagues (Zahn-Waxler et al., 1990). Research on children who witness interadult anger and domestic violence has been reviewed by Osofsky (1999).

### **Summary**

Children's social effectiveness is closely linked to their accurate appraisal of emotional states in others. Even if the expressive cues are ambiguous, they learn to infer what emotions others might be experiencing, based on their expanding knowledge of common elicitors of emotion relevant to their subculture. Preschoolers can anticipate that atypical emotional responses may be experienced, if they are provided with fairly explicit cues. By the early school years, children take into account what they know about another's personality or unique circumstances to infer the target's emotional response. Research on individual differences indicates that maltreatment of children compromises or distorts the development of these social-cognitive skills.

### **Social Effectiveness and Skill 3: Use of a Vocabulary of Emotion and Expression**

With language and symbols, we can traverse time and space to communicate with others about our own and their emotions. Modern technology seems especially designed to promote such communication with "instant messaging," e-mail, and cell phones everywhere. Social psychologists have investigated why it is that we are so compelled to share our emotional experience with oth-

ers, and one hypothesis has been the "stress and affiliation effect" (reviewed in Luminet, Bouts, Delie, Manstead, & Rimé, 2000): When we feel badly, we want the company of others, and, more specifically, we want *to tell* others how we are feeling (with the interesting exception of when we feel shame). This implies that communicating our feelings to another initiates change. Such change may be found in how we experience our subjective feeling state (e.g., internal emotion regulation is affected), or with the support of others, we may devise different ways to cope with a problematic situation.

From a developmental perspective, the "stress and affiliation" pattern is the hallmark of many attachment studies with young children. We also know that young children and their mothers are more likely to use emotion-laden language when there is a dispute or some negative event occurs (Denham, Mitchell-Copeland, Strandberg, Auerbach, & Blair, 1997; Dunn & Brown, 1991; Dunn, Brown, & Beardsall, 1991). Indeed, as Chambers' review indicates (1999), family discourse is critical to young children's learning about emotions, how to speak about feelings, and how to cope with emotion-laden situations. Awaiting further study is how the social psychological research on emotion disclosure undertaken with adults might manifest itself in children's emotion disclosures to peers. On one hand, Gottman et al. (1997) would contend that school-age children should not disclose their feelings to peers if they are to be accepted. On the other hand, with the advent of close friendships in childhood and early adolescence, disclosure of vulnerability-inducing feelings (e.g., anxiety, sadness, or hurt) is more likely to occur (e.g., Asher & Rose, 1997; Saarni, 1988). However, let us return to the beginning: how young children acquire a lexicon of emotion that permits them to represent their own and others' emotional experience.

### ***Ability to Use Concepts, Lexicon, and Scripts Relevant to Emotion and Expression***

The ability to represent emotional experience through words, imagery, and symbolism of varied sorts allows children to communicate to others what they want and what problems they are encountering as well as to describe their delight and pleasure. With words, the child can further elaborate these representations of emotional experience, integrate them across contexts, and compare them with others' representations about emotional experiences. Some of the developments in awareness of one's own multiple emotional responses or in understanding

others' atypical emotions, described earlier, could not be undertaken if children did not have access to a language or representational system (e.g., sign language) for symbolically encoding and communicating their emotional experiences.

Assuming an intact nervous system and an environment that is not overwhelmingly trauma filled, children do show some commonalities in our culture in learning how to represent emotion. However, individual differences and cultural influence are again strong forces in the development of language-based emotion concepts, which is not surprising, since one of the critical functions of an emotion lexicon is to be able to communicate with others, which obviously entails their reciprocal communication about emotion (e.g., Dunn & Brown, 1991).

**Development of Emotion Lexicon.** Bretherton, Fritz, Zahn-Waxler, and Ridgeway (1986) reviewed the relevant literature on children's acquisition of emotion words, and they noted that many toddlers could use emotion words toward the end of the 2nd year. However, they cautioned that what was included as an emotion word, for example, crying, may simply be a behavioral action noted by the young child and conceivably was not used by the child to indicate an internal emotional state. By 3 years of age, children could much more readily label the emotions of others in addition to their own feelings. Increasingly, they could also verbally address the consequences of emotional states as well as the situational causes of emotions; for example, "Grandma mad. I wrote on wall."

Researchers have also studied parents' reports of their children's understanding and use of emotion-descriptive words. Using parents' ratings on checklists of words indicating emotion states (e.g., "happy"), emotion traits (e.g., "good"), and physical states (e.g., "sleepy," "clean"), Ridgeway, Waters, and Kuczaj (1985) tabulated the percentages of children at 6-month intervals (starting at 18 months and extending to 6 years of age) comprehending the emotion word and also using it. The most frequently understood words at 18 months were sleepy, hungry, good, happy, clean, tired, and sad (50% to 83% comprehension). By age 6, children comprehended such words as "nervous" (83%), "embarrassed" (77%), "jealous" (60%), and "miserable" (53%). Their corresponding production of these words was one-half to two-thirds of the percentages for comprehension.

Children can also apply emotion terms to pretend play by age 2 to 3, and, indeed, listening to children talk as they enact fantasies with their figurative toys (e.g., dolls, action figures, stuffed animals) is an excellent way to observe a young child's competence with emotion language, for they construct both the causes of the figure's emotional response and the consequences of the emotion, including how the figure copes. Denham and Auerbach (1995) analyzed the emotional content of mothers and preschoolers' dialogues while looking at picture books together (whose contents were emotion laden). They found that such an interaction was rich with adult-child exchanges that included affect labeling and causes and consequences of emotional experience. In addition, both mothers and children used their emotion-descriptive language in ways that suggested social influence of the other; for example, mothers who limited themselves to simple comments about the emotion-laden material in the picture books had children who asked more questions to engage their mothers more. However, those mothers who made use of verbal explanation to a very great degree appeared to stimulate their children further to use more complex and elaborated emotion-descriptive language. These children tended to respond with more guiding and socializing language about the characters' emotional experience.

**Conversations about Emotional Responses.** The classic research on this topic was undertaken by Dunn et al. (1987) who investigated naturally occurring conversations in the home between young children and their mothers and siblings. They were particularly interested in determining what sorts of functions conversations about emotional reactions had in the social exchange in the home and how children communicated causes of emotional reactions in their exchanges with others. They followed the young children from age 18 months to 24 months and found that conversations about causes of emotional experience increased significantly in the 6 months they tracked the children. They also found that the vast majority of emotion-laden conversations were with the mother as opposed to the older sibling, although such conversations involving all three occurred more often than between just the two children. This finding suggests that access to an adult who is interested in one's emotional reactions may be pivotal to children having opportunities both to talk about emotions and have their understanding of emotions elaborated. Mothers tended to use conversations about emotional responses as a

functional way to guide or explain something to their children, whereas the children were more likely to use emotion-descriptive words simply to comment on their own reaction or observation of another. Thus, they were learning to communicate their own self-awareness of emotion states to their mothers, who in turn were likely to communicate meaningfulness to their children by using guiding, persuading, clarifying, or otherwise interpretive emotion-related language.

Dunn et al. (1991) continued their research on naturally occurring conversations about emotions in the home, but this time extended their longitudinal study of children from when they were 3 years old to age 6. They again focused on children's and mothers' exchanges around causes and consequences of emotions and additionally tracked how disputes and conflicts in the home provided occasions for emotional growth by how children were exposed to and had to use emotion-descriptive language to negotiate the conflict. They found a tremendous range in variability among the children in frequency of "emotion talk"—from 0 to 27 occasions per hour of observation. The mothers also showed a similar variability, ranging from 0 to 22 occasions of "emotion talk" per hour of observation. Unfortunately, Dunn et al. did not provide information as to whether the mother-child dyads were matched in their rates of "emotion talk." Given the findings of their earlier study where mothers were pivotal in providing opportunities for children to verbally communicate about their emotional reactions, we can only speculate that if a mother did not talk much about emotions and related inner states, very likely her child did not either.

Another study by Dunn and Brown (1994) sheds further light on the effects of family emotional expression on children's acquisition of emotion-descriptive language. Again, they found that occasions of negative emotional reactions on the part of the child were when most emotion-related discourse occurred between mother and child. This study also documented that families characterized as high in frequency of anger and distress expression had children who were less likely to be engaged in discourse about emotional experience. However, if the families were low in frequency of negative emotional expression, when a negative emotional event did occur for the child, there was a greater likelihood of an emotion-related conversation to ensue between child and parent. This research suggests that children's acquisition of

emotion-descriptive language is anchored in relationship contexts: If everyone is angry or distressed a lot of the time, an episode of distress on the part of a child may be viewed as trivial. What may be metacommunicated in such families is that a child's emotional reaction is not very important. We can surmise how differences in the families' emotional milieus provide varying preparatory stages for their children's later emotional experiences in the world beyond the home (e.g., Du Rocher Schudlich, Shamir, & Cummings, 2004).

A recent study by Laible (2004) on mother-child discourse sheds further light on the role that the parent-child relationship plays in children's acquisition of emotion understanding and internalization of behavioral expectations. Attachment classification and proneness to negative emotional reactivity were evaluated in her preschool sample, and then conversations between the mother and her child were examined for elaborative style and discussion of negative emotions. Two discourse situations were sampled where (1) the mother and child reminisced, and (2) they read a story together. It was primarily in the first discourse context in which the mother and her child discussed the child's past experience that Laible found that attachment security was related to maternal elaboration and the dyad's discussion of negative emotions. In turn, such maternal elaboration was associated with children demonstrating higher levels of behavioral internalization and higher levels of emotion understanding. Interestingly, if mothers perceived their children as prone to negative emotional reactivity, they were more likely to elaborate in the reminiscence task and discuss negative emotions more frequently (probably because their children experienced them more often due to their proneness to negative reactivity).

**Structural Analysis of Emotion-Descriptive Language.** Russell and Ridgeway (1983) examined emotion-descriptive adjectives used by children in elementary school. They found that these words could be statistically analyzed with principal-components analyses and multidimensional scaling. The result was that two bipolar dimensions were found that provided an organizational structure for the many emotion-related terms used by school children. These two dimensions were: (1) degree of pleasure or hedonic tone and (2) degree of arousal.

This dimensional analysis of emotion concepts is of interest for it suggests something about the way emotion is categorized and perhaps even organized as subjective experience. A number of cross-cultural comparisons have been made on emotion concepts used by adults in other languages (reviewed by Russell, 1991), and the pleasure/displeasure dimension has been reliably found in all the cultures studied. Russell suggests that hedonic tone is relevant in all cultures in how feeling states are differentiated, but the English word "emotion" is not necessarily present in all languages, although an equivalent term is more the rule than the exception (exceptions appear to be the Tahitians, the Bimin-Kuskusmin of Papua New Guinea, the Gidjingali aborigines of Australia, the Ifalukians of Micronesia, the Chewong of Malaysia, and the Samoans; cited in Russell, 1991). In these few cultures where no term similar to emotion exists, internal affective states may be referred to as arising in certain body parts or organs; for example, the Chewong view the liver as the source of what for them might be called thoughts and affective responses. The significance of the virtually universal presence of the pleasure/aversion dimension in emotion-descriptive concepts may indicate that what experiencing pleasure/aversion does for us is a basic function: It is embedded in our approach-avoidance actions in relation to the contexts we live in and thus supports the functionalist theoretical perspective espoused in this chapter.

**Emotion Script Learning.** Acquisition of emotion-descriptive concepts continues throughout childhood and into adolescence, but little research has examined these older age groups. Further development of emotion language in the school-age child and adolescent may be found in their greater ability to add variety, subtlety, nuance, and complexity to their use of emotion-descriptive words with others. What may also develop is that children's scripts for understanding emotional experience are reciprocally influenced by their growing access to increasing complexity of emotion concepts. Russell (1991) defines emotion scripts as "a knowledge structure for a type of event whereby the event is thought of as a sequence of subevents" (p. 442). Russell notes that even in the same culture scripts for the same emotions may differ from person to person because emotion scripts are linked to other belief networks. This is a significant point because, for example, if a script for anger is linked to a network of concepts about sex role, the anger script may well have

additional emphases or omissions if a person's machismo or femininity is implicated in the anger episode. What is important to consider is that scripts for different emotions may merge (or one emotion may cycle into another) under certain circumstances, particularly if individuals appraise a situation as salient for certain beliefs they hold about themselves (see also Lewis, 1992, for a discussion of links between gender and shame scripts).

Emotion scripts may merge with gender role socialization as suggested by some of the sex differences found for how anger and sadness are talked about in families. For example, gender differences in learning to talk about emotional experience were found by Dunn et al. (1987) in their study of young British children and their mothers. Little girls received more comments and inquiries about emotions from their mothers and from their older siblings than did little boys; however, the boys and girls themselves were similar in their initiation of conversations about emotions. In a similar vein, Fivush (1991) undertook an exploratory study with mothers of 3-year-old boys and girls and found that mothers tended to talk in a more elaborated fashion about sadness with their daughters and more about anger with their sons. She found that mothers tended to embed their discussions of emotions in social frameworks more with their daughters than with their sons. Relative to script notions, she also found that when anger was involved, mothers emphasized relationship repair with their daughters and were more accepting of retaliation by their angry sons.

More recently, Widen and Russell (2002) examined young children's attributions of emotion to story characters who varied in gender but who were engaged in identical emotion-eliciting situations. Through computer image manipulation, the faces of two young adolescents, a boy and a girl, were merged into a single androgynous image. The images were then further manipulated by having either a masculine or a feminine stereotyped hairstyle. Boys more often inferred the male protagonist to be feeling disgusted and girls more often inferred the female protagonist to be feeling fearful. Prior research had indicated that preschoolers often attributed anger to boys and sadness to girls when the emotion being felt was ambiguously presented (e.g., Karbon, Fabes, Carlo, & Martin, 1992). But what the authors suggest—that is even more intriguing from a developmental perspective—is that different emotions may be conceptualized by young

children by relying on different cues. Their results indicated that clear facial expressions of happiness, sadness, and anger were not “swayed” by gender cues, whereas the emotional displays of disgust and fear appear to be influenced more by gender stereotypes and the verbal label provided.

Last, cultural influence and the acquisition of an emotional lexicon are inseparable, for societies use language to regulate emotion in social interaction. Many societies emphasize some emotional responses over others by attaching special importance to certain emotion-descriptive words. In American culture, the word “love” is such an emotionally loaded word. Much anthropological research has been done that examines emotion-descriptive language. The reader is referred to an edited volume on this topic (Russell, Fernández-Dols, Manstead, & Wellenkamp, 1996). Another useful perspective is that of ethnotheories (or folk theories) of emotion lexicons (e.g., Lutz, 1988). Illustrative of this perspective are Ochs’ (1986) review of Samoan children’s acquisition of emotion-descriptive language and A. Eisenberg’s (1986) ethnographic study of the emotional and social functions of verbal banter (teasing) in recently immigrated Mexican children.

### **Summary**

Young children show a rapid increase in acquiring an emotion lexicon. Having words for their emotional experience allows for seeking support in distressing circumstances, for reciprocal sharing with others about emotional experience, and for being able to conceptualize lexically their emotions and how they came about as well as what the consequences for the self and others might be. Without an emotion lexicon, how could children and youth reflect on themselves as emotion-experiencing individuals? Indeed, we see in cases of severely abused and traumatized children and youth a deficit in the ability to conceptualize what they experience emotionally (e.g., alexithymia; see also Camras, Sachs-Alter, & Ribordy, 1996). This skill of emotional competence functions somewhat like a pivot for the other skills, for it is with access to the language of emotion concepts that children learn to predict how they themselves are likely to emotionally react, to understand others’ emotional responses, and to respond empathically and sympathetically to others, as we discuss next.

### **Social Effectiveness and Skill 4: The Capacity for Empathic and Sympathetic Involvement**

Empathy and sympathy are emotional responses that connect us with others. Beginning with early infancy, it is clear that very young babies respond to the crying states of other neonates (Martin & Clark, 1982). This early attentiveness to emotional-expressive cues may pave the way for later vicariously induced emotion, for they cannot be induced to experience another’s emotional state unless they notice it and consider it salient. Sympathy differs from empathy in that it can also be experienced when responding to purely symbolic information, such as reading about someone’s distress or by hearing about someone’s unfortunate circumstances. Empathy tends to be defined as a more immediate emotional response that is experienced by the observer on witnessing someone’s emotional state. Empathy may include emotion contagion, but with older children and adults we more often assume that there is some ability to take the perspective of the distressed person, and, consequently, we experience vicariously what we believe the target person to be experiencing. Sympathy is an affective response that contains elements of sorrow or concern for the distressed person. When feeling sympathetic, we do not necessarily vicariously experience the same or similar negative affect of the target (Eisenberg, 2003).

It is hard to imagine that a person could be socially effective and not be empathically involved in their interaction with others. Yet, paradoxically, sometimes too much empathy with another’s negative emotional response can disrupt socially effective engagement with the distressed person, resulting in personal distress rather than being able to focus on the other person and respond appropriately. In a number of well-conducted studies, Eisenberg and her colleagues found that children also need to establish psychological boundaries so that they can respond sympathetically and not become overwhelmed by another’s distress (e.g., Eisenberg et al., 1996). Such personal distress leads to a preoccupation with their own negative affective response, which then short-circuits their prosocial, sympathetic behavior. Zahn-Waxler and Robinson (1995) have argued that personal distress reactions are most likely to occur when the other’s emotional-expressive display is particularly vivid and intense, and if there appears to be little that an individual can do to ameliorate the other’s distressing situation. An individual might also experi-

ence personal distress when his or her sympathy is undesired by the target of their concern, as might occur when a distressed individual is further distressed by being made to feel self-conscious, helpless, or somehow inadequate through another's sympathetic overtures. We are not aware of any empirical developmental research on this latter topic.

There has been considerable debate among social and developmental psychologists as to whether empathy is a mediator of altruistic and prosocial behavior. Readers are referred to Eisenberg (2003), Eisenberg, Fabes, and Spinrad (Chapter 11, this *Handbook*, this volume; Eisenberg & Fabes, 1998) for a review of the issues. Prosocial behavior can occur simply from wanting to be sociable with others, not necessarily from being empathic to their feelings (Dunn, 1988). However, Roberts and Strayer (1996) present fairly persuasive evidence that empathy, in conjunction with being able to take the perspective of others, does predict prosocial behavior to some degree.

What seems critical to address in empathy research and its influence on children's and youths' relationships is how it combines with a sense of values to predict socially responsible behavior that is accompanied by a sense of compassion. Children who feel a sense of responsibility to help others are among those most likely to behave prosocially (Chapman, Zahn-Waxler, Cooperman, & Iannotti, 1987). There is also research that demonstrates that failures in empathy are implicated in adolescents with conduct disorders (D. Cohen & Strayer, 1996). Arsenio and Lemerise (2001) are particularly vocal in their call for the need to address moral values in research on aggression, and one of the pivotal mediators between values and prosocial behavior may well prove to be empathy.

We need to know more about the sources of individual differences in the capacity for empathic engagement without becoming overwhelmed by one's own personal distress. One possibility is how children develop a tolerance for ambiguity. Would those children and youth who can tolerate ambiguity to greater extent also be those children who turn out to have a higher threshold for tolerating another's intense distress without being overwhelmed by it and becoming personally distressed themselves? Social psychological research indicates that when people are distressed, they are more likely to impulsively indulge themselves in something pleasurable to make themselves feel better, but what they indulge themselves in is not likely to be prosocial (Tice, Brat-

slavsky, & Baumeister, 2001). If a person could tolerate uncertainty about a course of action, such as to how to intercede or not, and thereby gather more information, they might ultimately be more capable of responding not only prosocially but also more effectively in ameliorating the other's distress. This question has not been investigated to our knowledge, or at least not with children and youth; it would appear that tolerance for ambiguity would also be moderated by self-regulatory abilities and cognitive perspective-taking skill. Indeed, Eisenberg and colleagues (e.g., Eisenberg et al., 1996) provide data that show, for children to experience sympathy rather than personal distress in an emotion-evocative situation, they need to be capable of neuro-physiological regulation, use attentional control processes, accurately appraise emotion-eliciting events, infer others' internal emotional states, and cope with situational demands. We turn next to a more in-depth discussion of individual differences in empathy and sympathy, and their relation to socially adaptive behavior in children and youth.

**Disposition for Over-Arousal.** A significant contributor to experiencing personal distress rather than the more functional sympathetic response is the disposition to experience emotional over-arousal and more intense levels of vicariously induced negative emotion (e.g., Eisenberg et al., 1988). These researchers found that heart rate acceleration was associated with a personal distress response, but sympathy co-occurred with heart rate deceleration. In the latter study, children's heart rate and facial expressions were better predictors of their subsequent helpful overtures than their self-report.

**Early Parental Attunement.** While there may also be genetic and biological contributions to individual differences in empathic responsiveness and sympathy (reviewed in Eisenberg, 2003), we concur with the position taken by Zahn-Waxler (1991), who argued that the origins of prosocial and altruistic behavior are to be found in the dynamic emotional exchanges of the attachment relationship between parent and infant. She notes that the processes of joint attention, social exchange, and cooperative turn taking between caregiver and infant "create a world of shared meaning, empathic understanding and appropriate linking of one's own emotions with those of others that then generalize beyond the parent-child dyad" (p. 156). In sum, the emotional attunement between parent and baby is essentially the crucible

in which empathy and concern for others' well-being are forged.

Related to this early crucible as the foundation for empathy is that for the most part it is mothers whose attunement with their infant is evaluated. Indeed, women undertake the majority of nurturing and caring for others in close relationships. Zahn-Waxler and Robinson (1995) noted that girls are socialized to be attuned more to their relations with others and to feel responsible for others' well-being. When feeling responsible for others is conjoined with discomfort, guilt and empathy may merge together, particularly if family socialization patterns have led children to acquire an overgeneralized sense of responsibility for others' well-being. They argued that young girls are more likely to develop this pattern and consequently may become more "vulnerable to establishing beliefs about their over-responsibility, unworthiness, and blameworthiness for the problems of others" (Zahn-Waxler & Robinson, 1995, p. 165). Such self-attributions are evident in depression, and, by early adolescence, girls exceed boys in incidence of depression. It appears that a healthy dose of self-interest may inoculate young girls against such feelings, and a masculine sex-role orientation (regardless of one's gender) appears to protect against depression as it is associated with assertive self-interest (see also Ruble & Martin, 1998; Zahn-Waxler, 2000).

**Influence of Socialization.** A recent multi-method, multi-source study on how parents might influence their children's empathy was carried out by Strayer and Roberts (2004a) who found paths between parents' empathy and their children's empathy, but the relationship was mediated by children's anger. More specifically, empathic parents had children who were *less* angry and who also demonstrated more empathy. Parents who were low in empathy were also more controlling, and they subsequently had children who were more angry and less empathic. It was the child's anger and the parents' controlling disciplinary style and associated parenting practices that appeared to mediate the relationship between parent and child empathy.

This relationship between parental insensitivity and negative reactions toward their child and subsequent ineffective social behavior in the child was also substantiated by Snyder, Stoolmiller, Wilson, and Yamamoto (2003). In their observational study, they found that children's anger was associated with frequency of

parental behaviors (e.g., displays of anger, contempt, criticism, domineering, threats, stonewalling) shown toward the child. When the parents were unable to provide the child with sensitive and constructive ways to handle anger, their children tended to carry grudges and develop covert antisocial behavior (e.g., retaliation). The authors also found that the children displayed relatively less fear and sadness, and they suggested that a deficit in those more vulnerable feelings might also be associated with a deficit in empathy in these angry, belittled children. Their use of hazard analyses (essentially analyzing the "risk of recurrence" rates of children's anger displays during parent-child interaction as a function of parents' negative emotion) to infer the likelihood of subsequent emotional responses also constituted a methodological innovation in how to examine the mutually influencing effects of parent and child when in an immediate interaction.

Strayer and Roberts (2004b) also investigated more intensively how children's anger and aggression might be related to their empathy. They observed the play behavior of 5-year-olds and found that whereas empathy accounted for 18% of the variance in observed anger and aggression, it only accounted for 8% of the variance in prosocial behavior. Thus, empathic children are less angry, less verbally and physically aggressive, and were involved in fewer object struggles with their peers. In terms of social effectiveness and the ability to be empathically engaged, this study suggests that more harmonious relationships with others are clearly associated with higher levels of empathy.

In terms of sympathy, modeling by the parents appears to be an important factor in children showing more sympathy (see review by Eisenberg, Fabes, Carlo, & Karbon., 1992). Adult women who report empathy after watching distressing films also describe their families of origin in ways that indicate that positive emotions and sympathetic and vulnerable feelings were freely expressed. Along similar lines, in the investigation undertaken by Eisenberg, Fabes, Schaller, Carlo, and Miller (1991), parents' attitudes were assessed using the Parental Attitude toward Children's Expressiveness Scale (PACES; Saarni, 1990), which was modified for use with preschoolers. Parents of children who reported restrictive attitudes toward their children's emotional displays had children who seemed more inclined to experience personal distress rather than sympathetic concern when describing their reaction to another's

distress. This effect was more noticeable when the parents espoused controlling beliefs about their children's emotional displays, even when the emotional displays simply expressed the child's own vulnerable feelings (e.g., sadness, anxiety) as opposed to showing one's genuine feelings without regard for whether they could also hurt someone else's feelings (e.g., showing annoyance toward a well-intentioned gift giver). Parents who restricted their children's emotional displays in circumstances where others' feelings might be hurt—but not when their children expressed vulnerable feelings—appeared to have more sympathy-oriented children. The most impacted children appeared to be boys of mothers who endorsed controlling attitudes about their sons' display of emotions in situations where only self-related vulnerable feelings were involved; these boys were the most likely to show personal distress reactions.

Recently, Valiente et al. (2004) examined the relations between parental expressive style, children's ability to access effortful control, and the children's likelihood of responding with empathy. They found that children prone to personal distress were more likely to have low effortful control; in contrast, children who could access greater effortful control were more likely to respond with sympathy rather than with personal distress. Several complex relationships were found with parental expressive style, and the authors concluded that a high level of parental negative expressive style was associated with their children's likelihood of experiencing personal distress, irrespective of their children's attempts at effortful control. We infer from this research that parental derogation (as indexed here by a negative expressive style) undermines children's abilities to regulate their empathic response such that they experience personal distress rather than being able to invoke effortful control and transform their empathy into sympathetic behavior toward a distressed victim. Research by Gottman et al. (1997) yielded similar results: Parental derogation of the child ill prepares the child for harmonious peer relationships or, for that matter, academic achievement. Indeed, Raver (2002) in a Social Policy Report for the Society for Research on Child Development also called for intervention at the levels of family, community, and child-care setting to facilitate young children's emotional development so that their school readiness would be enhanced.

A pair of longitudinal studies that examined empathy and family influence are worth mentioning. Eisen-

berg and McNalley (1993) examined relations between mothers' child-rearing practices over an 8-year period and their adolescents' (age 15 to 16) perspective taking and vicariously induced emotion. They found that mothers who expressed positive emotions and minimal negative affect with their children were more likely to have sympathetic daughters and sons who scored lower in personal distress. Warm maternal communication was also associated with increased perspective taking in youth of both genders. However, mothers' own sympathy was not significantly related to their adolescents' sympathy.

The last study was undertaken by Koestner, Franz, and Weinberger (1990) with adults who had been participants in a longitudinal study since their preschool years. Empathic concern at age 31 was most strongly related to the following variables assessed when the participants were 5 years old: Fathers' involvement in child care, mothers' tolerance of their children's dependency, inhibition of children's aggression, and satisfaction with the role of mother (fathers had not been asked about their satisfaction with their parental role, but their high involvement with their children would seem to show that they were). The authors' conclusion is worth quoting: "children are most likely to grow up to be empathically concerned adults when both of their parents enjoyed being involved with them and when their affiliative and aggressive needs were differentially responded to, with the former being permitted and encouraged and the latter inhibited" (p. 714).

### *Summary*

Empathy and its derivative, sympathy, are critical to emotional communication; indeed, responsiveness to others' emotions is critical to human evolution (e.g., Cosmides & Tooby, 2000). The development of empathy such that it becomes linked with altruistic, prosocial behavior obviously promotes the well-being of those who need support or help, but it also facilitates the well-being of individuals who respond sympathetically. The preceding research suggests that such individuals enjoy more favorable relations with their peers, may themselves be more effective parents, and are able to regulate their emotional arousal such that they can effectively intervene to assist another. The reviewed research also indicates that complex, often indirect, relationships exist between parenting behaviors and children's empathic, sympathetic, and prosocial behavior toward others.

### Social Effectiveness and Skill 5: Skill in Differentiating Internal Emotional Experience from External Emotional Expression

Whether a person is trying to protect his or her vulnerability, enhance some advantage to her- or himself, or promote the well-being of another about whom they care, being able to monitor individual emotional-expressive behavior and action tendencies strategically is adaptive, and children learn to do so with increasing finesse as they mature (Saarni, 1989, 1999). In the following discussion, this discrepancy between internal emotional state and external emotional expression is referred to as emotional dissemblance. The term *emotion management* will also be used to refer to children's regulating their experience of emotion by monitoring their expressive behavior. This last topic is also a significant link to the discussion of Skill 6 involving children's coping with aversive emotions in social contexts.

By the preschool years, if not earlier, young children learn how to introduce disparities between their internal emotional state and their external expressive behavior. Such discrepancies indicate that young children have begun to differentiate their inner emotional experience from what they express in their behavior—especially to others. Perhaps the earliest form of this differentiation between internal state and external expression is the exaggeration of emotional-expressive behavior to gain someone's attention (a trivial injury becomes the occasion to howl loudly and solicit comfort and attention). An early observational study by Blurton-Jones (1967) reported that children, ages 3 to 4, in a free-play situation were more likely to cry after injuring themselves if they noticed a caregiver looking at them; they were less likely to cry if they thought they were unattended. Minimization may be the next to appear; it consists of dampening the intensity of emotional-expressive behavior, despite feeling otherwise. Neutralization describes the adoption of a "poker face," but it is probably relatively difficult to carry off, and, indeed, in early research by Ekman and Friesen (1975) it was found that substitution of another expression that differs from what one genuinely feels is probably a more successful strategy (e.g., smiling despite feeling anxious).

Children learn to manage their expressive behavior by taking into account relationship dimensions such as closeness of relationship, power or status similarity/difference, and the degree to which they are exposed (e.g., public versus private situations). Gottman and his col-

leagues (1997) demonstrated in their longitudinal research that children who were most effective with their peers knew how to regulate their external expressive behavior, but we contend that children believe that it is important to find an adaptive balance between self-presentation, which may require dissemblance as well as genuine display of emotion. An early interview study indicated that school-age children believed that the display of genuine emotion was as regulated as the display of dissembled emotion (Saarni, 1989b). In older age groups, children nominated more reasons or occasions for when it would be appropriate to express one's genuine emotional response. In descending order of frequency, the categories for when it would be appropriate to express one's genuine emotional response were: (a) if the emotion was very intense; (b) if one was sick, injured, or bleeding; (c) if one was with certain people, such as parents or friends (note the close relationship dimension here); (d) if special or unusual misfortunes occurred such as being in a fire; (e) if one was in a special setting that allowed for the display of genuine emotion, such as in an amusement park or while attending a horror movie; (f) if one was a young child; (g) if one was being scolded or had just been caught doing something wrong; and finally (h) if one had been unjustly accused, one should show how one felt about it.

The pattern of responses indicated that with increasing age children demonstrated increased flexibility in the deployment of emotional-expressive behavior, whether it was dissembled or genuine in display. Their expectations also suggest the implicit use of social scripts that take into account age status and relationships (items f and c, respectively), setting (item e), and implied lack of controllability (items a, b, and d). The last two categories (items g and h) suggest interesting relationship contexts that appear to be associated with children's recognition that their expressive behavior can influence the affective and cognitive states of those who are either scolding them or unjustly accusing them. That topic has little empirical research associated with it among older children—with several important exceptions (Fuchs & Thelen, 1988; Saarni, 1992; Shipman, Zeman, Nesin, & Fitzgerald, 2003). Research undertaken by Shipman and Zeman (2001) indicated that children do indeed have expectations that their emotional-expressive displays will be responded to supportively by others, especially parents or adult caregivers. Shipman et al. (2003) also found in their interview study that younger elementary school children

(7 years old) were more likely than older children (10 years old) to believe their expressive behaviors would be acceptable and would elicit support. Interestingly, in this research, which used vignettes as the vehicle for eliciting children's expectations, there was little difference whether the expressive behavior would be directed at mother, father, or best friend (although for the latter, children thought there might be more tolerance of aggressive displays).

### *Components of Emotional Dissemblance*

As summarized some time ago by Shennum and Bugental (1982), children gradually acquire *knowledge* about when, where, with whom, and how to express behaviorally their emotional reactions. They also need to have the *ability to control* the skeletal muscles involved in emotional-expressive behavior. They need to have the *motivation* to manage their emotional-expressive behavior in the appropriate situations. They also need to have reached a certain complexity of *cognitive representation*. We address each of these components in turn as they are reflected in recent research.

**Knowledge.** As noted earlier, children can readily nominate reasons for showing their genuine emotions to others, and indeed, across all ages, the most common reason cited for when genuine emotions would be expressed was if they were experienced as very intense (i.e., and thus less controllable; Saarni, 1979). School-age children can also nominate reasons for dissembling their expressive behavior, and that early study found that the majority of their reasons referred to wanting to avoid embarrassment or derision from others for revealing vulnerable emotions such as hurt or fear. Getting attention, making someone feel sorry for you, and getting help were also among the reasons mentioned for dissembling emotional expressive behavior (cf. Shipman et al., 2003). The older children were more likely to make reference to the degree of affiliation with an interactant, status differences, and controllability of both emotion and circumstances as contextual qualities that affected the genuine or dissembled display of emotion.

Other research has elaborated on these contextual influences in children's understanding of emotional-expressive behavioral management. For example, Underwood, Coie, and Herbsman (1992) found that elementary school children reported that they would be more likely to mask angry expressive behavior with their teachers than with their peers, thus recognizing

the salience of authority and possible risk if anger were to be directly expressed. Underwood (1996) also found that age differences in reporting dissemblance of emotion varied according to the emotion felt, with older children reporting greater likelihood of masking disappointment and blunting of very positive affect and younger children (8 years) more likely to mask anger. Across emotion, girls expected more negative reactions from peers to "mismanaged" emotional-expressive behavior than boys did, and children generally expected less positive peer response to "extremely honest" emotional displays (see also Saarni, 1988).

Parker and her colleagues (2001) examined children's knowledge of dissemblance strategies for anger in a hypothetical vignette about unfair treatment of one child by another and then compared their conceptual knowledge with their actual behavior in playing a competitive game with an unfamiliar peer confederate in which they were unfairly made to lose and the confederate overtly cheated. Relative to the vignette, children's strategies for dissembling angry expressive behavior were coded as behavioral (e.g., leave the situation, cover their face) or as cognitive (e.g., focus their mind on a happier event). The investigators also monitored whether children who had been nominated by their peers as aggression prone would behave any differently during the unfair game. Their results were complex, but essentially what they found was that children reported they would feel angrier, be more likely to express their anger, and be less likely to dissemble their anger in the hypothetical story in contrast to what they reported and expressed after having lost to the cheating confederate in the unfair game (similar pattern of results obtained by R. Casey, 1993). The children rated as aggression prone did report feeling angrier and their displays were more intense and lasted longer during the unfair game, but otherwise there was little to distinguish them from the nonaggressive children (i.e., both groups of children had similar understanding of dissemblance strategies).

Another interesting study examined children's ability to conceptualize the difference between internal emotion state and facial expression and how this conceptualization might be related to their *miniaturization* of emotional expression when alone versus when engaged interpersonally (Holodynski, 2004). Children between the ages of 6 and 8 were exposed to a "slot machine" that dispensed a package of candy or an empty package. They coped with the capricious slot machine in two conditions: (1) alone or (2) accompanied by an adult

research assistant. They were also extensively interviewed about their understanding of discrimination between expression and feeling, with a summary score denoting the degree of conceptual complexity in making this discrimination. Holodynski argued that the miniaturization of expressive behavior when alone emerges at around 6 years of age as children learn to self-regulate, similar to the earlier transition from private speech to internal speech serving to facilitate self-regulation (Berk, 1992). Indeed, his results revealed that his oldest age group (8 years old) reliably reduced the intensity of their expressions when alone as opposed to being with the research assistant; the 6-year-olds revealed similarly intense expressions across both conditions. Likewise, he found a significant and positive correlation between complexity of conceptualization about emotion state and expression and subsequent miniaturization of expressive behavior when alone and coping with the capricious slot machine. This research is very thought provoking, because Holodynski may have provided the explanation for some of the discrepancies found in research on children's expression of emotion when faced with different emotion-eliciting circumstances. As noted earlier, the degree of exposure, alone or engaged with others, affects emotional-expressive behavior in ways that can evoke expression amplification when with supportive others (Holodynski's study) or expressive dissemblance when faced with disagreeable confederates (the Parker et al. study, 2001; see also Underwood, Hurley, Johanson, & Mosley, 1999).

#### **Ability to Implement Emotional Dissemblance.**

Control of skeletal muscles, especially in the face, is critical to being able to modify one's emotional-expressive behavior and thus dissemble the outward expression of one's emotional response. Children become capable of this modification voluntarily at a young age (2 to 3 years), and it is readily apparent in their pretend play; for example, they mimic postures, expressions, vocal qualities, and the like of assorted fantasy characters. However, when it comes to deliberately adopting emotional expressions, posing of facial expressions proves to be difficult, especially negatively toned expressions (e.g., M. Lewis, Sullivan, & Vasen, 1987). The difficulty in posing fear, disgust, sadness, and the like may be due to the fairly consistent socialization pressure in our culture to inhibit negative displays of emotion. As Lewis et al. point out, when asked to produce a scared face (i.e., looking afraid), the young children in their

sample produced scary faces instead (as though getting ready for Halloween).

A more recent study examined children's ability to control their facial muscles when asked to suppress expressions of pleasure, which was elicited by a funny routine acted out by a clown (Ceschi & Scherer, 2003). Seven- and 10-year-olds were interviewed about their knowledge of emotional expression control strategies and then divided into two groups: one group saw the clown routines without any instruction to suppress their expression and the second group were asked to try to conceal their amusement during the clown routine. Both groups apparently found the routine fairly intensely amusing, and thus the second group's ability to suppress their mirth was limited. They were able to reduce the duration of their positive expressive behaviors, but not the frequency. They did try to use control behaviors such as pressing their lips together and showed more "false smiles." Noteworthy is that the children were not alone: both the clown and the experimenter were present (cf. Holodynski's research, 2004). There was no noteworthy age difference in expressive behavior in the two groups or in the knowledge of emotion control strategies. The knowledge of emotion control strategies also did not predict either frequency or duration of expressive control strategies in the suppression group. However, Ceschi and Scherer did confirm that those control strategies that were used (false smiling, lip press, lip suck/pucker) were all in the lower part of the face, and muscle contractions in the upper part of the face and around the eyes were not influenced by the suppression condition. They also suggested that evaluating children's knowledge of emotion control strategies might be better done by having them engage in a recognition task rather than having to freely produce or nominate their control strategies.

**Motivation.** One of us has investigated children's knowledge of how to manage emotional-expressive behavior and their expectations about what motivated story characters to undertake such management strategies (Saarni, 1979). When the children were asked to explain why the story character's emotional reaction had not been genuinely expressed, four broad categories of motivation were apparent in their responses. These four motivation categories are elaborated as follows:

1. Avoidance of negative situational outcomes or enhancement of positive situational outcomes: This com-

mon motive is well illustrated in a study by Davis (1995). She had children play a game in which a desirable prize and an undesirable one were placed in two boxes, visible only to the child. The children were told to deceive the experimenter by pretending to like both prizes, and if they succeeded in “tricking” the experimenter to believe they really liked both, they would be able to keep both prizes. If they did not succeed, then the experimenter took both prizes. Thus, for the children to get the attractive prize, they had to persuasively manage their expressive behavior so as to look positive for both attractive and unattractive prizes. The results showed that the girls were more successful at suppressing negative expressive behaviors toward the unattractive prize than the boys. The girls also revealed a greater number of social monitoring behaviors (e.g., rapid glancing at the experimenter) as well as tension behaviors (e.g., touching one’s face), and they appeared to monitor the social exchange more closely than the boys, which may have facilitated their expression management. Davis concludes that girls do have more ability in managing the expression of their negative emotions, and she suggests that individual differences (e.g., temperament) may interact with sex-role socialization to yield the gender pattern she observed.

**2. Protection of one’s self-esteem:** Meerum Terwogt and Olthof (1989) found that boys were reluctant to express fear because they worried they would be viewed as cowards by their peers. Fuchs and Thelen (1988) also reported that boys were loathe to reveal their sadness to their fathers but might consider doing so with their mothers. Maintenance of self-image appeared to be the chief motive for these boys and emotion management was sought by adoption of a stoic “emotional front.”

DePaulo (1991) reviewed the earlier literature on what is known about the development of self-presentation, emphasizing nonverbal behavior. One point she made was that as children grow older, more of their peers and adult networks hold them accountable for being able to regulate and manage their emotional-expressive behavior. Thus, there is a continual reinforcement of motivation to manage how one presents oneself to others. There is a great need for further research on how children’s needs to self-protect or to enhance their self-image in the eyes of others are linked to emotion dissemblance strategies and self-presentation, but this topic, relative to children, has been underresearched in recent years. More common is research on lying and deception (e.g., Talwar & Lee, 2002). Anderson, Ansfield, and DePaulo (1999) have

provided a review of deception and its links to self-presentation in relationships; although their review focuses on adults, it is suggestive for how research could be extended to children and youth and framed in a developmental inquiry.

**3. Maintenance or enhancement of relationships and concern for others’ well-being:** As an illustration of this last motive for emotional dissemblance, von Salisch (1991, 1996) probed how children actually regulated a relationship by monitoring what they expressed. She developed a computer game that was rigged: The computer was cast as the “opponent” and two children were to play as a team. If the airplane “crashed” on the screen, it meant the children had lost; however, its demise was random but appeared to the children to have been caused by one of them. The participating children were 11-years old, and she was able to have the pairs consist of either best friends or of casual acquaintances. In her analyses of the actual conflict episodes, the most frequent expressive behavior was smiling, followed by signs of tension, then contempt, and last by anger (only 3% of the expressions). In many cases, the children also verbalized reproaches about the “crash,” but then accompanied the reproach by smiling. With close friends, the incidence of smiling was even greater than with acquaintances, and among girls in close friend pairs, genuine smiles were especially notable in their reciprocity, even through these girls more frequently verbalized their negative feelings about their friend’s game-playing skill (or ostensible lack thereof). The boys in close friendship pairs tended to verbalize less, but they showed more signs of tension than any other group. In essence, these preadolescent boys and girls used their smiles to reassure their friend that the relationship was still on firm ground, despite their reproaching their friend for their “incompetence” in making them lose the game against the computer. Expressive behavior has among its functions more than simply the display of emotion; it is also a social message. What von Salisch’s research shows us is that children are adept at using this social function of emotional-expressive behavior to manage their relationships, and they do so in a discriminating fashion.

**4. Observance of norms and conventions:** These are the cultural display rules that provide us with consensually agreed on scripts for how to manage our emotions. A couple of 9- to 10-year-old children’s responses illustrate their notions of what are norms for emotional dissemblance: “You should smile when you get a gift, even

if you don't like it much," "You shouldn't yell at a grown-up," and "you should apologize, even though you don't feel like it." It is probably noteworthy that cultural display rules often have "shoulds" associated with them (e.g., Gnepp & Hess, 1986). At least a couple of factors might account for why children do not consistently perform cultural display rule scripts, despite knowing them: First, the social stakes may not be sufficiently high for them to feel motivated to do so; second, their distressed, hurt, or angry emotional responses may be experienced as too intense to allow for emotional dissemblance. As mentioned earlier (Saarni, 1989b), intensity of emotional response was cited by school-age children as the chief reason for when emotions would be genuinely expressed. Research by Garner and Power (1996) also indicated that emotional intensity as a temperament factor may influence the likelihood of adopting emotional dissemblance in certain situations.

These four categories for why we may be motivated to dissemble the expression of our emotional responses are not necessarily exhaustive nor are they mutually exclusive, but they all have one significant feature in common: They are concerned with interpersonal consequences, and it is the varying nature of these social consequences that yields the differences among motives. Even the self-esteem motive for dissemblance does not occur in a social vacuum, for the self is embedded in a history of social relationships.

**Cognitive Representation.** As suggested by Josephs's (1994) research, a pragmatic or implicit knowledge of emotional dissemblance is likely to precede an articulated and verbalized understanding of expressive dissimulation. In the "theory of mind" literature, a large body of research has emerged concerned with children's understanding of real versus apparent phenomena, and this distinction has been applied to inner emotional state as "real" and external expressive behavior as "apparent." By school entry, children generally understand that how one looks on one's face is not necessarily how one feels on the inside (e.g., Harris, 1989; Harris & Gross, 1988). Thus, relatively young children understand that the appearance of one's facial expression can be misleading about the actual emotional state experienced. By age 6, many children can provide justifications for how appearances can conceal reality, in this case, the genuine emotion felt by an individual.

Harris and Gross (1988) examined young children's rationales for why story characters would conceal their emotions by adopting misleading facial expressions. A significant number of the 6-year-olds interviewed gave very complex justifications that included describing the intent to conceal their feelings and to mislead another to believe something other than what was really being emotionally experienced (e.g., "she didn't want her sister to know that she was sad about not going to the party"). Children younger than age 6 can readily adopt pretend facial expressions, but they are not likely to be able to articulate the embedded relationships involved in deliberate emotional dissemblance. Developmental research that illustrates children's understanding of false beliefs and social perspective taking and the relation between these two cognitive markers and coordinated communication with a playmate was undertaken by Slomkowski and Dunn (1996). They suggested that these cognitive aptitudes are indicative of children's abilities "to read each other" as they regulate and coordinate their conversations and behavior with their peers. Harris (1998) also reviewed the relevant literature on emotional appraisal as it relates to young children's pretend play, and one of the features that he emphasized was young children's attributions of *agency* to make-believe others and their appraisal of fictional material in ways that induces emotional experience. In his words, "the creation and consumption of fictional worlds is a pervasive human enterprise" (Harris, p. 353) and is sustained by our engagement with emotional experiences derived by our appraisal of imaginary events. By the 2nd and 3rd year of life, normal children show this capacity for imagination and fantasy play, thus indicating that critical cognitive skills are developing that also become part of their cognitive repertoire for representing what is real and what may be dissembled and being able to attribute agency and emotionally significant meaning to both the genuine emotion and the dissembled expression.

### Summary

A person's ability to maneuver emotional-expressive behavior according to interpersonal contexts and emotional responses gives them a rich repertoire of communicative behavior. The intermingling of emotional experience and social interaction is also evident in children's acquisition of emotional dissemblance and emotion management strategies. There are highly adaptive and functional reasons for humans to be able to dissoci-

ate their emotional-expressive behavior from their internally felt, subjective emotional experience: One is being able to have reasonably satisfactory relationships with others; another is to be able to get others to provide support and validation for oneself; still another is to exert one's influence on others—as in impression management, persuasive communication, and the like. A reason that children are particularly likely to endorse is that it helps one to avoid getting into trouble, and last, the omnipresent self-appraisal system has its antennae out to try to create experiences that strengthen or protect the self rather than undermine it. Coping effectively with interpersonal conflict and other situational stressors has much to do with how we regulate both our subjective experience of emotion as well as with what we communicate expressively to others.

### **Social Effectiveness and Skill 6: Skill in Adaptive Coping with Aversive Emotions and Distressing Circumstances**

Accumulated research indicates that adaptive coping requires at least three conditions to be met: (1) regulation of one's emotional arousal, (2) adequate appraisal of the problematic situation and what is realistically under one's control, and (3) resolution that yields a sense of mastery and/or resilience (e.g., Aldwin, 1994; Compas, Connor, Saltzman, Thomsen, & Wadsworth, 1999; Wolchik & Sandler, 1997). We address each of these three conditions relative to how they contribute to social effectiveness. In this section, we also briefly comment on research that raises interesting questions about socialization influence and context effects on the development of adaptive coping.

### ***Emotion Regulation***

The issues surrounding emotion regulation recur in this chapter for good reason: The topic is theoretically rich with possibilities for understanding emotion processes and for clinical and educational application. We addressed previously some of the contemporary research on emotion regulation and implications for social competence, and we elaborate further some of the current research in this area. The reader is referred to the special issue on emotion regulation that appeared in *Child Development* (vol. 75, 2004) for thoughtful discussions on how to conceptualize emotion regulation, and, in par-

ticular, the distinction should be made between emotion regulating something else (e.g., another's social response to the self) and emotion itself being regulated (e.g., self-soothing). As noted earlier, emotion regulation is dynamically integral to emotion generation itself, and the complexity of feedback in emotion processes will occupy researchers for some time to come. However, for the purposes of linking emotion regulation with social effectiveness, we emphasize that being able to modulate one's degree of emotional arousal facilitates one's coping with an environmental stressor or conflict. This does not mean simple inhibition; amplification of emotional experience and expressive display may also be strategically effective in a particular situation.

Research on children's emotion regulation may take into account:

- Temperamental reactivity (see Rothbart & Bates, 1998)
- Processes that involve deployment of attention (including effortful control as operationally defined by Eisenberg and colleagues; e.g., Valiente et al., 2003)
- Components of emotion (physiological, expressive, and subjective experience)
- Approach/avoidance tendencies, whereby the latter is understood to include individual differences in inhibition and "niche picking" (i.e., seeking out situations in which desired emotional experiences are likely and avoiding those situations in which aversive emotions are likely to be evoked; see Campos et al., 2004)

Brenner and Salovey's (1997) definition of emotion regulation combines these elements: It is the relative capacity to manage one's emotional reactivity (including intensity and duration of arousal) such that alterations in one's physiological-biochemical system, behavioral-expressive system, and experiential-cognitive system are affected. We also add the emphasis of the relational and functionalist perspective used in this chapter such that emotional regulatory processes should be understood as occurring in contexts construed as personally meaningful to the individual. Finally, *optimal* emotion regulation *over time* should also contribute to a sense of well-being or emotional equilibrium, a sense of self-efficacy, and a sense of connectedness to others to the extent that effective emotion regulation facilitates constructive problem-solving strategies and appropriate appraisal of social contexts.

### *Development of Emotion Regulation and Coping*

Thompson et al. (2003) reviewed the maturing emotion regulatory capacities of the infant's nervous system and concluded that during the 1st year, excitatory and inhibitory processes are stabilized so that infants gradually develop a greater ability to inhibit or minimize the intensity and duration of emotional reactions, and at the same time they also acquire a greater diversity of emotional responses. Examples of early regulation of emotional arousal are young infants' soothing themselves through sucking or withdrawal from excessive stimulation, but equally critical is that caregivers assist infants in learning how to regulate their arousal through attending to their infants' distress and providing comfort. Caregivers also regulate the situations that infants are exposed to so that infants' emotional experience is moderated. Thompson has also argued that parents' emotion regulatory interventions may, over time, contribute significantly to their children's style of emotion regulation. His illustration is that of parents who wait until their child's upset has escalated to high levels before they intervene. The effect is that they reinforce their child's rapid rise time of distress and high intensity of responding, which in turn makes it harder for the parents to soothe their infant due to his or her high level of emotional arousal.

By toddlerhood, we can more readily see how emotion regulation plays a *mediating* role between evocative stressors and how young children cope with a particular taxing situation: By regulating their emotional arousal, they can delay their reaction such that they may be able to adopt a different sort of coping behavior than simply fleeing or lashing out at the stressor (e.g., by age 2 children can approach a peer or small animal). However, emotion regulation, viewed from the standpoint of management of emotional-expressive behavior, might in other contexts play a *moderating* role between the interpersonal circumstances one faces and one's motives for a social outcome. For example, sustaining the duration of the expressive display of happiness (a genuine smile) or amplifying one's smile influences the likelihood that one's interactant will respond positively in kind. Managing one's emotional-expressive behavior can be used to increase or decrease the sorts of social interaction one desires with another (e.g., see the discussion of emotion communication in interpersonal negotiation in Saarni & Buckley, 2002; for preschool examples, see Barrett, 1997). Mutually regulating behaviors that involve the exchange of

emotional-expressive signals has a long history of research, for the most part with infants and their caregivers (e.g., Gianino & Tronick, 1988; Trevarthen, 1993). Less research has been undertaken with school-age children, but a number of studies suggest that children are well aware that their expressive displays (self-presentation) influence their peers' subsequent responses to them (e.g., Carlson Jones, Abbey, & Cumberland, 1998; Gottman, Guralnick, Wilson, Swanson, & Murray, 1997; Halberstadt et al., 2001; Hubbard, 2001; Parker et al., 2001; Saarni & Weber, 1999; von Salisch, 1996; Zeman & Shipman, 1997).

### *The Influence of Temperament*

The notion of temperament is a multifaceted one and fraught with many definitional and measurement problems (e.g., Rothbart & Bates, 1998, and Chapter 3, this *Handbook*, this volume), but it is a useful construct for thinking about what are some of the influences on how children develop different styles of emotion regulation and coping. Temperament may be viewed as a collection of dispositions that characterize the individual's style in responding to environmental change (or the lack thereof). These dispositions include reactivity, arousability, and temporal dimensions such as latency of response. Some theorists also include as temperamental traits sociability, approach/avoidance tendencies, and degree of attentional control. Most theorists working with temperament regard these dispositions as applicable to both emotional and nonemotional behavior, and many theorists contend that temperamental dispositions have a biophysiological contribution that is influenced by one's genetic makeup.

When we look at temperament as applied to how a person responds emotionally to evocative stimulation, we can examine the intensity of emotional response (both negative and positive valence), the threshold of arousal of emotional response, the duration (and other temporal aspects) of the emotional response, and even the proclivity for what sort of hedonic tone of emotional response is generated (i.e., negative versus positive reactions to change). The construct emotionality has typically been used to refer to temperament's influence on emotional experience; "high" emotionality is often assumed to refer to high intensity of emotional reaction, frequently combined with a negative hedonic tone (but see Strelau, 1987, for a review of six different definitions of emotionality, some of which do not associate a negative hedonic tone with high levels of emotional intensity of response).

Although temperament is a general proclivity in an individual to approach or withdraw from a novel situation and to react strongly or not to a novel situation, temperament is *not* the same as the emotional response elicited in the individual that requires regulation, rather temperament can be thought of as the background on which the emotion plays out. Emotions are also highly contextualized and dependent on the individual's goals and motives of the moment (Campos et al., 1994; M. Lewis, 1997); their nuances and variety are captured by the huge number of emotion-related words in the English language (White, 2000).

Metaphorically, temperament is rather like a season of the year, but emotions are the mercurial weather conditions that shift from day to day, demanding adjustment and accommodation on a frequent basis. In this metaphor, the season provides constraints on the daily weather, just as temperament may provide some degree of limitation on the experience of emotional response. Temperament influences emotion regulation as in figure-ground relationships; it is the ground, but emotions and their regulation are the figure. Thus, the child who is relatively inhibited in temperament (prone to withdrawal from novel situations) and who tends to react strongly to novel situations (less likely to modulate intensity) may be the child who will more often experience emotions of anxiety, fear, and shame. But this same child may also respond to familiar situations with pleasure, sympathy, and caring. Indeed, we find that the more inhibited child is also the one who is more compliant with parents and internalizes a moral conscience more readily than those young children characterized as more bold and active (reviewed in Kochanska & Thompson, 1997).

Using temperament in this fairly global fashion as having to do with how we dispositionally tend to modulate our emotional reactions, we can examine how individual differences in temperament may influence coping efficacy. This approach was taken by Eisenberg and her colleagues in several different research projects on preschoolers' coping efficacy relative to their social functioning. In one investigation, Eisenberg et al. (1993) looked at 4- to 6-year-old children whose temperament-influenced emotional intensity level was rated by both their mothers and their teachers and then examined by the children's social competence (teacher ratings) and sociometric ratings (peer popularity). They also evaluated the children's coping strategies by having the teachers and mothers rate the children's likelihood of using assorted coping strategies in hypo-

thetical situations. Among their very complex results were that greater social competence of boys (but not girls) could be predicted by their displaying constructive coping strategies (e.g., problem solving) and not displaying excessive negative emotion. For girls, social competence could be predicted from their use of avoidant coping strategies rather than by their engaging in acting out or conflict-escalating behaviors. For both boys and girls, high emotional intensity was associated with lower levels of constructive coping and with lower levels of attentional control (shifting and distractable attention versus focused attention, as assessed by teachers). In short, those 4- to 6-year-olds who frequently showed high intensity negative emotions were more likely to be distractable and to demonstrate less constructive coping. They were also regarded by their teachers as less socially mature and by their peers as less attractive as playmates.

In a second study with the same 4- to 6-year-olds, Eisenberg, Fabes, Nyman, Bernzweig, and Pinuelas (1994) investigated relations among temperament (more specifically, emotionality, operationally defined as intensity of reaction and negative tone of emotion, and their ability to control their attention), coping skills, and their management of anger with their peers. The pattern of their findings was complex with some results occurring only for teacher-rated behaviors but not for mother-rated behaviors. Gender of the child was again a variable that affected some of the patterning of results. Overall, children whose temperament was characterized by low levels of emotionality, displayed reactions that were socially desirable—the children used nonhostile verbal strategies to try to deal with the anger provocation. This pattern was stronger for boys than girls, and boys who used socially desirable and constructive responses to anger were also rated as higher in attentional control. Girls who tended to escape the situation when angered were viewed by teachers as socially skilled—the girls' avoidance of anger was apparently seen as not contributing to an escalation of conflict, a desirable outcome from teachers' standpoint. Although the authors were not studying sex-role socialization, it is noteworthy that teachers' approval of sex-typed behaviors (e.g., the girls' avoidance of conflict), even at this relatively young age, may be influencing children's subsequent style of coping with such gender role-laden emotions as anger.

Although the construct of temperament allows us to consider what children might inherently bring with them as they seek to cope with stressful circumstances, it is

unlikely that temperament solely affects how constructive one's coping style is. The social environment has also been modulating and giving meaning to the young child's emotional behavior all along, which includes such temperamental dimensions as intensity, hedonic tone, temporal factors, and the like. Cultures that value expressive restraint might ascribe rather different meanings to, for example, intensity of emotional response, than cultures that do not have such an orientation. In the end, adequacy of coping will be best determined by whether individuals experience themselves as efficacious in the sociocultural context in which they find themselves.

### ***Effective and Ineffective Coping and Emotion Regulation with Peers and Family***

We find that children who are "good copers" can modulate their emotions such that they can continue to attend to what is going on socially (e.g., Gottman et al., 1997) and that they can avoid negative emotional escalation by circumventing problematic situations (Eisenberg et al., 1993, 2004). Research has also shown that children who enjoy substantial family support and moderate structure have a larger repertoire of coping strategies (Hardy, Power, & Jaedicke, 1993), and it makes sense that a broader repertoire of coping strategies permits adaptation to a wider variety of emotion-provoking circumstances.

One provocative study by Ramsden and Hubbard (2002) described how parental coaching might affect children's emotion regulation (as measured by the Emotion Regulation Checklist; Shields & Cicchetti, 1997), which in turn was hypothesized to predict children's aggression at school. Their coding of parental coaching of emotion included three dimensions: (1) acceptance of child's emotion, (2) awareness of child's emotion, and (3) instruction about emotion to the child. Their results indicated that the most robust link to aggression was the child's own emotion regulation rating, but parental acceptance of child emotion was positively related to higher emotion regulation, and the overall degree of negative expressivity in the family (as measured by the Family Expressiveness Questionnaire; Halberstadt, 1986) influenced the child's emotion regulation rating in a negative way. Thus, family emotion processes, such as acceptance of children's emotion, and the emotional "climate" of the family, in this case, negative emotional expressivity,

may indirectly affect children's relations with peers, but they do so by influencing children's emotion regulation ability.

Another study also examined maternal self-reported acceptance or control of their children's emotional expressiveness as it related to their children's attachment status and their emotion regulation in a frustrating game (Beat the Bell). Berlin and Cassidy (2003) modified the Parent Attitude toward Child Expressiveness Scale (Saarni, 1985, 1990) for use with mothers of preschoolers, who were participants in a longitudinal study. As infants, the children had been classified in the Strange Situation as securely attached, insecure-avoidant, or insecure-anxious. Their results indicated that children with insecure-avoidant attachment classifications were more likely to suppress their anger and not share their sadness in the frustrating game with their mothers, and their mothers reported that they were more controlling of their children's emotional expressivity. Children with an insecure-anxious attachment had mothers who reported significantly less control of their children's emotional expressivity. Mothers of securely attached children were moderate in both their acceptance and control of their children's emotional expressivity. Interestingly, no significant relations were found between attachment classification and children's emotion regulation during the frustrating Beat the Bell game. The authors speculated that this particular game may not have tapped into the emotion regulation abilities of children that are associated with earlier infant-mother attachment.

Peer interaction has also been studied relative to emotion regulation and coping. As an illustration, Wilton, Craig, and Pepler's (2000) research on *victims* of bullies determined that there appeared to be two prototypical coping styles when accosted by a bully in the classroom. The first coping style consisted of a cluster of behaviors that escalated the bullying episode: aggressive reactivity, expressive displays of anger, contempt, interest, and joy, and an emotion regulation disposition to high intensity arousal of negative affect. This cluster was found in 43% of the bullying episodes.

The second coping style was more oriented toward problem solving and tended to de-escalate the bullying episode. Fifty-two percent of the bullying episodes fell in this second group. This cluster was subdivided into two further patterns, which the authors referred to as the passive problem-solving approach (84%) and the ac-

tive problem-solving approach (only 16%). Both patterns yielded either resolution or de-escalation of the bullying, but with rather different outcomes: For the passive problem solvers, there was essentially capitulation to the bully or avoidance. The authors inferred that such victims were primarily reacting with anxiety and sadness. The authors surmised that this submissive stance would invite further bullying because the bully gets his or her way. As for the active problem solvers, they responded assertively and the bullying episodes were resolved. What is unknown is whether these children effectively reduced their being threatened by the classroom bullies over time. Last, the authors examined same gender and cross-gender bully victim interactions and found no differences in the prevalence of these two general patterns in victim response. Given the recent attention to girls' social and relational aggression (e.g., Underwood, 2003), we would be very interested in seeing observational research that looks at coping styles of the victims who are targeted by girls (and boys) for relational aggression scapegoating.

Research that links coping and emotion regulation with relationships among children and youth needs to address the influence of context, for example, which emotion is elicited under what sort of circumstances and in what sort of relationship. Much of the existing research is also based on hypothetical vignettes or on adult ratings of children's coping. Interestingly, in a recent study that did compare observations of children's anger management strategies with their verbal hypothetical reports, children showed less anger in the live situation compared to what they reported they would express in the hypothetical situation (Parker et al., 2001). Alternatively, Dearing, Hubbard, and Ramsden (2002) found that children nominated by their peers as aggressive were more likely to handle roughly the materials of a rigged game, yet their awareness or knowledge of anger regulation strategies was not directly related to aggressive status.

### ***Coping Strategies***

It is not always clear whether coping is different from emotion regulation. Some researchers refer to coping as an aspect of self-regulation because effortful or purposeful responses may be involved when one copes with a challenging situation (e.g., Compas, 1987). Other investigators use the terms *coping* and *emotion regulation* interchangeably (e.g., Brenner & Salovey, 1997), argu-

ing that both are implicated when children use available strategies to manage stressful encounters. Coping research has typically focused on *strategies* used to manage stress-provoking experience or aversive emotions that are evoked by challenging circumstances. From this perspective, coping follows emotion regulation in a temporal sense: first, a person modulates his or her emotional arousal and then seeks to resolve the stressful encounter to his or her benefit. However, given the dynamics of transactional and reciprocal relations in children's and youths' social worlds, it is unlikely that emotion regulation and coping are so simplistically distinguished according to a linear temporal path (e.g., Campos, Frankel, & Camras, 2004; Lazarus, 1999).

Coping researchers often develop new categories to which they assign various coping strategies: (a) Lazarus and Folkman (1984; Lazarus, 1999) proposed a basic dichotomy between emotion-focused coping and problem-focused coping, (b) others simply use approach (active) versus avoidance (passive) to characterize coping efforts, or (c) primary versus secondary control coping strategies (Marriage & Cummins, 2004), or (d) engagement versus disengagement coping (Ebata & Moos, 1991). Ayers and Sandler (1996) used factor analyses to distill a four-factor model of dispositional coping strategies that were also invariant across gender in a preadolescent sample; the factors were active, distraction, avoidant, and support-seeking. Sandstrom (2004) combined various approaches to the assessment of children's coping strategies into a new instrument for evaluating how children cope specifically with peer rejection. Her four coping categories for describing how children cope with this socially aversive context included:

1. Active coping (e.g., problem solving, assertiveness, getting help/support, constructive distraction, humor)
2. Aggressive coping (e.g., retaliation, teasing, arguing, getting angry, getting others to turn against them)
3. Denial coping (e.g., tell oneself it does not matter, do not care, forget about it, ignore)
4. Ruminative coping (e.g., worry about it, withdraw, wish it were not happening)

One of us (Saarni, 1997) examined children's beliefs about "best" and "worst" coping strategies. Five categories of coping strategies were compiled from the research literature, including problem solving, support-seeking (subdivided into solace-seeking and

help-seeking), distancing/avoiding, internalizing, and externalizing. The children (ages 6 to 12) read five different vignettes accompanied by schematic drawings and each vignette featured a negative emotion (e.g., fear, hurt, anger, shame, or sadness). All vignettes were ascertained to have moderate controllability of outcome, featured the protagonist as experiencing moderately intense emotions, concerned peer interaction, and were gender neutral. The results indicated that the younger children's justifications were less complex for which coping strategy was nominated as best or worst, but there were no age differences in the choice of what was thought to be the best or worst strategy. Overall, children preferred beneficial coping strategies such as problem solving and support-seeking, except for the vignette featuring "hurt feelings" for which children picked the distancing strategy as the "best." Aggressive externalizing coping responses were most often selected as the worst option across all emotion-category vignettes. For the most part, children's justifications for their best coping choices emphasized the social situational gains, and parallel losses were cited as justifications for the worst coping choice (e.g., externalizing responses).

More research is needed to determine if children know what generally adaptive coping strategies are, and what gets in the way when they do not employ them. One possibility is self-appraisal, attribution of responsibility for the outcome, and controllability (of one's own emotion and the situational aspects) all interact to influence how children and youth cope in taxing circumstances. To add to this complexity is the role that temperament, especially proneness to negative emotionality and attention deficits, plays in children's ability to recruit adaptive and socially effective coping strategies.

### *Developmental Change in Coping Strategies*

In examining what changes about coping strategies as children mature, we find that although use of situation-oriented problem solving is accessible throughout childhood, it becomes more targeted to the specific problem at hand, and children's repertoire of problem-solving strategies broadens with age (e.g., Altshuler & Ruble, 1989). With age, children's ability to consider a stressor from a number of different angles increases, thus older children can more readily consider different problem solutions relative to these different perspectives (Aldwin, 1994). They learn to recruit social support more effectively and subtly, for example, through effective self-

presentation strategies that garner social approval. They expand their capacity to tolerate aversive emotion to the degree that appraisal processes can be redirected and thus reduce distress (e.g., Band & Weisz, 1988). If appraisal indicates that control over the situational stressor or conflict is minimal or extremely risky, effective emotional regulation may also involve distraction, cognitively reframing the meaning of the difficult situation, and use of cognitive blunting or sensitizing (Miller & Green, 1985). Denial and dissociation appear to be less adaptive coping strategies in that emotions are split off from their eliciting context for short-term gain but at long-term expense (e.g., Fischer & Ayoub, 1993).

Last, perceived control over the stressful situation is relevant to how coping efforts are undertaken. As children mature, they become better able to distinguish uncontrollable stressors from controllable ones (Aldwin, 1994). For the uncontrollable situations, older children are more likely to nominate "secondary control" coping strategies, which include reframing, distraction, and avoidance through anticipatory planfulness (e.g., Mariage & Cummins, 2004). Younger children's avoidance is more often of the escape sort such as hiding under the bed to avoid an unpleasant event (Aldwin, 1994). A large literature has developed examining the different coping strategies mentioned earlier, and for further elaboration, the reader is referred to Aldwin's (1994) volume on stress, coping, and development, and reviews by Compas, Connor-Smith, Saltzman, and Thomsen (2001); Skinner and Wellborn (1994); Wolchik and Sandler (1997); and Wyman, Sandler, Wolchik, and Nelson (2000).

Brenner and Salovey (1997) proposed a framework for the analysis of coping that includes several important dimensions that are relevant to developmental change in coping strategy use: (a) the controllability of the stressor, (b) the degree to which the individual invokes solitary strategies as opposed to socially interactive ones, and (c) the use of internal/intrapsychic strategies as opposed to situational-focused strategies. We elaborate on the dimensions of solitary-social strategies and intrapsychic-situational strategies below as they manifest themselves in children at different developmental stages.

The solitary-social dimension in regulatory strategies is readily illustrated by our use of physical exercise to dissipate tension, frustration, and other dysphoric states. Children soothe themselves with physical activities such as thumb sucking; they also make good use of solitary fantasy play as a regulatory strategy (Slade,

1994). Alternatively, throughout our lives we seek social support (e.g., help, comfort) as a way to cope with stressors and regulate our emotional experience. However, the younger the child, the more significant is the need for social support (e.g., Thompson et al., 2003). Young children rely on adults to provide safe environments such that their ability to cope is not overwhelmed, and caregivers provide direct teaching of coping strategies and modeling on how to cope (e.g., Miller, Kliweer, Hepworth, & Sandler, 1994; Valiente, Fabes, Eisenberg, & Spinrad, 2004). Rossman (1992) found that young elementary school-age children (6 to 7 years) were more likely to cite parents as sources of support, whereas older children were more likely to turn to their peers.

The internal-external dimension becomes more salient in older children's coping and emotion regulation due to their ability to introspect and use metacognition in their understanding of themselves. Meerum Terwogt and Olthof (1989) reviewed a number of studies that suggested that the cognitive developmental gains of middle childhood facilitated self-reflection, thus permitting children to use more cognitive strategies to render emotional experience less aversive (by using distraction, thinking optimistically, and being able to shift perspectives to allow for more positive appraisals). However, Harris and Lipian (1989) found what they called "cognitive slippage" in school-age children when dealing with immediate and acute stress (hospitalization). Compared with unstressed children, the hospitalized children seemed to regress to less mature ways of thinking and understanding cognitive and emotional processes. Similarly, in a recent review of depression, temperament, and coping, Compas and his colleagues (Compas, Connor-Smith, & Jaser, 2004) suggested that children and youth who had more control over attentional processes were more likely to make use of more complex cognitive coping strategies, including shifting their attention away from pain (e.g., blunting), reinterpreting the situation in more positive ways, and being able to selectively attend to positive thoughts and circumstances, thereby ameliorating the likelihood of depression.

A methodological concern is that virtually all of these studies used children's and youth's verbal self-report, which may confound the increased ability to use internally focused strategies with the greater verbal skills that also accompany maturation. It is probable that young children (preschoolers) can also access intrapsy-

chic strategies, although they cannot verbalize for us that they are doing so. For example, dissociation is an intrapsychic coping strategy, and it is used by young children as a way of distracting themselves from an intensely stressful situation. It is also useful when children feel powerless and overwhelmed.

### *Family Influences on Children's Coping*

**Attachment.** A potentially significant influence on children's coping strategies is their early attachment experience with significant caregivers. Cassidy (1994) has theorized how attachment history and emotion regulation may be linked; the reader is referred to her work for further detail and to the *Handbook of Attachment* (Cassidy & Shaver, 1999). We provide only a brief summary of her thinking. She argues that negative emotions, such as anger and fear, for the securely attached infant come to be associated with maternal sympathetic assistance and that these negative feelings are neither associated with any sort of invalidation of the young child nor with denial of the negative feelings. For emotional regulation, this means that the young child comes to be able to tolerate aversive emotion temporarily such that it can begin to make sense of the frustrating or conflictual situation that faces it and figure out an adaptive coping response. The anxious-avoidant attached infant, however, has often experienced its caregiver's rejection when it sought comfort for its distress. Such an infant learns that some emotions are not acceptable and maybe not even safe. The infant develops a wariness and avoidance of his or her caregiver and begins to regulate his or her distress by minimizing their emotional expression when in the presence of the caregiver. The infant's strategy appears to be that when experiencing emotional distress, it suppresses any negative emotional display so as to maintain caregiver involvement—the infant's emotional regulation strategy seems to be, "Mom will stay with me if I don't raise any fuss." The cost, however, to the infant is constant emotional vigilance and suppression of normal distress. In short, development of adaptive problem-solving and support-seeking coping strategies may be short-circuited for insecure infants.

Related research on infants' attachment classification and their propensity to experience different kinds of emotion was examined by Kochanska (2001). She found that over a 26-month period that (a) infants classified as avoidantly attached become progressively

more fearful, (b) resistantly attached children appeared to have difficulty responding with joy or pleasure, (c) young children with disorganized attachment classifications became more angry, and (d) the securely attached children showed less fear and anger than children with the other attachment classifications, in spite of being placed in situations designed to elicit those emotions. One study worth mentioning examined adolescents' attachment classification relative to how they coped with distress. Howard and Medway (2004) included measures of attachment, coping style, life stress, and a questionnaire about whom the respondent would turn to in times of stress. Their results indicated that adolescents with secure attachment status were more likely to use family communication as a coping resource and less likely to turn to substance use as a way to avoid coping with distress. Insecure attachment, alternatively, was related to negative avoidant coping strategies. Less report of stress was also associated with secure attachment and more stress was reported by those with insecure attachment scores. Adolescents also tended to prefer their friends over their parents when they did feel distress.

**Family Conflict and Dysfunction.** Given the relatively few studies that have tracked quality of attachment to children's subsequent coping competence, the ways that families contribute to individual children's coping competence are far from being well understood. There is a larger body of research that has examined the effects of marital conflict and anger on children's functioning—the latter having some links with how well children cope with the aversive feelings that they themselves experience. Cummings and his colleagues (e.g., Cummings, Goeke-Morey, Papp, & Dukewich, 2002) have conducted a number of investigations on this topic, and, not surprisingly, the general conclusion that they reach is that many children do not fare well when faced with frequent and intense marital conflict. If verbal and physical aggression is common between spouses, the boys in particular appear to develop aggressive, externalizing behavior problems. Daughters also demonstrate behavior problems, but more of the girls also show acute distress. Angry exchanges between parents are felt by children as very stressful, even when they play no role in the dispute, and the immediate coping strategies that children bring to bear on such a family crisis probably pivot on the children's perception of controllability of the dispute.

Children growing up with depressed or psychiatrically disturbed parents have also been studied for how such a family environment influences children's emotional and social functioning. Obviously, parental dysfunction co-occurs with higher frequency with other stressful events for children such as divorce, chronic unemployment, and spousal conflict. Goodman, Brogan, Lynch, and Fielding (1993) investigated the socioemotional functioning of children (ages 5 to 10) who had a depressed mother; the children were subdivided further into three groups: (1) some also had a disturbed father in the home, (2) some were in mother-custody homes, and (3) some had a well father in the home. They also had a comparison sample of children whose mothers and fathers were neither depressed nor psychiatrically disturbed.

Their results indicated that it was the combination of a depressed mother and a disturbed father that was associated with the greatest number of problems among older children as opposed to younger children (cf., Zahn-Waxler, 2000). Apparently, as the children matured, living in an emotionally strained household with two psychiatrically ill parents began to take its toll. Younger children did not yet demonstrate such negative effects. Their study also reconfirmed the problematic effect that divorce has on children when living with a depressed parent, particularly on self-regulation variables. Such children tended to be rated as undercontrolled, for example, more often aggressive and impulsive. Children who had a well father and a depressed mother and who were still married and living together did not differ from the children of well parents except for being rated by their teachers as somewhat less popular among their peers.

**Parenting Style.** Valiente et al. (2004) looked at mothers' and fathers' expressive style (self-reported) and their supportiveness toward their children as the latter coped with ordinary, daily stressors. Their results indicated that mothers who more often used "negative-dominant" expressive style, which included hostile and derogating expressive behavior, had children whose coping was *less* constructive, and who, perhaps as a consequence, reported experiencing more stress in their daily diaries, maintained over a 2-week period. Fathers' expressive style did not correlate with their children's coping ability. Mothers who reported using more supportive strategies had children who, in turn, were more able to access and use constructive coping strategies.

Hardy, Power, and Jaedicke (1993) examined several parenting variables (supportiveness, structure, and control) and children's coping with "daily hassles." Given the homogeneous middle-class sample, they found that only maternal supportiveness and structure were related to children's coping. Specifically, very supportive mothers in moderately low-structured homes had children who generated more coping strategies across situations; mothers who provided more structure had children who used fewer aggressive coping strategies. Supportive mothers also had children who reported more avoidant coping strategies when the children perceived the stressor as uncontrollable. Overall, parental supportiveness was found to be significantly related to the breadth of repertoire of coping strategies. We infer that parental supportiveness is likely to be associated with an ongoing secure attachment between child and parent; thus, supportiveness may be a "proxy" for how attachment may mediate children's development of coping strategies.

Eisenberg and her colleagues (Eisenberg, Gershoff, et al., 2001) found that nonsupportive mothers, in particular mothers who expressed hostile negative emotion, appeared to influence their children's social competence and externalizing behaviors through the children's ability to regulate their emotional arousal. They examined a couple of other alternative models, but found that the earlier pattern best fit their data. Interestingly, they found less relationship between maternal negative expressivity and children's manifesting internalizing problems.

Turning now to an older group of youth, Zimmermann (1999) assessed adolescents' attachment classification, using the Adult Attachment Interview (George, Kaplan, & Main, 1985). He also had the adolescents respond to several questions about five hypothetical social rejection vignettes, about which they were to imagine that the various incidents of social rejection happened to them. He evaluated their open-ended responses by how flexible their appraisal of the distressing social rejection was, how flexible and variable their behavioral strategies were for coping with the social rejection, and how clearly they could articulate how they would feel as well as what sort of rationale they provided for why they would feel that way. The resulting scores were transformed and aggregated to provide a score indicative of "adaptive emotion regulation." The adolescents were also rated by their best friend, their parents, and by two psychologists with the California Adult Q-sort (Block &

Block, 1980) for degree of ego resiliency, which is often used as a personality prototype. The results showed that the securely attached teens obtained a robustly positive correlation between adaptive emotion regulation and ego resiliency ( $r = .57$ ) whereas the correlation coefficient for dismissing (insecure-avoidant) teens was  $-.32$  and for preoccupied (insecure-preoccupied) it was  $-.41$  (both significant). This study suggests that ego resiliency is likely influenced by style of emotion regulation, which in turn may be influenced by attachment history. The small sample size prohibited this kind of analysis, but Zimmermann's work is very useful for suggesting how personality organization may change as a function of emotion regulation style and attachment status.

### Summary

As children mature, their growing cognitive sophistication, exposure to varied social models, and breadth of emotional-social experience contribute to their being able to generate more coping solutions to problematic situations. The older they are when faced with serious distress, the more able they are to see the situation from various perspectives (including those held by other people who may be part of the problematic situation) and figure out a way to resolve it. With maturity, they become more accurate in their appraisals of how much control they really have over the situation and what risks might accompany taking control of a very difficult situation (e.g., intervening in a fight). Effective coping in Western cultures involves acknowledgment of one's emotional responses, awareness of one's self as having some degree of agency, and a functional appraisal of the problematic situation and one's role in it. By late childhood or early adolescence, Western children who have enjoyed secure attachment in their supportive families and escaped severe trauma should generally be capable of emotionally competent coping with concomitant social effectiveness.

### Social Effectiveness and Skill 7: Awareness of Emotion Communication in Relationships

This skill requires that the individual minimally recognize that emotions are communicated differently depending on a person's relationship with an interactant, but this particular skill goes beyond that of impression management or self-presentation strategies as defined in

Skill 5. With this skill, we also want to include the awareness and use of emotional experience to differentiate the organization of a person's relations with others. Implied then are the following skills:

- Recognition of the interpersonal consequences of one's emotion communication, not only of how the other is impacted, but also of how the relationship itself is affected.
- The ability to distinguish among different sorts of relationships and thus tailor one's emotion communication accordingly.
- An understanding of how emotion communication is a vehicle for power or control and thus has the potential to shape the "relational space" between the interactants.

The use of the term *emotion communication* entails verbal statements and all channels of nonverbal expression that can convey affective information to an onlooker or interactant.

By middle to late childhood, children recognize and can articulate to some degree that emotion communication varies as a function of the nature of the relationship that they have with someone (e.g., Saarni, 1988). Research also confirms that children distinguish emotion communication between close friends versus ordinary peers (e.g., Asher, Parker, & Walker, 1996). Likewise, children differentiate how they communicate with mothers versus fathers (Fuchs & Thelen, 1988). Not surprisingly, disclosure of emotionally vulnerable information is more often made to close friends and mothers. Observational research also indicates that children use expressive strategies to maintain relationship equilibrium (such as smiling more often) even as they simultaneously express negative feelings (such as contempt or irritation) toward their friends (von Salisch, 1991). In addition, girls (in Western societies) may be more likely to smile than boys as a way of influencing the relational dynamics (e.g., Saarni, 1992).

### ***Secret Keeping and Secret Sharing***

Watson and Valtin (1997) investigated children's understanding of interpersonal relations relative to keeping or sharing secrets, and secrets by their very nature are intensely emotion laden. Their results are important here for how they revealed children's use of relationship knowledge in choosing whether to share a secret. The

youngest children (5 to 6 years) were more likely to tell mother more secrets than the older children, whereas the older children were more likely to share secrets with their friends—as an expression of, maybe even testimony to, their friendship—than with their mother. The exception was sharing of embarrassing secrets (i.e., wetting one's pants) by the older boys: Very few would confess this to their friend, whereas the older girls were more willing to share "bodily loss of control" with their same-sex friends. Humiliation and fear of loss of reputation were among the reasons cited by the older boys for not telling a friend, but they might tell their mother, because she could be counted on not to embarrass them. As for guilty or dangerous secrets, older children felt a clear sense of tension about whether to maintain their friend's secret as an act of trustworthiness, even as they also worried that perhaps an adult "should" know about the guilt-laden activity (i.e., theft) or dangerous event (i.e., lighting a fire in an empty garage). As one girl put it, "Mother is like half a friend—so sometimes you can share some secrets with her" (p. 448–449, Watson & Valtin, 1997).

From the standpoint of understanding how relationship structure affects our emotional communication, the older children were more consistently concerned with how trust defined a relationship, and by implication, with trust comes a degree of reciprocity and mutuality. Good friends should be able to trust one another. Emotional communication is profoundly affected by the degree of trust one feels toward another with the result that the greater the trust, the more likely one will disclose information about one's experience that is emotionally vulnerable. Emotionally vulnerable information about oneself or about another, such as in secrets, is invariably anxiety provoking, and it takes a mutually respectful relationship for anxiety-laden exchanges to be reassuringly heard.

### ***Interpersonal Closeness***

Strayer and Roberts (1997) undertook an ingenious study to examine how emotion processes such as empathy might mediate or moderate children's "felt" closeness toward video-taped characters. They used a felt wall hanging that had a mirror mounted in the center, and the children were asked to place Velcro-attached photos of video characters relatively close or far from the reflected image of themselves, depending on how comfortable they felt with the video-taped character

(e.g., a physically punitive parent versus a girl who is excited about an elephant ride at the circus). The results indicated a nearly linear relationship between the degree of empathy (as measured by the Empathy Continuum, which evaluates the degree of affective sharing, perspective taking, and interpersonal understanding) the children felt for the character and how close they placed the character's photo near their own mirror image. This relationship increased with age and was somewhat stronger in girls. Familiarity, status, authority, and intensity of affect might all play a role in how close we allow another into our personal space, yet this study suggested that if empathy were present, then the emotion communication that transpired defined the relationship as different: We can step into the shoes of the other, even if their personal attributes are quite different from our own and they are unfamiliar persons. We would like to encourage the use of this particular methodological technique in other studies of emotion communication with children and youth, especially those that are also concerned with self-representations, boundaries, and relations with others.

### ***Social Roles and Emotion Communication***

Relatively uninvestigated is how emotion is differentially communicated and conceptualized relative to different social roles. Social roles refer to age roles, sex roles, occupational roles, authority and/or leadership roles, and so forth. Some research exists on how gender (and by implication, sex role) influences both the pattern and frequency of emotion discourse (e.g., Ruble & Martin, 1998; Shields, 1995). But we do not know how children integrate their knowledge about social roles with beliefs about emotion communication. Research on children's acquisition of social scripts as they are related to different venues of emotion communication is minimal, although children's use of scripts may be implicit in their expectations about emotion expression (e.g., Underwood et al., 1992) and about best versus worst ways to cope with aversive feelings (e.g., Saarni, 1997).

Relative to sex role, young children endorse emotion-specific gender stereotypes that are common in Western societies, such as males are expected to experience more anger and females more sadness (Karbon et al., 1992). Shields (1995) provided a review of how various aspects of emotional experience are gender-coded (e.g., the expressive/emotional female versus the instrumental/rational male), and she was particularly interested in how

children are socialized into expressive styles that are gender-coded (e.g., the conciliatory style of little girls when faced with a conflict compared with the more coercive style of little boys). She also noted the dearth of studies on the developmental processes that link emotional development with gender identity development.

Harter and her colleagues (1998) looked at "level of voice" in adolescents relative to the degree to which they adhered to sex-role stereotypes. Level of voice was assessed by a questionnaire developed by the authors to ascertain whether the adolescent felt confident about being able to disclose his or her feelings and opinions to others (i.e., to reveal a "true self"). Their interesting results showed that stereotypically feminine adolescents had a lower level of voice in public exchange compared to their more androgynous female peers but no difference was obtained in private exchanges. For male adolescents, stereotypically masculine male adolescents had a more assertive level of voice in public exchange but were not as confident or open in "true self" level of voice in private exchanges (e.g., between close friends) as were androgynous male adolescents. Thus, we see in this research a convergence on emotion communication, sex-role beliefs, and the context of relationship (public versus private and close).

### ***Summary***

Although we have research that substantiates that socialization is mediated by parental and peer communicated emotion (e.g., derogation is an emotion-laden communication that directly informs the target that the interactant disapproves of both the target and the behavior of the target), we have relatively little research that examines how children and youth recognize and use emotional communication to differentiate the organization of their relations with others. Related issues include how children and youth construe the interpersonal consequences of their emotional communication with the relationship for themselves *and* for their interactants (the focus being on the relational space between the interactants); how they maintain the relationship quality (e.g., equilibrium) or alter it (e.g., by deepening or attenuating it); and how they apply power and control in the relationship. Some research on the meaningfulness of friendship is relevant (e.g., Asher & Rose, 1997), as is Gottman et al.'s (1997) work on parents' coaching their children in ways that facilitate their children's understanding of emotional experience. Infant

intersubjectivity and attunement are also examples of emotion communication, but what is missing in our research base is how children and youth acquire an awareness that emotion communication varies as a function of their affectional ties to an interactant, their status (or dominance) relative to the interactant, and the unique emotion-evoking circumstances in which the interaction is embedded (e.g., public or private).

### **Social Effectiveness and Skill 8: Capacity for Emotional Self-Efficacy**

This final skill of emotional competence entails an individual's acceptance of his or her emotional experience, whether eccentric or conventional, negative or positive. With this skill, individuals can tolerate and not feel overwhelmed by intense negative emotion (e.g., despair, melancholy, outrage, or anguish) because they do not view their emotional responses as unjustified. They feel relatively in control of their emotional experience from the standpoint of mastery and positive self-regard. Indeed, a sense of global self-worth may lie at the heart of emotional self-efficacy (Harter, 1999). In our opinion, this sense of emotional self-efficacy is probably not achieved until adolescence, for it is undoubtedly dependent on cognitive development, including the ability to consider the realm of possibility and of reality. We also hypothesize that the emotionally self-efficacious individual has acquired the preceding seven skills of emotional competence to a relatively mature degree.

As for relationships, emotionally self-efficacious adolescents learn that they cannot have it all: Not everyone will adore them or want to spend time with them, and they may feel lonely at times. But rejection does not leave them in a puddle of devastation and self-pity; instead, emotionally self-efficacious individuals seek to resolve the situation relative to their values. They treasure their friendships (Asher & Rose, 1997) and choose a course that is also guided by a moral compass (e.g., Walker & Hennig, 1997). Research on relationship quality in adolescence also suggests that adherence to a true self is more often associated with perception of self-worth and with youth engaged in relationships that were supportive as opposed to contingent on the youth's pleasing either parents or friends (reviewed in Harter, 1999; see also Eisenberg, Spinrad, & Morris, 2002).

Individual differences in emotional self-efficacy may be influenced by personality; for example, agreeableness appears implicated as a significant aspect of

emotional intelligence (e.g., Davies, Stankov, & Roberts, 1998), by appraisal style (e.g., a positive appraisal style promotes a general sense of subjective well-being; Lazarus, 1991), which in turn is associated with mood states, and by temperament (e.g., Eisenberg & McNally, 1993; Eisenberg et al., 2004). As diverse as these research inquiries are, they may help to guide us in figuring out how to conceptualize the relations among personality traits, mood states, and emotion processing relative to the benefits for emotional self-efficacy for the developing adolescent. We turn next to that debate.

### ***Personality, Mood, and Emotion Processes***

How does an individual maintain some degree of emotional balance or even a sense of well-being in the face of adverse events and painful circumstances? Granted, there are buffering or protective factors that facilitate resilience (e.g., secure attachment, supportive relationships), but what does the individual bring to that crucible of adversity that allows him or her to experience appropriate negative affect but then be able to resume her or his life course with equanimity and perhaps even greater insight into her- or himself? Clinicians may have intuitive answers to this question (e.g., Janoff-Bulman & Frantz, 1997), and perhaps the Blocks' research on ego resilience is relevant (e.g., Block & Block, 1980). What we would like to see investigated from a developmental psychology perspective is how emotion-directed information processes such as perception, attention, judgment, and memory recognition and recall (including recall of one's own personal life-history events) are influenced by personality and mood states (both enduring and transient moods). It seems to us that the maintenance of emotional self-efficacy would require the ability to access at least two sorts of emotion-directed information processes: First, the emotion-directed information processes need to provide feedback about our own emotional experience such that we can evaluate it; second, these processes need to provide feedback about the emotion-evoking circumstances such that we can accept our emotional response to the circumstances and then turn our focus to resolving or accepting the adverse circumstances. As an example, an adolescent might experience the divorce of his or her parents as very aversive, but if some degree of emotional self-efficacy has been developed, he or she can accept the feelings of sadness, anger, and anxiety as appropriate to the painful situation, but then redirect his or her focus toward his or her own positive goals and values (e.g., friendships, aca-

demic achievement, or community service) rather than ruminating on his or her parents' conflicts and breakup.

Interestingly, a study by Lyubomirsky and Nolen-Hoeksema (1995) provides empirical support for the value of a person redirecting their focus, which they refer to as distraction. They found that rumination by dysphoric participants led to generating less productive solutions to hypothetical interpersonal problems and having a more pessimistic outlook about their future. However, a second group of dysphoric participants were told to distract themselves (i.e., redirect their focus), and this group did not differ from the nondysphoric participants in optimism and effectiveness in problem solving. In sum, a person can feel miserable (dysphoric), and their misery might be very well justified by the circumstances, but being able to redirect their focus rather than to ruminate on the adversity may well facilitate effective problem solving and influence their expectations for an improved future. This outcome is similar to that found by Weyer and Sandler (1998) in a short-term longitudinal study of children whose parents had recently divorced: Efficacy of coping was negatively related to propensity to ruminate. Likewise, O'Brien, Margolin, and John (1995) found that children who could distance themselves from their parents' divorce appeared to fare better.

Rusting (1998) has provided us with a valuable integration of the research on mood states and personality traits as they affect emotion-congruent information processing. She noted that it is the trait theorists, who have posited that an individual's enduring personality traits, for example, proneness to positive or negative affectivity, most strongly influence their mood-congruent information processing. More specifically, if one is predisposed to positive affectivity (trait), one is more likely to report experiencing more positive mood states, and this results in one's retrieval of more positive memory associations, which in turn probably facilitates the continuance of the desirable mood (and the converse being true if one is predisposed to negative affectivity). This "proneness to positive versus negative affectivity" sounds similar to the earlier discussion in this chapter on temperamental disposition to negative emotionality and reflects some personality development theoretical positions that advocate that personality traits are significantly influenced by temperamental dispositions (e.g., Caspi & Silva, 1995).

However, other theorists have emphasized the influence that *temporary* mood states have on emotion infor-

mation processing. This body of research often involves inducing either a positive or negative mood in the research participants and then giving them various cognitive tasks that involve perception, attention, judgment, and recall. An early study by Carlson and Masters (1985) did just that: They induced positive emotional states (self-focused or other-focused) in one group of 5- to 6-year-old children and a control group had a neutral induction. The first group displayed happier facial expressions and did not demonstrate the usual reduced generosity after inequality of rewards as long as they had received the self-focused happy mood induction. The authors interpreted their results as supportive of the position that temporary positive mood states facilitate tolerance of aversive experiences.

What Rusting proposed—and which is relevant to emotional self-efficacy—is that both temporary mood states and more stable personality styles or traits will influence how one processes emotion-laden cues, for these cues evoke memory associations, which in turn are influenced by both personality disposition and temporary mood. Reframing this so that it helps to elucidate emotional self-efficacy is suggested by the following case:

Lily's younger sister, Sharon, age 10, died of cystic fibrosis, and the family was in profound grief, for it had seemed for awhile that Sharon might survive for a number of years more and then she unexpectedly worsened and died. Lily (age 15) had been neither a "difficult" nor an "easy" baby: She had had her share of difficult-to-soothe crying spells in infancy and seemed to have a rather low threshold for pain (e.g., reacting quite intensely to vaccinations and injections). Upon Sharon's death, she felt very bereft and experienced her grief somatically as well (abdominal pain). She stayed home from school for a week, and subsequently, with her parents' help, she created a photo montage to take to Sharon's elementary school classroom. She also collected Sharon's drawings that she had made over the past few years while undergoing therapy in conjunction with her frequent medical interventions and assembled them into a book. She had the book copied in color and gave the copies to various relatives as gifts to remember Sharon's creativity. Lily focused on Sharon's vibrancy rather than her final months of ravaging coughing and breathlessness, and Lily's turning outward to the former school mates and to the extended family drew her into supportive and rewarding social contact. At the time of the first anniversary after Sharon's death, Lily was able to weep easily over the loss of her sister, but she was also able to feel good about herself, appreciated her parents more from an empathic perspective of what they had gone

through, was perceived by her peers as a mature and trustworthy person, enjoyed a moderate social life, and had easily maintained her standing on the honor roll. Lily was optimistic about her future plans, and she was looking forward to a community service volunteer position for the summer in the chronically ill children's ward at the local hospital. (author developed, C. Saarni)

Noteworthy in this case is that Lily is not a ruminator, yet she does not minimize or avoid her negative affect. Her personality style appears to be one of moderation; her coping style is a socially engaged one rather than one of withdrawal or avoidance of others, in spite of some initial somatogenic reactions to Sharon's death. Importantly, her parents appear to be able to provide supportive scaffolding, even as they too grieved for Sharon. Lily is future oriented and playful with the expectancy that what lies ahead will be positive and satisfying. She is expressive but neither overnor undercontrolled. The fact that her peers view her as trustworthy and mature suggests that her emotional communication with them is respectful, genuine, and insightful. She is probably a good listener, and her peers confide in her. Lily demonstrates emotional self-efficacy: She accepts her grief, she accepts the loss of her sister, yet she finds balance and meaningfulness in her life. In spite of deeply felt adversity, she demonstrates well-being and resilience over the long term (see also Wyman et al., 2000).

### Summary

Emotional self-efficacy is obviously a superordinate construct, much the way that emotional competence is. It overlaps with resilience in the face of adversity and entails well-developed skills of emotional competence as described in the preceding sections. One of us (Saarni, 1999) has also argued that emotional self-efficacy must entail a moral sense and a willingness to make choices that support one's beliefs that one is doing "the right thing" even if it is uncomfortable or unpopular (Colby & Damon, 1992; Walker & Hennig, 1997; Wilson, 1993). Such moral choices require thoughtfulness and self-reflection and very likely a sense of moral justice tempered with sympathy and compassion. Social effectiveness is also part of emotional self-efficacy: A person's emotion-directed information processing while engaged in a social encounter, especially a challenging or emotionally evocative one, will be influenced by his or her memory associations of similar past encounters and by their current emotional state. Assuming a sup-

portive family history and a personality style that is not burdened by the double hazard of proneness to negative affect and deficits in attention, then a person's memory associations should be benign or resilient and their current emotional state should be moderately regulated. The challenging social encounter should then unfold with minimal defensiveness, appropriate assertiveness, and demonstration of personal integrity (i.e., a person's moral sense).

In conclusion, further theoretical development of the construct of emotional competence is needed; for example, how does it differ from emotional intelligence (Mayer, Salovey, & Caruso, 2000; Saarni, in press) and how might emotional competence skills be structured hierarchically (as has been done with the construct social competence; Rose-Krasnor, 1997). The skills of emotional competence are dynamic and transactional, for these skills are part of an interpersonal exchange that unfolds in a unique context. Indeed, one could design interesting studies simply by pairing together children or teens who differ in the degree to which they can employ the skills of emotional competence and then observe how their interpersonal negotiations unfold.

### CONCLUSION

In science, progress is measured not so much by how many questions have been answered, but by how many new ones have been raised. Such is the case in the study of emotion, where there has been a plethora of significant contributions to knowledge in recent years. In conclusion, we review a few of the unresolved issues that we believe represent the frontier of research into emotional development. Given the generally functionalist perspective taken in this chapter, our proposed research questions emphasize goals, the relational rather than the intrapsychic properties of emotions, the flexibility rather than the reflexive nature of emotional behavior, and the embeddedness of emotion in interpersonal transactions.

The functionalist approach liberalizes the study of emotion, but has not yet profoundly influenced how emotions are studied. Consider the following: If one were to do a census of studies on emotions, one would find, even today, an extraordinary overrepresentation of research in which emotions have been treated primarily as responses—as outward signs of internal states. Stud-

ies of emotions as antecedents and organizers of personal and social behaviors have been much less prevalent. When emotions are considered purely as responses, the tendency is to stop there, and not consider how those responses can be in the service of changing or maintaining person-environment relations. This imbalance between emotions considered as responses and emotions conceptualized as organizers generates a number of major new areas of research.

One of these areas concerns new aspects of emotional communication. For instance, there is a discrepancy between the wealth of information we have about individual differences in emotional responding (i.e., temperament), and individual differences in emotional perception and subsequent behavior regulation (a phenomenon for which we do not even have a noun, and about which there are consequently few studies). One of the first research questions we raised in several sections about emotional development concerned the little we know about how emotion perception originates, how such perceptions lead to functional consequences for the child, and how infants and children come to react, and subsequently to become dismissive, hyper-vigilant, or appropriately attuned, toward different cues of emotion expressed by others. We also need to investigate which contributing contextual features promote sensitivity to such cues, how such sensitivities eventually become biases to respond, and what are the personal characteristics of infants and children that lead them to be disposed to react appropriately or to make biased attributions of emotion. Volumes await the description and explanation of the answers to these questions.

If emotions are primarily social and relational, the boundary of social psychological research and developmental study becomes very permeable. For instance, the self, it has been said, develops under the watchful eye of the other. This statement captures our point that it is not just cognitive developments linked to the self that lead to so-called self-conscious emotions. The child must notice the presence of such watchful eyes, realize that the eyes reside in significant others, identify what emotion the eyes are communicating, and subsequently behave to have an appropriate effect on those eyes—such as by hiding from them in shame, or showing off to them in pride. The social context and the social signals (expressions) provided by significant others are thus constitutive of new emotions. This phenomenon has not been adequately studied, in comparison to studies of the relation between cognitive and emotional development. Put

another way, rules and standards, and the construct of the self, may not be sufficient to generate later-appearing emotions like pride, shame, and guilt; these emotions may also require the affective sting of the emotional communications of others. If so, we need to study the value added by emotional signals to the imposition of rules and standards.

Another topic at the interface of developmental and social psychology is that of attention in dyadic and group settings. Basic issues such as the targeting of joint attention between two individuals and the quality of the emotional messages exchanged between them may determine the specific emotion generated in such interchanges. The meaning of a joyful reaction by a significant other in the presence of a child has different functional consequences depending on (a) whether the joy is targeted toward an action of the child (laying the basis for the child to experience pride), (b) whether the joy is merely witnessed by the child (leading to an empathic affect sharing but not pride), or (c) whether the joy is oriented toward the child himself or herself (resulting in the child developing affiliative or attachment bonds). Similarly, the quality of the emotion message manifested by the other in such social interactional exchanges (i.e., its fearful nature or its scornful nature) may have dramatically different results on the child. The first permits the child to “catch” the fear of an object expressed by another; the second potentially enters into the generation of shame (as noted before). It seems an inescapable conclusion that emotions are relational processes. If so, the field must develop paradigms that do justice to that relational nature, and permit functional consequences of those emotions to be observed. Few paradigms exist that permit the richness of emotion to be discerned and quantified. Where the paradigms do exist, as in studies involving naturalistic or field observations, the coding schemes often do not do justice to the many different facets and manifestations of emotional behavior.

Emotions, though, do not always seem to be relational. Indeed, they seem to be intrapsychic and private events. For instance, we weep for the loss of a loved one in the privacy of our own room, with no one present, and no apparent social target for the tears. Is it the case that emotions are primarily private and nonrelational? If they *are* relational, as we propose they are, how do they become private, and do such private events themselves have functional *sequelae*? We cannot answer these questions at this time. The process by which emotions considered as

external and relational become internal and private has not been the focus of any systematic research to date. We know that in language speech shifts at 5 to 6 years of age from being primarily or exclusively external to potentially internal and private. Such interiorization has great relevance for the growth of self-regulation. Is there a similar process of interiorization that occurs for emotion? Does the interiorization of emotion take place at the same age as the interiorization of speech? And does such possible interiorization have implications for emotion regulation, by analogy to the consequences of the interiorization of speech for self-regulation? The recent work of Holodinski and Friedlmeier (2006) draws our attention to such interiorization processes. We believe that these authors have identified what may be a major yet unsuspected developmental transition in emotional life—one that takes place in the middle of the 1st decade of life. Their theorizing and research proposals can help reconcile two drastically differing views of emotion: (1) emotion as intrapersonal (a relatively late stage in the ontogeny of emotion) and (2) emotion as interpersonal/relational (a process present throughout the life span but not necessarily evident in all manifestations of emotion in older children and adults).

There is another challenge to the view that emotions are relational. Some emotional phenomena such as esthetic emotions do not appear to be in the service of any apparent goal. Music not only soothes the savage beast but also the very young infant. Is the infant's reaction to music an exception to the view that emotions serve a person's strivings? Or is music, as Lazarus argues, a process that draws on reintegration of cues from memory in which some aspects of a musical composition serve as prods bringing to mind previously experienced emotions (in the manner that the sound of drumbeats in music can remind us of our heartbeat in a state of fear)? This type of question is amenable to test, but to date no thorough study has been conducted on music and emotion in early life. Therefore, we cannot provide evidence relevant to Lazarus's functionalist argument or its nativist counterpart. Systematic study of esthetic emotions thus seems very relevant in evaluating the limits of applicability of a functionalist approach to emotion.

The approach to emotion we have taken is not only relational but also nonmechanistic. It considers emotions not as reflexive but as flexible, even in the very young infant. The functionalist approach stresses that the same event can produce quite different emotions, and the

same emotion can result in quite different, indeed equipotential, transactions with the world. The equipotentiality of emotional behaviors renders them flexible rather than reflexive. However, most research on emotion to date has not done justice to the flexibility and equipotentiality characteristics of emotion. Our methods often constrain the possibility of observing flexibly manifested emotional behaviors, or of noting how the same event can be construed differently by different children. Moreover, the research objectives in most studies typically center on the search for the *coherence* of emotional behaviors—the more highly intercorrelated we find behaviors to be, the better we think our findings are. However, emotional behaviors are rarely highly intercorrelated. Such low-to-modest correlations are precisely what one would expect if emotional behaviors are equipotential. Low correlations due to equipotentiality of response would then reflect, not the presence of error variance, but a true state of affairs. How does one statistically and conceptually tease apart situations in which low correlations among behaviors are expectable from those in which there is error variance? This is a vexing problem for researchers to address, and our usual statistical models do not help disentangle the two possibilities. Only research designed to predict what behaviors are shown in what contexts can do so. Attachment researchers address this problem by the use of interpretational methods and judgmental, though reliable, coding systems such as those that quantify maternal sensitivity or classify the meaning of the infant's behaviors into categories such as avoidant, ambivalent, disorganized, or secure. Perhaps we need to quantify emotions using similar approaches but on different emotional phenomena than attachment. To reiterate, we believe that we cannot continue to ignore the problems created (a) by the same event being interpreted differently by different individuals, and (b) by different behaviors being recruited in the service of the same emotion. We stress again: Our paradigms must allow for the manifestation of the flexibility of emotion.

Another important issue in the functionalist approach is the critical role of context. One instantiation of the importance of context is again at the interface of social and developmental psychology. It relates to when and how children's disclosure of differently valenced emotions to different categories of people takes place (e.g., peers versus adults, close relationships versus distant ones, and so forth). Relevant individual differences to consider in

such an investigation include personality disposition (e.g., degree of inhibition) and children's cognitive perspective-taking skills. Children's social cognitive expectancies about the reactions of others to emotion-laden disclosures are also relatively underinvestigated.

Also related to context is the process of how individual differences in the capacity for empathic engagement by the child without the child becoming overwhelmed by his or her own personal distress. We raised the possibility of tolerance for ambiguity as related to having a higher threshold for tolerating another's distress as the witnessing person considered avenues of appropriate action for how to help or intervene. Important contextual features of the relationship that exist between target and sufferer are also under investigated; such features can differentially contribute to personal distress reactions. For example, if the target is more dominant or powerful than the actor and now something affects the target to render her or him distressed, at what age will children intervene to assist sympathetically—and in a genuine manner, rather than instrumentally or strategically—as opposed to feeling personally distressed?

A central aspect of context in emotion is that of the role a person is expected to assume. One cannot understand many emotions without understanding the role a person is playing. However, we do not know very much about how children and youth integrate their knowledge about social roles (e.g., age roles, occupational roles, authority/leadership roles), how roles set the stage for different emotional reactions and different beliefs about emotional communication. Some research on gender roles exists, but it appears to be more related to socialization patterns (e.g., girls' conciliatory versus boys' coercive styles when faced with a conflict) or with attributions of propensity about which gender is more likely to experience what sort of emotion. We thus propose more of a focus on how children and youth organize their relationships with regard to social expectations, how those expectations affect the quality, frequency, and intensity of emotions, and how roles have an impact on various dimensions of emotional communication. For example, more smiling appears to occur among friends, even as they may also reproach or express negative affect more frequently with their friends (von Salisch, 1996). Presumably, there is also more emotion-laden disclosure to friends. How do youth differentiate their emotion communication strategies when they first embark on an intimate relationship? What is it that creates awkward-

ness as they begin to learn how to be warmly and genuinely intimate with a partner? How do children and adolescents figure out how emotional communication is different in intimate relationships as compared to their earlier same-sex peer friendships? Daily diary studies may well be a methodology that would prove useful, as would be studies that recruit dyads of adolescents who self-nominate themselves as partnered.

Another frontier of research deals with factors that influence emotion-directed information processes of perception, attention, judgment, and memory. How do individual differences in a child's personality and his or her development affect these psychological processes? How do enduring and transient mood states affect them? We raised the question of how emotional self-efficacy in adolescence may require the ability to access these emotion-directed information processes in ways that allow for feedback to their evaluation of their own emotional experience so that they can accept their emotional response (as opposed to denying their emotional response and having to defend themselves against it). With such emotional self-efficacy, they can then turn their focus to resolving the adverse circumstances.

A final set of questions brings us full circle to the objective of this chapter: Emotional development is the development of what? We need to do research on how some emotions are present in some rudimentary form at birth or shortly thereafter. These nonemergent emotions develop in the sense that new events elicit them, or new motives are served by them, but the relation between the event and the motive stays invariant. However, what is the process by which different events in relation to different goals yield the same emotion? We do not know the answer to the question of how such totally different transactions yield the same or similar emotions. Other emotions are not present from birth but become organized due to the intercoordination of processes such as cognition, exposure to events in the world, the social reactions and attitudes of others, the biological constitution of the child, and the differentiation of the physical and social self. Do these emotions emerge? Or are they evident in some rudimentary, not-readily measurable form early in life? Some recent research suggests that complex emotions such as jealousy, shame, and pride may be evident even in the 1st year of life, contrary to widespread belief (Draghi-Lorenz, Reddy, & Costall, 2001). In cognitive development, we have learned that phenomena once deemed to emerge in late infancy can

be shown in some meaningful form in the newborn or young baby. Are similar rudimentary precocities also identifiable in the development of nonbasic emotions? The possibility that emotions may be evident much earlier than the usual indices of emotion leads us to infer that this is an important question. We hope that future editions of this *Handbook* may report answers to the unresolved issues we pose.

salient personality differences between people? What gives rise to these differences? Do personality differences shape important life outcomes? How might personality influence the emergence of psychopathology? Answers to these questions are crucial for those who wish to describe, explain, and predict the nature of individual lives across time.

---

Work on this chapter was supported by grants from the National Institute of Mental Health (MH-45070 and MH-49414), the Medical Research Council, and the William T. Grant Foundation. We

---

thank Terrie E. Moffitt, Brent W. Roberts, William G. Graziano, and Nancy Eisenberg for their helpful comments and ideas. This chapter reviews material available to us through July, 2004.

The fifth edition of the *Handbook of Child Psychology* was the first edition to include a chapter devoted to personality differences (Caspi, 1998; in editions prior to that, coverage of personality development had been scattered about in specialized chapters dealing, for example, with aggression or motivation). We were pleased to be invited to contribute a new chapter, but we had to ask ourselves: Was a new chapter needed? Given the slow progress of soft psychology (Meehl, 1978), it is heartening to recognize that there have been significant advances in research on personality development over the past decade. In this chapter, we have tried to reflect these advances and to anticipate future directions as well.

In reflecting on the past decade of research, we are struck that debates pitting the person versus the situation, nature versus nurture, and continuity versus change are increasingly being brought to a halt. These three tired debates have given way to a more nuanced understanding of personality development.

At the heart of the person-situation debate was the ontological status of personality traits: Are traits real? It is possible to distinguish among descriptive, dispositional, and explanatory conceptions of traits (Zuroff, 1986). According to the first, *descriptive-summary* conception, traits are summary variables that describe observable consistencies in a person's past behavior. As demonstrated by criterion-oriented studies, a descriptive-summary conception serves useful predictive purposes. However, because this conception bypasses the explanatory work of psychology, it is unlikely, by itself, to yield theoretical insights about personality development: "It contributes no more to the science of psychology than rules for boiling an egg contribute to the science of chemistry" (Loevinger, 1957, p. 641).

According to a second *dispositional* conception, traits represent a tendency to behave in certain kinds of ways if in certain kinds of situations. Personality differences are here treated as "if-then" conditional propositions (Mischel, 1990). Dominant individuals dominate when there are subjects for domination but not when they are alone. Likewise, intelligent persons solve problems given the presence of problems: A person does not constantly act smart. Dispositions differ from descriptive summaries in that they indicate nothing about the occurrence of behavior in the absence of eliciting stimuli (Wakefield, 1989; Zuroff, 1986).

According to a third *realist* conception, traits are explanatory concepts. Whereas the descriptive and dispositional conceptions of traits outlined earlier regard

behavioral attributes as "samples of response classes," a realist conception treats them as indicators or "signs of internal [psychological] structures" (Wiggins, 1973, pp. 368–370). Whereas the dispositional, if-then conception of traits is agnostic with regard to explanation, a realist conception attempts to postulate underlying processes that lead traits to cause certain intentional states (Tellegen, 1991):

Personality is and does something. . . . It is what lies behind specific acts and within the individual. The systems that constitute personality are in every sense determining tendencies, and when aroused by suitable stimuli provoke those adjustive and expressive acts by which personality comes to be known. (Allport, 1937, pp. 48–49)

According to the realist, neo-Allportian conception (Funder, 1991), traits are not observable entities but hypothetical constructs and, like all such constructs, their usefulness needs to be demonstrated and refuted through the procedures of construct validation. The process of "construct validation is nothing more or less than hypothesis testing" in which a construct becomes known by virtue of the interlocking system of laws in which it occurs (Hogan & Nicholson, 1988, p. 622), and the task of empirical research is to keep tightening the nomological net (Meehl, 1986). In this sense, researchers need to embed traits in process theories that lead to new and testable hypotheses about social, psychological, and biological phenomena throughout the life course. Trait explanations are not an end; rather, they are placeholders in an evolving search for fuller explanations of action and motivated behavior (Fletcher, 1993; Wakefield, 1989).

Whereas the 1998 version of this chapter had to justify its neo-Allportian focus on personality traits as real, this is no longer necessary because of advances in understanding the structure of personality. The first two sections of this chapter review this new evidence in detail. We delineate a taxonomy of measurable individual differences in temperament and personality in childhood and introduce a process-focused analysis of personality traits that details what is known about their developmental antecedents and their psychological and biological underpinnings. A personality taxonomy serves at least three research purposes. First, it improves research communication; connecting multiple and different measures of personality to an established and validated personality structure helps to organize and integrate diffuse research findings. Second, it helps

researchers to develop new measures of personality; locating new measures in relation to what is already known eliminates redundancy and elucidates psychological constructs. Third, it enables researchers to connect personality measures to more elaborate nomological networks and thereby to interpret research and generate new hypotheses about individual differences in personality. As becomes evident, the personality taxonomy discussed in the second section organizes the remaining sections of our review.

A second, related debate has pitted nature versus nurture. This is the longest-lived controversy in psychology, and there are signs that it too is dissipating. We begin the fourth section with an overview of research showing a genetic contribution to personality. But whereas the 1998 version of this chapter devoted a good deal of space to elaborating the logic of behavioral genetic designs, in this edition we proceed directly to summarizing and updating the empirical evidence and move on to discuss the contributions of molecular genetics to psychological research. The use of molecular genetic techniques is helping to replace the nature-nurture conjunction *versus* with the more appropriate conjunction *and*. Psychological research is being revolutionized by direct measures of specific genotypes for individuals, and this will increasingly allow researchers to investigate how nature and nurture work together to shape behavioral phenotypes.

A third debate has focused on continuity versus change, which also subsumes the question of whether personality traits matter. Trait models are often caricatured as static, nondevelopmental conceptions of personality. This misapprehension arises because personality traits are thought to represent stable and enduring psychological differences between persons; therefore, they are static. Few personality researchers subscribe to this conclusion. Rather, contemporary personality research has sought to formulate the ways in which personality differences, in transaction with environmental circumstances, organize behavior in dynamic ways over time. Personality traits are thus organizational constructs; they influence how individuals organize their behavior to meet environmental demands and new developmental challenges. As Allport (1937) noted, personality traits are “*modi vivendi*, ultimately deriving their significance from the role they play in advancing adaptation within, and mastery of, the personal environment” (p. 342). The fifth and sixth sec-

tions review new and accumulating evidence about continuities in personality development from childhood to adulthood and how personality differences influence various life outcomes. Whereas the 1998 version of this chapter did not include much information about psychopathology, in this edition we devote the seventh section to review how personality differences influence the development of psychiatric disorders. We are able to do this because the unproductive bifurcation of personality and clinical psychology is drawing to an end, and new, developmental research is highlighting etiological and practical considerations linking normal personality variants and clinical syndromes.

## THE DEVELOPING STRUCTURE OF PERSONALITY

In this first section, we address three issues that are central to the study of temperament and personality across the life course: (1) How should we conceptualize temperament and personality, and what is similar and distinctive about these two types of individual differences? (2) How are temperament and personality differences structured from infancy through adulthood? and (3) What do we know about personality types, and do these types add something important to our understanding of personality development? It is important that we address these foundational issues from the outset before turning to questions of how individual differences develop and affect the life course.

### Temperament and Personality: How Are They Similar? How Are They Distinct?

Humans display a wide range of individual differences during the life span—from birth to old age. Both child psychologists and adult personality researchers study these individual differences, but historically the two groups have done so in different research traditions: Child psychologists have typically studied temperament traits, whereas adult personality researchers have typically studied personality traits.

The contemporary empirical study of early temperament was spurred largely by Thomas and Chess, who initiated the New York Longitudinal Study to examine the significance of biologically based temperament traits in

infancy and childhood (Thomas, Chess, Birch, Hertzog, & Korn, 1963). Thomas and Chess challenged the way that social development was studied at the time because they emphasized that children are not merely the products of their rearing environments; rather, infants come into the world with biologically based behavioral tendencies. Like Thomas and Chess, most temperament researchers continue to focus on individual differences that emerge early in life, include differences in emotional processes, and have a presumed biological basis (Goldsmith et al., 1987). However, most contemporary researchers also recognize that temperament is shaped by both hereditary and environmental influences and that temperament includes components of self-regulation and emotion (Rothbart & Derryberry, 2002).

Personality is typically seen as including a wider range of individual differences in feeling, thinking, and behaving than is temperament. Personality differences include personality traits such as Extraversion and Neuroticism, but they also encompass goals, coping styles, defensive styles, motives, attachment styles, life stories, identities, and various other processes (McAdams, 1995). Although much of the research on children's individual differences has focused on traits labeled *temperament*, a great deal of productive research has already been done on childhood traits that could rightly be considered *personality*. Developmentalists have investigated a vast array of children's traits—aggression, delay of gratification, dominance, achievement strivings, empathy, anxiousness, and the list goes on—but sometimes have not explicitly labeled these traits aspects of children's emerging personalities per se (Shiner, 1998).

Recent empirical work has demonstrated a number of striking similarities between temperament traits and personality traits. First, although temperament differences between nonhuman animals have been recognized at least as long as humans have bred animals, important aspects of personality traits can be observed in nonhuman animals as well (Gosling, 2001; Gosling & John, 1999). Observers can rate traits as accurately in nonhuman animals as they can in humans (Gosling, Kwan, & John, 2003). Second, like temperament traits, nearly all self-reported and observed personality traits show moderate genetic influence (Bouchard, 2004; Bouchard & Loehlin, 2001). Third, like personality traits, temperament traits are affected by experience: Behavioral genetic studies have established that temperament in

infancy and early childhood is only partially heritable and is influenced by environmental events (Emde & Hewitt, 2001), including both pre- and postnatal experiences. Occasionally, researchers claim that individual differences measured later in childhood are not temperament because such traits have already been affected by environmental experiences, implying that only individual differences at birth represent genetically influenced temperament. The behavioral genetic findings reviewed later in this chapter reveal the fallacy of such a claim: From infancy through adulthood, to varying degrees and at varying times, genetic and environmental influences are at work shaping both temperament and personality traits. A fourth key similarity between temperament and personality traits is that many traits from both domains are characterized by specific habitual positive and negative emotions (Rothbart, Ahadi, & Evans, 2000; Watson, 2000). Although this point is widely accepted for the so-called temperament traits of Extraversion and Neuroticism, there is evidence that other major traits involve the experience or expression of emotions as well (Tobin, Graziano, Vanman, & Tassinari, 2000; Trierweiler, Eid, & Lischetzke, 2002; Watson & Clark, 1992). A recent study demonstrated that infants' positive and negative emotional expressions predicted their standing on all of the Big Five personality traits at age 3 (Abe & Izard, 1999). Thus, emotional experience and expression are associated with a wide variety of traits across the life span.

Many of the distinctions between temperament and personality traits seem to be breaking down. There may be some advantages to keeping a temperament perspective in view. Temperament traits tend to be defined as more narrow, lower-level traits (Strelau, 2001), a useful complement to the emphasis on higher-level traits in adult personality research. The concept of temperament also reminds researchers to investigate the early expressions, biological underpinnings, and basic processes underlying traits. But temperament and personality increasingly should be studied side by side. A useful approach may be to consider the broadest possible range of individual differences at each point in development rather than to exclude some individual differences from study on the presupposition that some traits are not aspects of temperament. Because temperament and personality traits share so much in common, we discuss temperament and personality systems together throughout this review.

### Personality Structure across the Life Span

One of the most striking points of convergence between temperament and personality is their similar structure across most periods of the life span; by structure, we mean the reliable patterns of covariation of traits across individuals. We later describe research findings on the structure of individual differences in infants and toddlers and the structure observed in young children, adolescents, and adults.

The establishment of a personality structure for describing adult personality has been a complicated, contentious enterprise; work on the structure of young children's individual differences is inherently even more complex. As children's motor, cognitive, emotional, and language abilities develop, the range of traits they can express similarly expands. For example, although infants may differ in temperament traits that are likely to be related to later aggression, infants cannot exhibit differences in aggression until they develop the motor and language skills necessary to direct aggressive actions toward others. Similar rapid growth occurs in children's emotional development. Children develop rapidly from manifesting only a small number of emotions during early infancy—interest, contentment, and distress—to manifesting an expanded set of emotions—including joy, sadness, anger, fear, empathy, pride, shame, and guilt—by age 3 (Eisenberg, 2000; Lewis, 2000). Thus, the structure of individual differences is likely to change over the course of childhood because of children's increasing capacities. Like many other aspects of development, children's individual differences are likely to become increasingly differentiated and complex over development. Despite the challenges in mapping the structure of individual differences in infancy and childhood, substantial progress has been made in this area.

As we illustrate in our description of temperament and personality structure, individual differences are organized hierarchically across the life span. Covariation among specific behavioral descriptors (e.g., talkative or friendly) is explained by lower-order traits, and the covariation among these more narrow, lower-order traits (e.g., sociability or social potency) is explained by broad, higher-order traits (e.g., Extraversion). Individual differences exhibit such a hierarchical structure in infancy and early childhood (Putnam, Ellis, & Rothbart, 2001), middle childhood and adolescence (Shiner & Caspi, 2003), and adulthood (Digman, 1990; Markon,

Krueger, & Watson, 2005). We now turn to a discussion of the traits that can be observed (a) during infancy and early childhood and (b) during the preschool through adult years.

### *Structure of Individual Differences in Infancy and Early Childhood*

**Lower-Order Traits.** During infancy and early childhood, children display a limited range of traits. Much of the early research on temperament in these developmental periods was derived from Thomas and Chess's nine-trait model (Thomas et al., 1963). Thomas and Chess identified a number of traits that have proven to have great clinical significance, particularly children's tendencies toward the intense expression of anger and frustration and toward fearful withdrawal from new situations (Maziade et al., 1990). More recent research has uncovered some limitations of the original Thomas and Chess model, however (for a summary, see Rothbart & Derryberry, 2002, and Shiner & Caspi, 2003), and other models are increasingly used in research instead.

Current models of temperament in infancy and early childhood derive in part from research on caregiver-report questionnaires. A number of different caregiver temperament questionnaires for young children have yielded very similar sets of lower-order traits. Some of the relevant caregiver questionnaires include: the Infant Behavior Questionnaire (Rothbart, 1981); the Infant Characteristics Questionnaire (Bates, Freeland, & Lounsbury, 1979); the Colorado Childhood Temperament Inventory (Rowe & Plomin, 1977); and the Toddler Behavior Assessment Questionnaire (Goldsmith, 1996). Additional evidence for early childhood traits derives from item-level factor analyses of the questionnaires designed to measure Thomas and Chess's original nine-trait model: Although these factor analyses generate fewer than nine factors, they provide consistent support for a smaller set of traits measured across several questionnaires (Martin, Wisenbaker, & Huttunen, 1994). Structured laboratory tasks and home observational systems also provide evidence that a number of traits can be observed and measured reliably in infants and toddlers. For example, the Laboratory Temperament Assessment Battery assesses five traits in young children: (1) Pleasure/Joy, (2) Fearfulness, (3) Anger Proneness, (4) Interest/Persistence, and (5) Activity Level (Goldsmith & Rothbart, 1991). A home-observation coding system developed by Bornstein and colleagues (Bornstein, Gaugh-

ran, & Homel, 1986) permits assessment of Positive Affect, Negative Affect, Persistence, Motor Responsivity, and Soothability.

Taken together, the caregiver-questionnaire studies, laboratory-based tasks, and observational models provide the strongest support for the following lower-order temperament traits in the infant and toddler years (Kochanska, Coy, Tjebkes, & Husarek, 1998; Lemery, Goldsmith, Klinnert, & Mrazek, 1999; Martin et al., 1994; Rothbart & Bates, 1998; Rothbart & Mauro, 1990):

- *Positive emotions/pleasure*: This trait measures the child's propensity toward the expression of positive emotions, including smiling and laughter as well as pleasure and excitement in social interaction. Observational and questionnaire measures for infants demonstrate that the disposition toward positive emotions is distinct from the disposition toward negative emotions (Belsky, Hsieh, & Crnic, 1996; Kochanska et al., 1998).
- *Fear/inhibition*: This trait addresses the child's tendency to withdraw and express fear in the face of stressful or novel situations (both social and nonsocial). This trait expresses itself in fearful, withdrawn, and avoidant behavior in situations with strangers and unfamiliar, unpredictable objects (Kagan, 1998; Kochanska et al., 1998).
- *Irritability/anger/frustration*: In early childhood, this trait includes fussing, anger, and poor toleration of frustration and limitations. This trait is an important component of Thomas and Chess's difficult child type. Infants' expressions of distress during the first 3 months of life often do not predict later expressions of distress (Barr & Gunnar, 2000). However, by around 4 months, infants' tendencies toward fearfulness and anger can be distinguished and show some predictive validity for later temperament (Rothbart, Chew, & Gartstein, 2001). Further, fear and irritability each appear to be influenced by unique genetic and environmental sources, further demonstrating the distinct nature of these two traits (Goldsmith, Lemery, Buss, & Campos, 1999).
- *Discomfort*: Infants and toddlers differ in the extent of their negative emotional reactions to irritating or painful sensory stimulation (e.g., loud noises, cold touches, or sour tastes; Kochanska et al., 1998). A similar trait termed *Threshold* is obtained in factor analyses of New York Longitudinal Study question-

naires (Martin et al., 1994); this trait taps children's sensitivity to various sensory experiences.

- *Attention*: Between the 4 and 8 month period, infants vary in their attentiveness to environmental stimuli (Rothbart, Chew, et al., 2001). Questionnaire measures of this trait tap infants' duration of attention to stimuli and their ability to notice environmental variation. In toddlers, this trait also includes the ability to sustain attention over time and persist at a task (Martin et al., 1994).
- *Activity level*: Activity level is an important component of most temperament models; however, the meaning of this trait is likely to change with development. Motor movement in infancy is associated with both anger and positive emotions, whereas motor movement in the toddler years is linked in complex ways with early markers of high Extraversion and low self-control (Eaton, 1994). When activity level is defined as positive activity, it is already highly correlated with markers of Extraversion by the toddler years (Lamb, Chuang, Wessels, Broberg, & Hwang, 2002).
- *Soothability/adaptability*: The evidence for this final trait is not as consistent as that for the preceding six traits. Soothability, as measured by the Infant Behavior Questionnaire (Rothbart, 1981), assesses children's capacity to be soothed when comforted by caregivers. A similar trait indexing early regulation of emotion emerges in factor analyses of questionnaires stemming from Thomas and Chess's model. This trait, labeled Adaptability, taps children's tendencies to exhibit mild emotional responses and to adjust quickly and quietly to various potentially stressful environmental events (Martin et al., 1994). Adaptability is moderately negatively related to measures of Irritability, and further work is needed to determine if these two traits are truly distinct from one another.

**Higher-Order Traits.** Most research on early temperament has focused on narrowly defined, lower-order traits. Rothbart and colleagues have more recently explored the structure of higher-order temperament traits in infancy and the toddler years by examining the factor structure of two newly expanded caregiver-report temperament questionnaires (Gartstein & Rothbart, 2003; Putnam et al., 2001; Rothbart & Derryberry, 2002). In samples of American infants and toddlers, three factors emerge. In infancy and the toddler years, a Surgency

factor taps children's tendencies toward an eager, positive approach to potentially pleasurable activities; vocal reactivity (in infants) and sociability (in toddlers); expression of positive emotions; enjoyment of high-intensity activities; and high activity level. In infancy and the toddler years, a Negative Affectivity factor taps both children's tendencies toward sadness, irritability and frustration, and fear as well as their abilities to quiet themselves after high arousal (reversed). The third factor differs in the two periods. In infancy the third factor measures soothability, cuddliness, ability to sustain attention, and pleasure in low-intensity situations, whereas in the toddler years this factor (labeled Effortful Control) includes these traits and more sophisticated self-regulatory abilities. The third factor appears to tap young children's emerging behavioral constraint and regulation. As described in the next section, these three higher-order traits are highly similar to three higher-order temperament and personality traits observed among older children and adults.

### *Structure of Individual Differences from Childhood through Adulthood*

We begin by describing studies of personality structure among adults, and then turn to the study of personality structure in younger age groups.

**Personality Structure in Adulthood.** One of the great achievements in the study of adult personality over the past 2 decades is greater clarity about the higher-order structure of personality. Prior to this emerging consensus, debate raged about which traits are most valid and important. Researchers were prone to the "jingle-jangle" fallacy of studying the same trait under different names (jingle) or using the same name to describe different traits (jangle) (Block, 1996). Research on adult personality has been energized by emerging consensus about personality structure because researchers can now focus their attention on a common set of traits.

The most widespread support has been obtained for a five-trait structure, dubbed the Big Five or the five-factor model (John & Srivastava, 1999; McCrae & Costa, 1999); these traits include Extraversion, Neuroticism, Conscientiousness, Agreeableness, and Openness to Experience/Intellect. Support for this model derives from two main sources of evidence. First, a number of factor analyses of questionnaires designed to measure a broad range of individual differences yield the Big Five traits

(e.g., Costa & McCrae, 1988; McCrae, Costa, & Busch, 1986); in other words, the Big Five traits emerge in measures designed to assess other sets of traits. Second, research stemming from the lexical tradition provides some support for the five-factor model. According to the lexical hypothesis, the most socially relevant and salient personality characteristics have become encoded in everyday language. Accordingly, the personality terms contained in the natural language may provide an extensive, yet finite, set of attributes that people who share that language have found important and useful in their interactions with each other. In most lexical studies, a set of adjectives is drawn from the dictionary to provide a representative sample of personality traits that are important in the natural language. Factor analyses of adjectives drawn from dictionaries in countries, such as the United States, Germany, Poland, and Holland, have resulted in five factors that are at least somewhat congruent across samples (Saucier, Hampson, & Goldberg, 2000); the strongest support has been obtained from lexical analyses of languages deriving from northern European origins.

Several three-factor models of adult personality have also received some support: Eysenck's (1991) three-factor system, Tellegen's (1985) model of personality structure, and Cloninger's model of temperament (Cloninger, Svrakic, & Przybeck, 1993). For example, biologically oriented theorists have often pointed toward three higher-order domains that correspond with postulated neural structures underlying personality: (1) An approach domain manifested in positive emotions, (2) an avoidance domain manifested in negative emotions, and (3) a constraint domain manifested as tendencies to inhibit or express emotion and impulse.

Although there are important differences among these three-factor models and the five-factor model, they overlap to a considerable degree. Extraversion or Positive Emotionality is common to all systems; it describes the extent to which the person actively engages the world or avoids intense social experiences. Neuroticism or Negative Emotionality is also common to all systems; it describes the extent to which the person experiences the world as distressing or threatening. Conscientiousness or Constraint describes the extent and strength of impulse control in task-focused domains; whether the person is able to delay gratification in the service of more distant goals or is unable to modulate impulsive expression. To these three dimensions, the

five-factor model adds two more: (1) Agreeableness and (2) Openness to Experience/Intellect. Agreeableness describes a person's interpersonal nature on a continuum from warmth and compassion to antagonism. Agreeable persons are empathic, altruistic, helpful, and trusting, whereas antagonistic persons are abrasive, ruthless, manipulative, and cynical. Openness to Experience (also called Intellect) describes the complexity, depth, and quality of a person's mental and experiential life.

**Personality Structure in Childhood and Adolescence.** Consensus about the structure of adult personality traits has important implications for developmental research: We now have greater clarity about the adult personality traits that childhood studies should be trying to predict over time. Developmental researchers have explored the possibility that childhood personality structure might map onto the structure observed in adults, and there is now evidence (from the preschool years through adolescence) from a variety of sources that such is the case. First, factor analyses of questionnaires, adjective lists, and the California Child Q-Set have often produced factors similar to the Big Five traits in studies of children from approximately age 3 through late adolescence. A five-factor structure has been obtained in parent reports (Barbaranelli, Caprara, Rabasca, & Pastorelli, 2003; Halverson et al., 2003; John, Caspi, Robins, Moffitt, & Stouthamer-Loeber, 1994; Lamb et al., 2002; Mervielde & De Fruyt, 1999, 2002; van Lieshout & Haselager, 1993, 1994) and in teacher reports (Barbaranelli et al., 2003; Digman, 1994; Digman & Inouye, 1986; Digman & Shmelyov, 1996; Digman & Takemoto-Chock, 1981; Goldberg, 2001; Graziano & Ward, 1992; Mervielde, Buyst, & De Fruyt, 1995; Resing, Bleichrodt, & Dekker, 1999; van Lieshout & Haselager, 1993, 1994; Victor, 1994). Factor analyses of self-report questionnaires have found evidence for five-factor structures in one study of children ages 9 and 10 (Barbaranelli et al., 2003) and in studies of adolescents (De Fruyt, Mervielde, Hoekstra, & Roland, 2000; McCrae & Costa, 2004). There is also some evidence that many preadolescents, even as young as 5 years of age, can provide coherent, reliable self-reports of the Big Five traits (Graziano, Jensen-Campbell, & Finch, 1997; Markey, Markey, Tinsley, & Ericksen, 2002; Measelle, John, Ablow, Cowan, & Cowan, 2005).

Second, further support for several of the Big Five traits derives from temperament research in older chil-

dren and adolescents. As noted previously, Rothbart and colleagues have identified three higher-order temperament traits in infants and toddlers—Surgency, Negative Affectivity, and Effortful Control. Rothbart and colleagues have obtained evidence for the same three higher-order traits in children ages 3 to 7 (Ahadi, Rothbart, & Ye, 1993; Putnam et al., 2001; Rothbart, Ahadi, Hershey, & Fisher, 2001) and in young adolescents ages 10 to 15 (Capaldi & Rothbart, 1992; Putnam et al., 2001). An additional fourth factor is obtained in early adolescence; this factor is labeled *Affiliativeness* and includes some components similar to the positive end of the Agreeableness trait. Possibly, a similar *Affiliativeness* trait could be identified in younger children as well, if such items were included in the relevant questionnaires. This temperament model yields traits highly similar in content to several of the Big Five traits: Surgency (Extraversion), Negative Affectivity (Neuroticism), Effortful Control (Conscientiousness), and *Affiliativeness* (Agreeableness).

Third, a variety of behavioral-task and observational measures provide support for traits similar to the Big Five (Shiner & Caspi, 2003). We describe specific behavioral-task and observational measures of traits in our detailed discussion of the content of the Big Five traits.

Thus, data from personality and temperament questionnaires, behavioral tasks, and observational measures converge on a Big Five trait structure in children and adolescents. To illustrate the meaning of the factors, Table 6.1 lists items defining the Big Five traits in three types of child measures: (1) teacher reports using a list of trait descriptors (Digman & Shmelyov, 1996), (2) parent reports using the California Child Q-Sort (John et al., 1994; van Lieshout & Haselager, 1993, 1994), and (3) children's self reports using a puppet interview (Measelle et al., 2005).

Some caveats must be noted regarding the appropriateness of the five-factor model for describing the structure of children's and adolescents' individual differences. First, the traits are sometimes measured in a less internally consistent fashion in younger children, especially preschool-age children (e.g., Lamb et al., 2002). Second, studies using the California Child Q-Set have provided evidence for additional traits such as irritability and dependency that are related to but distinct from the Big Five traits (e.g., John et al., 1994); the possibility of factors beyond the Big Five in children warrants further study. Third, the Big Five traits are

**TABLE 6.1** Examples of Trait Descriptors, California Child Q-Sort Items, and Self-Report Puppet Interview Items for Five Higher-Order Personality Traits in Children

Higher-Order Personality Trait	Trait Descriptors <sup>a</sup>	Sample Items	
		Child Q-Sort Items <sup>b</sup>	Puppet Interview Items <sup>c</sup>
Extraversion	Gregarious	Emotionally expressive	I'm not shy when I meet new people
	Cheerful	A talkative child	It's easy for me to make new friends
	Energetic	Fast-paced; moves and reacts to things quickly	If kids are playing, I ask if I can play too
	Withdrawn (rev.)	Inhibited or constricted (rev.)	
Neuroticism	Afraid	Fearful and anxious	I'm sad a lot
	Touchy	Tends to go to pieces under stress; becomes rattled and disorganized	I get nervous when my teacher calls on me
	Tearful	Appears to feel unworthy	I don't like myself
	Steady (rev.)	Self-reliant, confident (rev.)	
Conscientiousness	Diligent	Attentive and able to concentrate	I think it's important to do well in school
	Planful	Planful; thinks ahead	I try my best in school
	Careful	Persistent in activities; does not give up easily	When I can't figure something out, I don't give up
	Focused	Reflective; thinks and deliberates before speaking or acting	
Agreeableness	Considerate	Warm and kind toward others	I don't get mad at kids at school
	Trusting	Helpful and cooperative	If someone is mean to me, I don't hit them
	Spiteful (rev.)	Tends to give, lend, and share	I don't pick on other kids
	Rude (rev.)	Teases and picks on others (rev.)	
Openness to experience	Original	Curious and exploring	I learn things well
	Perceptive	Appears to have high intellectual capacity (whether expressed in achievement or not)	I have good ideas
	Knowledgeable		I'm a smart kid
	Curious	Creative in perception, thought, work, or play	
		Has an active fantasy life	

Note: Rev. = Item is scored in the reversed direction.

Caspi, in *Handbook of Child Psychology: Vol. 3. Social, Emotional and Personality Development*, fifth edition, N. Eisenberg (Ed.), 1998, New York: Wiley.

<sup>c</sup> Berkley Puppet Interview items defining the factor in a study of 95 children aged 5 to 7. *Source:* From "Can children provide coherent, stable, and valid self-reports on the Big Five dimensions?" by J. Measelle, O. P. John, J. Ablow, P. A. Cowan, and C. P. Cowan, 2005, *Journal of Personality and Social Psychology*, 89, 90–106.

sometimes defined by somewhat different clusters of items in children than in adults (van Lieshout & Hase-lager, 1993, 1994). For example, in one study Extraversion was defined by a much broader range of traits than the typical adult trait and included aspects of Agreeableness and Openness to Experience (Halverson et al., 2003). All of these findings highlight the need for continued study of potential developmental differences in the nature of the Big Five traits. More work is particularly needed in the preschool and early elementary

school years because children undergo such rapid developmental changes during these periods.

### Personality Types

Thus far we have used the term *personality structure* to refer to the pattern of covariation of traits across individuals. Personality structure can also refer to the organization of traits in the individual. Most research on personality development is *variable-centered*; it focuses

on the relative standing of persons on dimensional variables. However, the more appropriate unit of analysis may be the person, not the variable. *Person-centered* research focuses on the configuration of multiple personality variables in the person, on how different dimensional variables are organized in the person and how this organization defines different types of persons. Such a model of the person as a system of interacting components is absent from most studies of personality, although investigators have called for approaches in which the person, not the variable, is the focus of analysis (e.g., Bergman & Cairns, 2000).

Just as the study of personality traits has been hampered by the absence of a structural model, the study of personality types has been held back by the absence of empirically derived personality typologies. Typological models of personality need to be held to the same empirical standards as dimensional models of personality: replicability, generalizability, and construct validity. The history of empirical research on these problems is relatively new, dating to Block's (1971) *Lives Through Time*. Block had clinically trained judges complete independent Q-sorts of the study participants. In the Q-sort technique, a sorter describes an individual's personality by sorting a set of cards containing personality attributes into piles ranging from attributes that are least characteristic to those that are most characteristic of the individual. This produces a person-centered description because the sorter explicitly compares each attribute with other attributes in the same individual. The resemblance between two individuals is indexed by the correlation between their respective Q-sorts, which reflects the degree to which the attributes specified by the Q-sort are ordered the same way in the two individuals. The method of inverse factor analysis can then be used to identify clusters of individuals with similar Q-sort profiles.

Over the past decade, several research teams have built on Block's approach and uncovered evidence pointing to the existence of three personality types in childhood and adolescence (Asendorpf, Borkenau, Ostendorf, & van Aken, 2001; Asendorpf & van Aken, 1999; Dubas, Gerris, Janssens, & Vermulst, 2002; Hart, Atkins, & Fegley, 2003; Hart & Hare, 1997; Robins, John, Caspi, Moffitt, & Stouthamer-Loeber, 1996; Weir & Gjerde, 2002). The largest type of persons, labeled *Resilients*, is characterized by being adaptable to change, self-confident, independent, verbally fluent, and able to

concentrate on tasks. *Overcontrollers* are without many interpersonal skills, shy, and inward looking. *Undercontrollers* are impulsive, willful, and disagreeable and they show little concern for others. This convergence of three personality types across multiple studies is noteworthy as the studies differ in numerous ways, including age, gender, ethnicity, geographic location in which the study participants grew up, the source of personality information used to derive the types, and even the statistical methods by which the types were derived.

However, the convergence across studies is not perfect, especially in adult samples (Asendorpf, Caspi, & Hofstee, 2002). More typological research needs to be done before anything close to a comprehensive, generalizable personality typology can be said to exist. In this regard, five issues should be kept in mind. First, attention should continue to be given to the replicability of the types across different instruments of trait assessment, the judge or rater providing the personality data, and the method of deriving the types. Second, more information is needed about the generalizability of the types across sex, both in the structure of the types and their developmental correlates. Third, attention must be given to possible age differences in the personality types that are identified. Fourth, the search for replicable subtypes must continue. Although the three types identified thus far are good candidates to become an integral part of any generalizable person-centered typology, this does not mean that there are only three personality types, just as the five factor model does not imply that there are only five personality dimensions. It simply means that, at the broadest level of generalization, psychological theories must account for the development of these types. Fifth, attention needs to be given to the utility of types and their relative benefits, if any, over dimensional, trait models. Some researchers have suggested, on empirical grounds, that knowledge of a person's type membership is useful only because it is a convenient summary of his or her trait standing (Costa, Herbst, McCrae, Samuels, & Ozer, 2002); the evidence for the incremental validity of type membership (over dimensions) is sparse. Other researchers have suggested that fair tests of the incremental validity of types have not yet been carried out. Although types may not win, or fare better, in a head-to-head comparison of the predictive validity of personality types versus dimensions, Robins and Tracy (2003) suggest that for developmental researchers, "adopting a type approach is particularly

important because it is unlikely that environmental events and contexts ever influence a single trait in isolation. Parents, teachers, and other socializing agents interact with the whole child, not with one trait at a time” (p. 114). Still others have noted that, even if types do not offer incremental validity, they offer intuitive appeal and clarity. The practical implications of person-centered research are easier than trait-based research to communicate to policymakers and research consumers (Asendorpf, 2003; Hart et al., 2003).

**TEMPERAMENT AND PERSONALITY TRAITS: A PROCESS-FOCUSED, DEVELOPMENTAL TAXONOMY FROM CHILDHOOD TO ADULTHOOD**

In this section, we elaborate a taxonomy of personality traits in children and adolescents. We draw on three sources of data: (1) recent research on the structure of personality in children and adolescents, (2) developmental research on single traits, and (3) international studies of adult personality structure. Each of these sources of information is important for different reasons. First, the factor-analytic questionnaire studies in youths generate especially useful information about the structure of the higher-order traits. Second, developmental research provides a strong source of information about the nature of the lower-order traits because these traits have been studied using a variety of methods, including naturalistic observation and lab-based studies. Third, the recent work on personality structure in adults is also critically important to the study of individual differences in children. The adult personality research helps to link higher-order traits with their lower-order components and highlights potentially valid and important lower-order traits that may have been overlooked in de-

velopmental research. Further, adult personality research is increasingly international in scope (Church, 2001), particularly the research deriving from the lexical tradition. This international work has the potential to create a personality taxonomy that is more generalizable and replicable (Saucier & Simonds, in press).

It is important to include lower-order traits in our proposed taxonomy. The Big Five are too broad to capture all the interesting variations in human personality, and distinctions at the level of more specific traits are necessary. The advantage of broad categories, such as those described by the five-factor model, is their substantial bandwidth; the disadvantage of broad categories is their low fidelity (John & Robins, 1993). Lower-order traits may provide better prediction of behavioral outcomes than the higher-order traits (Paunonen & Ashton, 2001). Further, behavioral genetic research suggests that personality is “inherited as a large number of genetic dimensions that have relatively specific effects on personality phenotypes and a smaller number of genetic dimensions that have broader effects” (Livesley, Jang, & Vernon, 2003, p. 78). Thus, the lower-order traits are shaped in part by genetic influences that have effects on all of the components of the higher-order traits, but each lower-order trait is also influenced by unique genetic influences. It will not be possible to understand the genetic (and possibly environmental) origins of personality fully without considering the lower-order traits.

In this taxonomy, we integrate what is known about diverse aspects of each trait. First, we present a description of the Big Five traits and the lower-order traits likely to be subsumed by them (see Table 6.2). There is no a priori reason to assume that each higher-order trait will include an equal number of lower-order traits; thus, the number of lower-order components varies for each of the higher-order traits. We also note some of the lower-

**TABLE 6.2 A Proposed Taxonomy of Higher-Order and Lower-Order Personality Traits in Childhood and Adolescence**

Higher-Order Traits	Extraversion (E)	Neuroticism (N)	Conscientiousness (C)	Agreeableness (A)	Openness to Experience (O)
Lower-order traits	Sociability	Fear	Attention	Prosocial tendencies	Intellect
	Energy/activity level	Anxiety	Self-control	Antagonism	Creativity
		Sadness	Achievement motivation	Willfulness	Curiosity
			Orderliness		
	Low E + N	N + low A	C + A		
	Social inhibition	Anger/irritability	Responsibility		
		Alienation/mistrust			

*Note:* The lower-order traits shown at the bottom of the table typically load on both of the higher-order traits shown.

order traits that have been identified in adults that have not been studied in children but that may well emerge in childhood or adolescence. Some of the lower-order traits appear to load onto more than one higher-order trait in factor-analytic studies; we note instances where this occurs. We have presented earlier versions of this taxonomy elsewhere (Caspi, Roberts, & Shiner, 2005; Shiner, 1998; Shiner & Caspi, 2003) but have made revisions to it based on more recent research. Second, we review what is known about the early temperamental antecedents of each trait; although there is much more to study, a great deal has already been learned about the early childhood precursors of the personality traits seen in adults and children. Third, we survey theories and evidence about the processes underlying each trait. One of the great benefits of a consensually agreed-upon taxonomy of traits is that it allows researchers to train their lenses on how personality traits express themselves in everyday life and on the fundamental processes underlying variations in these traits. We thus review some of the most interesting current work on the psychological and biological underpinnings of each Big Five trait.

### Extraversion

Children vary in their tendencies to be vigorously, actively, and surgently engaged with the world around them. Extraverted children and adolescents are described in Big Five studies as sociable, expressive, high-spirited, lively, socially potent, physically active, and energetic. In contrast, introverted youths are quiet, inhibited, and lethargic. Observations of preschoolers reveal a similar, coherent set of behaviors: high positive affect, energy and zestful engagement, and eager anticipation of enjoyable events (Buckley, Klein, Durbin, Hayden, & Moerk, 2002). The Revised Class Play, a peer nomination measure for elementary school children, also yields a factor resembling Extraversion (Morison & Masten, 1991); children high on this factor are described by peers as outgoing, sociable leaders who wield considerable social influence. Based on observational measures, extraverted children indeed are more talkative, more dominant, and more involved and engaged in interaction than their introverted peers (Markey, Markey, & Tinsley, 2004).

#### *Extraversion: Lower-Order Traits*

Extraversion encompasses the lower-order traits of sociability and energy/activity level. Another lower-order

trait—social inhibition—is related to both Extraversion and Neuroticism. *Sociability* (or gregariousness) is the most prototypical lower-order component of Extraversion. It includes the preference for being with others rather than alone (A. Buss & Plomin, 1984; D. Buss & Plomin, 1975) and a variety of behaviors that suggest vigorous, active ways of making connections with others: talkativeness, friendliness, vivaciousness, and expressiveness (Peabody & De Raad, 2002).

Sociability can be distinguished conceptually and empirically from *social inhibition*, feelings of discomfort and reluctance to act in novel situations. As noted previously, fear/inhibition is a trait readily identified in infants and toddlers. Shyness appears to be one aspect of a broader inhibition trait in older children. Inhibition consists of a number of related but distinct behaviors: hesitance with new peers and adults, wariness in physically challenging and unfamiliar situations, difficulty with separation from parents, and acute discomfort in performance situations (Bishop, Spence, & McDonald, 2003). This trait has been measured through a variety of observed behaviors in toddlers, preschoolers, and older children, such as a fearful response to novel situations (e.g., a toy robot, a gorilla head mask, an adult dressed as a clown) and reticent, withdrawn behavior with unfamiliar adults or children (Kagan, Snidman, & Arcus, 1998; Pfeifer, Goldsmith, Davidson, & Rickman, 2002; Rubin, Burgess, & Hastings, 2002). Sociability and social inhibition represent distinct traits: Sociability is a pure marker of Extraversion, whereas social inhibition appears to be a more complex blend of low Extraversion and high fear or anxiety in the presence of novel situations (Asendorpf & van Aken, 2003b; Eisenberg, Fabes, & Murphy, 1995; Markon et al., 2005; Nigg, 2000).

*Energy* and *activity level* are aspects of Extraversion that are easily observed among children. Energetic engagement with pleasurable tasks is a component of Extraversion by around age 2 or 3 (Halverson et al., 2003; Lamb et al., 2002). Because people become less motorically active with age, activity level may no longer be a separate lower-order component of Extraversion by adulthood and instead may be manifest in greater talkativeness, enthusiasm, and energy (Eaton, 1994). As noted previously, activity level can be observed as a reliable individual difference in infants and is sometimes associated with negative emotions. Similarly, older children are also likely to exhibit individual differences in poorly regulated motor output (Goldberg, 2001), as evidenced, for example, in the fidgeting and impulsive

motor movements associated with Attention-Deficit/Hyperactivity Disorder (ADHD; American Psychiatric Association, 1994). Such poorly controlled, impulsive activity is not typically focused on the pursuit of productive ends as in high Extraversion and is more likely to be associated with low Conscientiousness and low Agreeableness in children (Goldberg, 2001). The two types of motor activity need to be distinguished in childhood.

Another possible component of Extraversion is *social dominance*, the tendency to be assertive, to exert control over others, and to capture and enjoy others' attention. Such tendencies are related to Extraversion in adults, but also may be associated with low Agreeableness (Markon et al., 2005). Because these traits are likely to be an important contributor to children's emerging capacities for leadership, positive expressions of social dominance are worthy of research attention in children.

#### ***Extraversion: Early Childhood Antecedents***

A number of early individual differences predict aspects of Extraversion later in childhood. First, questionnaire and observational measures of positive emotions, such as smiling and laughter, predict childhood Extraversion (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Rothbart, Derryberry, & Hershey, 2000). In one study, full-face positive emotions in the Strange Situation at 18 months (a presumed marker of high-intensity positive emotions) predicted Extraversion at 3.5 years (Abe & Izard, 1999). Other aspects of childhood Extraversion are also predicted by infant measures of sociability (Hagekull & Bohlin, 2003), positive activity level (Hagekull & Bohlin, 2003; Korner et al., 1985), shorter observed latency to grasp small objects (Rothbart, Derryberry, et al., 2000), and lower observed fear (Rothbart, Derryberry, et al., 2000). Measures of higher infant frustration also predict later aspects of childhood Extraversion (Rothbart, Derryberry, et al., 2000); we return shortly to this interesting link between anger/frustration and Extraversion.

Longitudinal research on social inhibition suggests that infant negative emotional reactivity to overstimulation predicts later inhibition and that inhibition is somewhat stable for a subset of children, particularly those who are extreme on these traits (Kagan et al., 1998; Pfeifer et al., 2002). However, maternal behavior appears to moderate these relations, such that inhibited children receiving intrusive, derisive, or overprotective parenting remain more consistently inhibited across time than inhibited children receiving other parenting

(Arcus, 2001; Park, Belsky, Putnam, & Crnic, 1997; Rubin et al., 2002). Finally, a 23-year longitudinal study found that highly confident, friendly, and zealous 3-year-olds exhibited high Extraversion as adults, whereas socially reticent, fearful 3-year-olds exhibited low scores on this trait in adulthood (Caspi, Harrington, et al., 2003).

#### ***Extraversion: Underlying Processes***

Three main models have been advanced to explain the basis of the Extraversion trait. Although each model emphasizes different aspects of the trait, the models are clearly related and can be integrated. Moreover, all three models of Extraversion help to make sense of the findings regarding the associations between the emergence of Extraversion and positive emotions, high energy and activity, and active social behavior in the early years of development.

First, Extraversion is often conceptualized as the predisposition to experience positive emotions (Tellegen, 1985; Watson & Clark, 1997). As noted, the expression of positive emotions in infancy is predictive of later markers of Extraversion. These links between Extraversion and the experience of positive emotions are robust in adulthood as well; a meta-analysis obtained an average correlation of .37 between Extraversion and the concurrent experience of positive affect (Lucas & Fujita, 2000). Individuals vary in the extent to which they act extraverted throughout the course of a day; at those times when they act more extraverted, individuals experience greater positive emotions (Fleeson, Malanos, & Achille, 2002). Extraverts also appear to be more motivated and skilled at prolonging the experience of positive emotions than introverts (Hemenover, 2003).

Why are Extraversion and positive affect linked so consistently? One possibility is that more extraverted individuals engage in activities that promote positive affect, such as spending time with friends. Extraverted adults do engage in more social activity, which results in positive affect, but social activity alone does not account for the Extraversion-positive affect link (Watson, Clark, McIntyre, & Hamaker, 1992). An additional explanation is a temperamental view of Extraversion—that there are endogenous links between Extraversion and positive affect. There is good evidence for this contention: Extraversion is robustly associated with both pleasant (e.g., happy, good) and activated (e.g., alert, excited) positive emotions in emotionally neutral conditions (Lucas & Baird, 2004). Extraverts experience more positive emotions than introverts even when alone.

Extraversion is also sometimes associated with increased activated (but not pleasant) positive emotions in pleasant conditions (Lucas & Baird, 2004); thus, there is some more limited evidence that extraverts show greater positive emotional reactivity to positive events. Behavior genetic research provides support for both a genetically and an environmentally mediated link between Extraversion and positive emotions: Sociability and the positive affects covary because of shared genetic and nonshared environmental influences (Eid, Riemann, Angleitner, & Borkenau, 2003).

Second and relatedly, Extraversion has been conceptualized as a biologically based behavioral activation, approach, or appetitive system. The most influential framework for understanding this approach system has been Gray's (1987, 1990) model of the Behavioral Activation System (BAS). According to Gray, the BAS is a neurobiological system that responds to incentives for appetitive behavior, including signals of reward, nonpunishment, and escape from punishment. Individuals with a stronger BAS should be highly attentive to such incentives: When this system is activated, individuals begin to approach or pursue goals. Measures of BAS functioning in children have recently been developed (Blair, 2003; Colder & O'Connor, 2004). Biological evidence for an approach system derives from Davidson and colleagues' work demonstrating that specialized neural substrates for behavioral approach exist in the left anterior cerebral cortex (Davidson, Pizzagalli, Nitschke, & Kalin, 2003). Adults with greater BAS sensitivity do appear to seek out experiences that produce higher levels of positive affect (Gable, Reis, & Elliot, 2000) and derive their sense of well-being from such positive emotional experiences (Updegraff, Gable, & Taylor, 2004). This approach model of Extraversion helps to make sense of the fact that Extraversion can sometimes be associated with experiences of anger and frustration in both adults and children, in addition to its more typical associations with positive affect (Carver, 2004; Donzella, Gunnar, Krueger, & Alwin, 2000); anger may be experienced to a greater degree among extraverted individuals when they fear they may not or actually do not obtain the rewards they pursue with such vigor.

A third, potentially fruitful model of Extraversion is that it represents the tendency to attract, maintain, and enjoy social attention (Ashton, Lee, & Paunonen, 2002). According to this model, Extraversion serves an adaptive, evolutionary function by holding others' attention in ways that provide rewards; thus, this model posits that the reward-seeking tendencies and positive emotions as-

sociated with Extraversion are simply correlates of the pursuit of social attention.

### Neuroticism

Just as children vary in their predisposition toward positive emotions, they vary in their susceptibility to negative emotions and general distress. In the Big Five studies, children and adolescents who are high on Neuroticism are described as anxious, vulnerable, tense, easily frightened, "falling apart" under stress, guilt-prone, moody, low in frustration tolerance, and insecure in relationships with others. Fewer descriptors define the lower end of this dimension; these include traits such as stability, being "laid back," adaptability in novel situations, and the ability to "bounce back" after a bad experience. As these descriptions of childhood Neuroticism illustrate, the trait appears to include both the child's experience of negative emotions and the child's effectiveness at self-regulating such negative emotions.

Neurotic individuals tend to be self-critical, insecure, and sensitive to criticism and teasing. Neuroticism may actually be part of an underlying personality dimension that includes self-esteem, locus of control, and generalized self-efficacy (Judge, Erez, Bono, & Thoresen, 2002). Neuroticism thus may be one key aspect of a more general tendency to view oneself and the world through a negative lens (Erez & Judge, 2001). Neurotic adults tend to be dissatisfied with major aspects of their lives, including their relationships, work, and health (Heller, Watson, & Ilies, 2004). Behavioral observations confirm the questionnaire descriptions of children high on this trait; childhood Neuroticism is associated with behaviors such as making self-critical statements, expressing a sense of self-pity and guilt, acting irritated, and showing signs of physical tension (Markey et al., 2004). Higher Neuroticism may also be linked with a variety of aversive interpersonal behaviors in childhood. In an observational study of parent-child interaction, higher Neuroticism was correlated with keeping parents at a distance, seeming detached, speaking sarcastically, and exhibiting low levels of upbeat, enthusiastic behavior (Markey et al., 2004).

### Neuroticism: Lower-Order Traits

Neuroticism is likely to include a number of lower-order traits, including fear, anxiety, and sadness. Two other lower-order traits appear to be related to both high Neuroticism and low Agreeableness: (1) anger/irritability and (2) alienation/mistrust.

Based on the extensive literature on negative emotions deriving from research on psychopathology, it may be possible to break down the negative emotions included in Neuroticism into at least three distinct but related lower-order traits: (1) fear, (2) anxiety, and (3) sadness (Barlow, 2000; Chorpita, Albano, & Barlow, 1998; Muris, Schmidt, Merckelbach, & Schouten, 2001). *Fear* represents negative affect and bodily symptoms arising from exposure to an actual or an imagined object or situation. The definition of fearfulness in the psychopathology literature is highly similar to the dimensions of fear/social inhibition described previously, in that these individual differences all involve negative emotions arising from actual exposure to a feared situation (e.g., a novel stimulus or exposure to unfamiliar peers); future research will need to determine whether fear and social inhibition should be seen as distinct traits. *Anxiety* taps tendencies toward nervous apprehension, general distress, worry, and physical tension when there is no imminent threat. The symptom-based measures of anxiety are highly comparable to the general measures of Neuroticism used with children and adults. *Sadness* includes behaviors associated with depression, including lowered mood, hopelessness, and dejection arising from experiences of disappointment and loss. Sadness is included as a lower-order trait in some temperament and personality models (e.g., Costa & McCrae, 1992; Rothbart, Ahadi, et al., 2001) but it is usually only a minor component of most Neuroticism measures, which tend to emphasize anxiety. The distinctive aspects of sadness thus may be obscured when only the general Neuroticism trait is assessed (Moon, Hollenbeck, Humphrey, & Maue, 2003). For example, relative to other aspects of Neuroticism, adult sadness is a more robust predictor of life satisfaction (Schimmack, Oishi, Furr, & Funder, 2004) and global self-esteem (Watson, Sulz, & Haig, 2002).

In general, much more work is needed to understand the development of individual differences in fear, anxiety, and sadness, especially given their links with a broad spectrum of psychiatric disorders (Watson, 2001). A great deal of productive work has focused on fear/inhibition as a risk factor for the development of anxiety disorders (Kagan & Snidman, 1999). The emergence of individual differences in anxiety and sadness will be equally important to study, especially given evidence that most adolescents with anxiety disorders do not show inhibited temperament as younger children (Prior, Smart, Sanson, & Oberklaid, 2000). A better under-

standing of how early Neuroticism develops could yield crucial information for prevention programs. Such research is important in light of evidence that children's average level of anxiety appears to have increased from the 1950s to the 1990s (Twenge, 2000).

As we noted previously, individual differences in anger and frustration relate to both the higher-order Neuroticism and Agreeableness traits. *Anger/irritability* taps outer-directed, hostile emotions such as anger, jealousy, frustration, and irritation (Halverson et al., 2003); in children, such hostility is often evoked by limits set by adults. In samples of American children and adults, an anger/irritability trait is moderately correlated with both high Neuroticism and low Agreeableness (Halverson et al., 2003; Kochanska, Friesenborg, Lange, & Martel, 2004; Markon et al., 2005). In a number of international lexical studies, anger/irritability is more clearly associated with low Agreeableness than with high Neuroticism (Ashton et al., 2004).

In some studies with both adults and children, anger/irritability has been viewed as part of an overarching Negative Emotionality trait that includes both Neuroticism and anger/irritability (Buckley et al., 2002; Lengua, 2002; Rothbart, Ahadi, et al., 2001; Tellegen, 1985). Questionnaire studies, lab tasks, and naturalistic observations have all demonstrated that children and adults who are prone to experiencing one type of negative emotion are prone to experiencing other types of negative emotions as well. It is important to separate Neuroticism from anger/irritability for several reasons. As noted previously, it is possible to distinguish fear/inhibition from anger/irritability beginning in infancy. These two types of negative emotions appear to require different regulatory strategies; for example, distraction works to reduce anger but not fear in infants (K. Buss & Goldsmith, 1998). Fear and anger have different and sometimes opposite effects on cognitive processing (e.g., fear promotes risk aversion, whereas anger promotes risk-seeking; Lerner & Keltner, 2000). The adaptive profiles associated with each trait differ as well. For example, whereas fearfulness appears to protect against childhood aggression (Raine, Reynolds, Venables, Mednick, & Farrington, 1998), anger and irritability put children at risk for later aggression (Loeber & Hay, 1997).

A final lower-order trait, *alienation/mistrust* has been identified in adults and, like anger/irritability, is related to high Neuroticism and low Agreeableness (Kochanska et al., 2004; Markon et al., 2005; Martin,

Watson, & Wan, 2000). This trait taps an individual's tendency to mistrust others and to feel mistreated (Tellegen & Waller, 1992). Individual differences in interpersonal alienation and mistrust have been identified in research on social information processing in youths (Crick & Dodge, 1994) and in the attachment literature (Sroufe, Carlson, Levy, & Egeland, 1999). In adults, this trait is highly linked with poor life adaptation and may emerge in part from repeated experiences of failure across development (Shiner, Masten, & Tellegen, 2002).

Childhood Neuroticism may include other aspects that are worthy of consideration, including children's tendencies toward *dependence*, low *self-confidence*, *vulnerability* in the face of stress and *emotional instability*.

#### ***Neuroticism: Early Childhood Antecedents***

A number of early childhood traits have been identified as predictors of Neuroticism and its components. Emotional expression in the Strange Situation procedure at 18 months predicts Neuroticism at 3.5 years (Abe & Izard, 1999); specifically, high-intensity full-face negative emotions (sadness and anger) predict Neuroticism positively, and milder, more regulated positive emotions (interest and joy) predict Neuroticism negatively (Abe & Izard, 1999). Consistent with this finding, childhood fearfulness and sadness are predicted by infant measures of high fear and low positive emotions (Rothbart, Derryberry, et al., 2000). Childhood sadness is additionally predicted by low infant frustration (Rothbart, Derryberry, et al., 2000). In contrast, childhood anger/frustration is not predicted by infant fear but, instead, is predicted by infant high frustration, high activity level, and short latency to grasp small objects (Rothbart, Derryberry, et al., 2000). Childhood anger/frustration is predicted by early markers of Extraversion, consistent with the previously discussed claim that high Extraversion may generate high frustration when goals are blocked. Thus, childhood fear and anger appear to have relatively distinct and separate antecedents, whereas childhood sadness shares some common infant antecedents with both.

Although fear and anger appear to be separate in childhood, over time greater anger may come to predict higher anxiety and distress. For example, in one longitudinal study, preschool-age children who were irritable, distractible, labile, and uncontrolled grew up to be more Neurotic as adults (Caspi, Harrington, et al., 2003); it may be the case that the greater adult anxiety experienced by previously angry, undercontrolled children

emerges as these children encounter the ill effects of their behavior.

#### ***Neuroticism: Underlying Processes***

Research with adults has helped to characterize the cognitive style, daily experiences, and interpersonal functioning of individuals high on Neuroticism. Developmental researchers have also studied the links between attention and executive control and children's experiences of negative emotions. In this section, we focus on the processes underlying the anxiety, fear, and sadness aspects of Neuroticism and discuss anger/irritability in our discussion of Agreeableness.

In cognition, adults high on trait anxiety show attentional biases toward information relevant to their personal fears; such biases are consistent with a model of anxiety as helping to prepare individuals for potentially dangerous situations by rapidly focusing attention on threatening material (Mineka, Rafaeli, & Yovel, 2003). In contrast, tendencies toward depression are associated with biases toward remembering and ruminating over past negative experiences (Mineka et al., 2003). Adults high on trait anxiety and adults high on depression are biased toward assuming they will encounter unduly negative experiences in the future. More generally, adult Neuroticism is associated with an emotionally negative tone in individuals' narratives about key experiences in their lives (McAdams et al., 2004) and with greater cognitive processing of unpleasant, negative information (Gomez, Gomez, & Cooper, 2002). Thus, there is good evidence that Neuroticism and its lower-order components are associated, at least in adulthood, with biases toward processing negative information, though the biases may vary somewhat for different lower-order components.

Developmental research provides an interesting perspective on why Neuroticism may be linked with various cognitive biases. Beginning in infancy and continuing throughout childhood, greater attentional control is associated with more effective regulation of negative emotionality (Eisenberg, Smith, Sadovsky, & Spinrad, 2004; Rueda, Posner, & Rothbart, 2004). Initially, parents are an important source of assistance with such emotional regulation, but over time children develop more of their own capacities for self-regulation. Neurotic individuals' bias toward attending to negative information may arise in part from difficulties in executive functioning, particularly with attention. The converse could also be true: Neuroticism may

bias individuals toward focusing on negative cues, which could interfere with the allocation of attention (MacCoon, Wallace, & Newman, 2004).

Just as Neuroticism is associated with negative cognitive biases, it is also linked with more negative daily experiences in adults. In lab-based studies, neurotic adults report more negative emotional responses to a variety of negative stimuli than less neurotic adults (Gross, Sutton, & Ketelaar, 1998). Experience-sampling studies have demonstrated that this negative emotional reactivity occurs in daily life as well: Neurotic adults have stronger negative emotional reactions to everyday problems, including both interpersonal conflicts and stress at work and at home (Bolger & Schilling, 1991; Gable et al., 2000; Suls, Martin, & David, 1998). Neurotic individuals may find daily problems to be more stressful, in part, because they tend to use ineffective coping responses, such as escape and avoidance, and high levels of interpersonal confrontation (O'Brien & DeLongis, 1996). Finally, more neurotic individuals tend to show some distinguishing patterns of interpersonal behavior, including more disagreeable and submissive behavior and less agreeable and dominant behavior (Cote & Moskowitz, 1998). Neurotic adults also show more lability across situations in their interpersonal behaviors (Moskowitz & Zuroff, 2004), which may lead others to form the impression that they are unpredictable. The interpersonal behaviors associated with Neuroticism in adults are consistent with the previously described aversive interaction style observed in more neurotic children. In summary, the process-oriented studies with adults have demonstrated that Neuroticism is associated with a variety of difficulties in emotional and behavioral regulation.

All of these findings regarding Neuroticism are consistent with the claim that individual differences in Neuroticism are associated with variation in a biologically based withdrawal, inhibition, or avoidance system. As with Extraversion, one of the most important frameworks for understanding this system has been a model developed by Gray (1987, 1990). According to Gray, individuals differ in the sensitivity of a neurobiological Behavioral Inhibition System (BIS), which serves to inhibit behavior in the face of potential punishment, non-reward, and novelty. Thus, individuals with a strong BIS should be sensitive to signals of threats and should be quick to withdraw or inhibit their behavior when they perceive such signals. Measures of BIS functioning in

children have recently been developed (Blair, 2003; Colder & O'Connor, 2004). As with Extraversion, Davidson and colleagues have shown that there are specialized neural substrates for behavioral withdrawal, in this case in the right anterior cerebral cortex (Davidson et al., 2003). In situations that present both incentives and threats, individuals may experience an approach-avoidance conflict. In such situations, the goal of avoidance is likely to win out over the goal of approach (Gray & McNaughton, 1996), perhaps because negative emotions have more widespread and lasting effects than positive emotions (Larsen & Prizmic, 2004). Although more Neurotic individuals may be motivated to avoid and minimize aversive experiences, they do not appear to be successful at doing so. Rather, they tend to experience more negative life events than less Neurotic individuals (Magnus, Diener, Fujita, & Pavot, 1993) and experience higher levels of negative emotions in response to such experiences (Gable et al., 2000). The findings on the biological and psychological processes associated with Neuroticism should provide impetus to study similar processes associated with the development of Neuroticism in children.

### Conscientiousness

An overarching Conscientiousness trait taps children's individual differences in self-control, in large part as control is used in service of completing tasks and striving to meet standards. In Big Five studies, highly Conscientious children and adolescents are described as responsible, attentive, persistent, orderly and neat, planful, possessing high standards, and thinking before acting. Children low on this trait are depicted as irresponsible, unreliable, careless, distractible, and quitting easily. The higher-order Conscientiousness trait is defined by a remarkably similar set of descriptors in lexical studies with adults across a wide variety of languages and countries, thereby providing strong international evidence for the nature of this trait in adulthood (Peabody & De Raad, 2002). Based on parental descriptions of children from a number of countries, parents rarely describe their children by traits linked with Conscientiousness at age 3 years but do use such descriptors more often by age 6 years (Slotboom, Havill, Pavlopoulos, & De Fruyt, 1998); parents may see these descriptors of Conscientiousness as inappropriate until their children are closer to school age. There is ev-

idence from at least one study that some of these more complex manifestations of self-control can be measured with moderate reliability in children as young as ages 3 and 4 years (Halverson et al., 2003). The numerous Big Five questionnaire studies demonstrate that these more complex traits can certainly be measured in children by middle childhood.

Rothbart, Ahadi, and colleagues (2001) have identified in children a similar temperament trait labeled Effortful Control, which includes children's capacities to plan behavior, inhibit inappropriate responses, focus and shift attention, take pleasure in low intensity situations, and perceive subtle external stimuli. In a series of studies, Kochanska and colleagues have developed a battery of tasks to measure children's emerging Effortful Control (Kochanska & Knaack, 2003; Kochanska, Murray, & Coy, 1997; Kochanska, Murray, & Harlan, 2000; Kochanska, Murray, Jacques, Keonig, & Vandegest, 1996): All of the tasks require a child to exert self-control by suppressing a dominant response in favor of carrying out a subdominant response. The tasks include delay of a pleasant behavior (e.g., waiting to unwrap a toy), slowing down fine or gross motor movements, suppressing a response to one signal and producing a response to another (e.g., producing different responses to red and green signs), whispering, and Stroop-like attention tasks requiring the child to ignore prominent features of a stimulus and to attend to other less salient features. Although children's performance on the tasks is less internally consistent at 22 months, the tasks reveal a more coherent set of behaviors by 33 months and measure a highly coherent, stable trait by 45 months. Thus, questionnaire and observational studies confirm that children differ reliably in their manifest levels of self-control.

Although temperament and personality models both include dimensions related to self-control, the content of these traits differs somewhat. Temperament models tend to emphasize attention and impulse control, which are individual differences that can be identified in a rudimentary form in very young children. In contrast, personality models include not only impulse control but also traits that children do not exhibit until they are older, such as orderliness, dependability, and motivation to meet goals and complete work. There is some preliminary evidence from one questionnaire study that Big Five Conscientiousness is highly related to Effortful Control (Halverson et al., 2003) but much more work

will be needed to clarify the similarities and differences between the personality and temperament conceptions of this higher-order trait. In particular, as we elaborate in our discussion of Agreeableness, temperamental Effortful Control may represent differences in control that can be applied to tasks and achievement (as in the case of Conscientiousness) and to social relationships (as in the case of Agreeableness). There is some evidence that childhood Effortful Control is linked with Agreeableness (Cumberland-Li, Eisenberg, & Reiser, 2004). Questionnaire studies of the Big Five in adults indicate that Conscientiousness and Agreeableness tend to covary and coalesce to form a superordinate trait (Markon et al., 2005); it is certainly possible that a basic tendency toward behavioral constraint versus disinhibition underlies both of these traits.

### *Conscientiousness: Lower-Order Traits*

Conscientiousness in children includes a number of lower-order components: attention, self-control, achievement motivation, orderliness, and responsibility. *Attention* versus distractibility taps children's capacity to focus attention, regulate attention by shifting mental sets, and persist at tasks in the face of distractions. As noted previously, individual differences in attention emerge in infancy. Attention versus distractibility is a lower-order component of Conscientiousness and Effortful Control in questionnaire measures for older children (Halverson et al., 2003; Putnam et al., 2001). Although attention is an important trait in most childhood temperament models (Shiner, 1998), it is not prominent in adult personality models. Descriptors related to attention may have been left out of adult personality questionnaire studies because such terms are often seen as more relevant to the domains of intellect and cognition than to the domain of personality. Further, by adulthood individual differences in attention and executive control may underlie most of the components of Conscientiousness; we return to this point in our discussion of the processes underlying Conscientiousness.

Four other lower-order components of Conscientiousness have been identified in factor-analytic questionnaire studies with children and adults. *Self-control* taps tendencies to be planful, cautious, deliberate, and behaviorally controlled (Peabody & De Raad, 2002; Roberts, Bogg, Walton, Chernyshenko, & Stark, 2004; Rothbart, Ahadi, et al., 2001). *Achievement motivation* (also called work or industriousness) taps the tendency

to strive for high standards, to work hard and be productive, and to pursue goals over time in a determined, persistent manner (Halverson et al., 2003; Peabody & De Raad, 2002; Roberts et al., 2004). *Orderliness* (or organization) reflects a propensity to be neat, clean, and organized rather than sloppy, disorganized, and disorderly (Halverson et al., 2003; Mervielde & De Fruyt, 2002; Roberts et al., 2004). These are all behaviors that involve the active structuring of a person's tasks and environment. *Responsibility* ranges from the tendency to be reliable and dependable to the tendency to be irresponsible and unreliable (Goldberg, 2001; Peabody & De Raad, 2002; Roberts et al., 2004); this subcomponent appears to measure Conscientiousness manifested in relation to other people and may be a blend of Conscientiousness and Agreeableness (Goldberg, 2001; Roberts et al., 2004). Achievement motivation, orderliness, and responsibility are traits typically left out of temperament models; these three lower-order traits seem likely to be important for children's development and warrant more thorough study.

Observations of delay of gratification have been used in a number of studies to assess children's self-control; the most well-known work on observed delay of gratification is Mischel's longitudinal research (Mischel & Ayduk, 2004). Delay of gratification is typically assessed in these studies by placing children in a situation in which they have to choose between an immediate but smaller prize and a delayed but larger prize. Although children's ability to delay in this paradigm is related to their attentional capacities, this measure is probably not a pure measure of self-control because children's approach tendencies are also likely to influence their abilities to delay (Eisenberg, Smith, et al., 2004).

### ***Conscientiousness: Early Childhood Antecedents***

Childhood markers of self-control are predicted in conceptually coherent ways by several early individual differences, and childhood self-control itself is remarkably stable by the preschool years. Not surprisingly, the ability to focus attention in infancy predicts Effortful Control later in childhood (Kochanska et al., 2000). Individual differences in persistence at tasks (similar to the lower-order attention trait described previously) have been found to be highly stable from the toddler to preschool years and from middle childhood to adolescence (Guerin, Gottfried, Oliver, & Thomas, 2003). As noted previously, observed Effortful Control itself is a moderately stable trait from 22 to 33 months and is a

highly stable trait from 33 to 45 months (Kochanska & Knaack, 2003). Early IQ has also been found to predict persistence at tasks (Guerin et al., 2003) and Effortful Control (Kochanska & Knaack, 2003) later in childhood.

Early differences in emotional reactivity also predict later self-control in several studies. Milder, more regulated positive emotions in the Strange Situation procedure at 18 months have been found to predict Conscientiousness at 3.5 years (Abe & Izard, 1999). In contrast, several early individual differences predict lower levels of self-control in childhood: Earlier anger and intense joy negatively predict preschool Effortful Control (Kochanska & Knaack, 2003), and shorter latency to approach and grasp small objects in infancy negatively predicts attention and self-control in childhood (Rothbart, Derryberry, et al., 2000). These findings regarding the links between early emotional reactivity and later self-control are provocative but difficult to interpret. It seems likely that infants and toddlers with stronger approach tendencies (those with intense positive emotions and a quick approach) and stronger anger may have more difficulty developing self-control because they have stronger emotions to regulate; they must work against their eager or angry tendencies to exhibit self-control. However, it is also possible that children's early expressions of anger and high-intensity positive emotions may partly tap early difficulties with self-control, which could account for why these early emotions predict later self-control. More work will be needed to clarify the transactions between the emotion-based traits and self-control across childhood.

### ***Conscientiousness: Underlying Processes***

Conscientiousness indexes a child's or adult's active engagement with various tasks; an individual high on this trait invests greater energy in completing work, upholding commitments, and maintaining order (Ashton & Lee, 2001). Conscientiousness thus should tap a person's capacity to exercise self-control in the service of effective task completion. The adaptive profile associated with Conscientiousness is consistent with such a view of the trait. As we review later in this chapter, childhood Conscientiousness predicts better academic achievement and improvement in academic achievement over time, and adult Conscientiousness is the best personality trait predictor of work success (Judge, Higgins, Thoreson, & Barrick, 1999). One reason that more conscientious adults may excel in school and work is that they tend to use planful problem solving as a way of handling stres-

sors in these domains of their life rather than trying to escape or avoid such problems (O'Brien & DeLongis, 1996). Conscientious adults also tend to set higher goals for themselves, are more committed to meeting those goals, and have greater confidence that they can meet those goals (Barrick, Mount, & Strauss, 1993; Judge & Ilies, 2002). The data on Conscientiousness make clear that this trait is highly relevant to effectiveness in the areas of striving and achieving; however, it is important to recognize that Conscientiousness may be detrimental to performance in certain contexts (see Tett & Burnett, 2003, and Yeo & Neal, 2004, for reviews). An important area of future research will be examining in closer detail the ways that conscientious children and adults approach and accomplish their daily tasks and goals.

The importance of Conscientiousness is not restricted to task-focused endeavors; rather, Conscientiousness is often associated with effective social functioning as well. For example, a study of observed interactions between school-age children and their parents showed that child Conscientiousness was (unsurprisingly) associated with greater exhibited intelligence and ambition and (unexpectedly) with better social skills, warmth, and cooperativeness (Markey et al., 2004). Childhood Conscientiousness also often predicts concurrent and later peer social competence and rule-abiding behavior (Lamb et al., 2002; Shiner, 2000; Shiner, Masten, & Roberts, 2003) and better conflict resolution with peers (Jensen-Campbell & Graziano, 2001). One straightforward reason that Conscientiousness may be linked with effective social functioning is that self-regulation is clearly important for maintaining social relationships in both childhood and adulthood (Eisenberg, Fabes, Guthrie, & Reiser, 2000; Vohs & Ciarocco, 2004).

A second, deeper reason for these links between Conscientiousness and social functioning may involve the underlying nature of the Conscientiousness trait. Based on socioanalytic theory, Hogan and Ones (1997) have argued that individual differences in Conscientiousness reflect variations in the adoption of and compliance with the rules and expectations of the group, as conveyed by various authority figures (e.g., parents and teachers in childhood; work supervisors in adulthood). Indeed, in adulthood some aspects of Conscientiousness are linked with greater valuing of conformity (Roccas, Sagiv, Schwartz, & Knafo, 2002). Consistent with this model, Effortful Control in childhood is associated with toddlers' and preschoolers' "committed compliance" or internalization of parental rules

(Kochanska, Clark, & Goldman, 1997; Kochanska, Coy, & Murray, 2001). Conscientiousness thus may reflect children's and adults' adoption of society's norms for regulated behavior.

Having considered the nature of Conscientiousness from a theoretical point of view, it is important to examine the more basic biological and psychological processes that are likely to underlie individual differences in this trait. Conscientiousness is not the same as self-regulation because self-regulation is relevant to other individual differences as well; however, research on self-regulation may shed some light on Conscientiousness. Researchers studying the biological basis of self-regulation have pointed to the importance of the prefrontal cortex for a variety of self-regulatory skills, including working memory, emotional processing, planning, novelty detection, resolving conflicting information, initiating action, and inhibiting inappropriate responses (Banfield, Wyland, Macrae, Munte, & Heatherton, 2004; Nigg, 2000). Posner, Rothbart, and colleagues (Posner & Rothbart, 2000; Rueda et al., 2004) consider many of these capacities to reflect individual differences in an overarching executive attention capacity, which they likewise link with the development of the frontal cortex, particularly the anterior cingulate cortex. These researchers have examined the development of executive attention across childhood. Infants show differences in alerting and orienting, which are both manifestations of a more reactive attentional system. However, by 9 and 18 months of age, infants also begin to show evidence of more voluntary control of attention. Children show marked growth in executive attention during the 3rd year of life, and this growth continues throughout childhood. Based on this model, children's manifest differences in Effortful Control are driven in large part by differences in executive attention. Some empirical evidence is beginning to substantiate the link between executive attention and Effortful Control (Rothbart, Ellis, Rueda, & Posner, 2003).

The trait of Conscientiousness is typically seen as involving more voluntary control of behavior, as implied by the labels *Effortful Control* (Rothbart, Ahadi, et al., 2001) and *Will* (Digman & Inouye, 1986). This type of executive control is separate from other types of relatively more involuntary tendencies toward inhibited behavior (Eisenberg, Smith, et al., 2004; Nigg, 2000). As we noted in our discussion of Extraversion and Neuroticism, children's behavior may be inhibited because of low approach tendencies (low Extraversion) or because

of high fear or anxiety (high Neuroticism); these types of more emotion-based inhibition can be distinguished from the executive control associated with Conscientiousness (Kindlon, Mezzacappa, & Earls, 1995; Nigg, 2000). Children's emerging capacities for executive control may serve, in part, to regulate the approach and avoidance systems in the service of adaptive behavior (Rothbart, Ellis, & Posner, 2004). Active, effortful control in early childhood predicts better self-regulation of anger and joy later in childhood (Kochanska et al., 2000), and, as noted previously, better attentional control is associated throughout childhood with better regulation of negative emotions.

However, much of self-regulation is likely to occur at an automatic, nonvoluntary level. Research with adults suggests that self-regulation of cognition (even working memory) is often automatic, and the same is proving to be true for regulation of emotion and behavior (Fitzsimons & Bargh, 2004). Nonvoluntary self-regulation is important, in part, because the ability to exercise voluntary control of cognition, emotion, and behavior appears to be limited. In a number of studies with adult samples, voluntary self-control appears to operate as a strength that can be depleted temporarily with use rather than as an unlimited resource (Schmeichel & Baumeister, 2004). In short, automatic nonvoluntary regulation may be necessary as a complement to the more effortful forms of self-regulation, given that effortful regulation has limits. It will be important for developmental research to explore the development of both automatic and more voluntary forms of self-regulation in childhood.

### Agreeableness

Agreeableness includes a variety of traits seen as very important by developmental psychologists; yet, historically, these traits have been left out of temperament models. The high end of Agreeableness includes descriptors such as warm, considerate, empathic, generous, gentle, protective of others, and kind. The low end of Agreeableness includes tendencies toward being aggressive, rude, spiteful, stubborn, bossy, cynical, and manipulative. In studies with both children and adults, Agreeableness also includes being willing to accommodate others' wishes rather than forcing one's own desires and intentions on others; for children this aspect of the trait also involves how manageable the child is for parents and teachers. Observations of Agreeable chil-

dren interacting with their parents are consistent with questionnaire descriptions of such children (Markey et al., 2004): Children's high Agreeableness is positively associated with expressing agreement and warmth, seeking agreement from parents, and seeming to like parents and is negatively associated with competitiveness, condescending behavior, and criticalness. In short, Agreeableness is linked with a variety of behaviors that are likely to foster congenial relationships with both peers and adults. Given the adaptive significance of this trait, it is not surprising that parents from many countries spontaneously offer a large number of traits from this domain when they are asked to describe their children (Havill, Besevegis, & Mouroussaki, 1998).

### *Agreeableness: Lower-Order Traits*

In our discussion of Neuroticism, we already noted two lower-order traits that are linked with both Neuroticism and Agreeableness: (1) anger/irritability and (2) alienation/mistrust. A number of other lower-order traits appear to be aspects of Agreeableness in childhood: prosocial tendencies, antagonism, and willfulness. *Prosocial tendencies* (also called helpfulness or nurturance) encompasses children's individual differences in traits that demonstrate concern for other people rather than interest only in themselves. Children differ in their tendencies to be empathic, kind, and nurturant (Eisenberg, Fabes, & Spinrad, Chapter 11, this *Handbook*, this volume). Individual differences in prosocial behavior are moderately stable during the preschool- and school-age years (Eisenberg et al., 1987; Graziano & Eisenberg, 1997); there is some preliminary evidence that prosocial behavior may be stable from childhood to early adulthood (Eisenberg et al., 1999). This aspect of Agreeableness may possibly comprise two sets of traits, one tapping warmth and affection and the other tapping altruism and generosity (Saucier & Ostendorf, 1999).

*Antagonism* ranges from the tendency to be peaceful and gentle to the tendency to be aggressive, spiteful, quarrelsome, and rude (Halverson et al., 2003): Children who are high on this trait express hostility openly toward others. The lower-order trait antagonism includes both physical aggression and relational aggression (e.g., gossiping and social exclusion). There is some evidence from older children, adolescents, and adults that physical aggression and relational aggression tend to covary in individuals (Cillessen & Mayeux, 2004; Rose, Swenson, & Waller, 2004; Tellegen & Waller, 1992), although

it is also important to separate the two types of aggression for more fine-grained developmental analyses.

*Willfulness* refers to the extent to which an individual attempts to assert his or her will over others through domineering behavior (Halverson et al., 2003). Children and adults who are high on this trait are described as bossy, manipulative, overbearing, and defiant rather than accommodating and flexible (Halverson et al., 2003; Peabody & De Raad, 2002). This trait captures some of the most central aspects of Thomas and Chess's difficult child construct (Bates, 1989) and is also similar to a childhood trait labeled by Bates as "resistance to control" (Bates, Pettit, Dodge, & Ridge, 1998). Children high on this trait are likely to pose significant management problems for parents and teachers. Willfulness involves children's tendencies to assert their wills over others; however, it is important to recognize that actual dominance over others is determined by multiple traits, including aspects of extraversion, as noted previously. Specifically, observed dominance is linked with Extraversion, low Neuroticism, and greater physical aggression in both humans and animals (Anderson, John, Keltner, & Kring, 2001; Gosling & John, 1999; Hawley, 2003; Pellegrini & Bartini, 2001).

Other potential aspects of Agreeableness may exist in children. *Modesty* versus conceitedness involves the extent to which an individual is humble rather than arrogant, self-important, or boastful (Goldberg, 2001; Peabody & De Raad, 2002; Saucier & Ostendorf, 1999). *Integrity* refers to the tendency to be honest, principled, sincere, and loyal versus deceptive and disloyal (Peabody & De Raad, 2002). Integrity appears to be close in content to internalized conscience and the moral self as these constructs have been studied by Kochanska and colleagues (Kochanska, Gross, Lin, & Nichols, 2002).

Although Agreeableness is a one-dimensional trait spanning prosocial traits at the high end and antisocial traits at the low end, it may actually turn out to be better thought of as at least two separate dimensions (Graziano, 1994; Graziano & Eisenberg, 1997). Agreeableness forms a single trait in some lexical studies of adults (e.g., English and German), but it splits into two separate factors in a number of languages (Peabody & De Raad, 2002; Saucier, 2003). One of these factors is typically defined by prosocial tendencies, modesty, and integrity, and the other factor is typically defined by antagonism and willfulness. Thus, one trait involves proso-

cial concern and respect for others, whereas the other trait involves irritable, aggressive, and hostile disregard for others. Although prosocial and aggressive tendencies tend to covary negatively later in childhood, they also co-occur in some youths (Haselager, Cillessen, van Lieshout, Riksen-Walraven, & Hartup, 2002) and, when combined, may confer social benefits in some Machiavellian children (Hawley, 2003). The two aspects of Agreeableness are likely to have some overlapping origins, but also some distinct origins (Krueger, Hicks, & McGue, 2001).

### *Agreeableness: Early Childhood Antecedents*

Although Agreeableness has emerged robustly and consistently in questionnaire studies that tap a wide range of children's behaviors, the traits encompassed by this superfactor are not included in most temperament questionnaires. Perhaps these traits have been seen as less basic than other temperament traits: Temperament researchers may have considered prosocial and hostile tendencies as the developmental products of more basic, early-emerging temperaments. There is some support for the idea that Agreeableness arises, in part, from early differences in positive and negative emotions and from early self-regulation, which we discuss later. However, it is also likely that there are unique genetic and environmental contributors to Agreeableness as well. Aspects of Agreeableness emerge fairly early themselves (e.g., aggression; Tremblay, 2002) and seem to develop alongside other temperament traits. Further, many nonhuman animals display Agreeableness-like traits, even though most of these same species do not display behaviors indicating Conscientiousness (Gosling & John, 1999). Thus, it is likely that Agreeableness is not merely a product of other temperament traits. It would be useful for more longitudinal research to measure early individual differences that may be more uniquely associated with later Agreeableness, such as early behaviors indicating affection, closeness to others, and soothability.

Graziano and Eisenberg (1997) have argued that Agreeableness is likely to have its origins in the self-regulation of negative emotions. Recent studies have provided good evidence for this claim. Agreeableness itself and several of its components are predicted negatively by early differences in high-intensity irritability and frustration and positively by early attention and self-control (Abe & Izard, 1999; Eisenberg et al., 2000; Kochanska,

Murray, & Coy, 1997; Kochanska et al., 2000; Laursen, Pulkkinen, & Adams, 2002; Rothbart, Derryberry, et al., 2000; Rubin, Burgess, Dwyer, & Hastings, 2003). Good attentional control may be particularly important for helping children to shift their focus from negative emotions to positive emotions when they are angry, frustrated, or aroused (Wilson, 2003). In contrast to the negative link between early irritability and later Agreeableness, early fearfulness may actually promote higher Agreeableness because fearfulness presages greater compliance and a stronger moral self (Kochanska et al., 2002), higher empathy (Rothbart, Derryberry, et al., 2000), and lower aggression (Raine et al., 1998). However, fear and anxiety may be negatively associated with prosocial behavior toward strangers (reviewed in Eisenberg & Fabes, 1998). The picture that is emerging is that Disagreeableness develops most strongly among children whose high irritability is not constrained by either good self-regulation or by the inhibiting power of fearfulness (see Caspi, Harrington, et al., 2003, for converging longitudinal evidence).

Positive emotions and Extraversion appear to predict childhood Agreeableness in a complex pattern. Mild, regulated positive emotions presage later Agreeableness (Abe & Izard, 1999). Similarly, positive emotionality and sociability are concurrently associated with prosocial behavior and with empathy in children (reviewed in Eisenberg & Fabes, 1998, and Graziano & Eisenberg, 1997) and with prosocial tendencies in adults (Krueger et al., 2001). Agreeableness itself is linked with higher jovial mood in adults (e.g., happy, cheerful, enthusiastic; Watson & Clark, 1992). Conversely, inhibited temperament is linked with less expressed empathy (Young, Fox, & Zahn-Waxler, 1999). Thus, regulated positive emotions and sociability are likely precursors of later prosocial tendencies, though more evidence is needed. In contrast, Extraversion positively predicts later aggression and externalizing behavior problems (X. Chen et al., 2002; Shiner, 2000). High-intensity positive emotions and shorter observed latency to grasp small objects in infancy likewise predict childhood aggression (Rothbart, Derryberry, et al., 2000). Higher approach tendencies may particularly lead to greater externalizing, antisocial behavior when self-regulation is poor (Eisenberg, Spinrad, et al., 2004). As we described previously, children's Extraversion may result in high levels of frustration and anger when goal seeking is thwarted; in turn, this anger and frustration may lead children with poor self-regulation to behave aggressively. Taken

together, the data suggest that well-regulated early Extraversion is likely to predict prosocial tendencies, whereas unregulated early Extraversion is likely to predict antisocial tendencies.

### *Agreeableness: Underlying Processes*

There are large psychological literatures associated with the processes underlying the various components of Agreeableness (for reviews, see the chapters by Dodge, Coie, & Lynam on aggression, Chapter 12; Eisenberg et al., Chapter 11, this *Handbook*, this volume, on prosocial behavior): This developmental research is highly relevant for understanding the nature of Agreeableness in childhood. Rather than attempt to describe these literatures, we focus here on research that specifically examines the Big Five trait of Agreeableness in children and adults and describe potential underlying biological systems.

A number of researchers have argued that Agreeableness reflects individual differences in the motivation to maintain harmonious relationships with others; from this point of view, Agreeableness taps differences in the willingness to forgo individual interests out of concern for others (Digman & Takemoto-Chock, 1981; Graziano & Eisenberg, 1997; Graziano, Hair, & Finch, 1997; MacDonald, 1995). A number of recent studies have provided evidence that Agreeableness does reflect individual differences in the motivation to maintain harmonious relationships. One rather straightforward piece of evidence is that, among college students, Agreeableness is moderately correlated with prizing benevolence as a value, meaning concern for people one knows (Roccas et al., 2002). Based on data from experience-sampling studies, high-Agreeable adults react differently to interpersonal situations than do low-Agreeable adults. Specifically, high-Agreeable adults are more distressed than low-Agreeable adults when they face interpersonal conflicts (Suls et al., 1998) and report more negative affect when they themselves behave in a quarrelsome manner (Cote & Moskowitz, 1998). They also report more positive affect when they engage in warm, agreeable behavior than do low-Agreeable adults (Cote & Moskowitz, 1998). When more Agreeable college students anticipate participating in a competitive situation, they expect the situation to be less rewarding and more challenging than do less Agreeable students (Graziano et al., 1997). The data from these diverse studies support the idea that high-Agreeable individuals are concerned with maintaining harmonious relationships and are distressed by potential

and real interpersonal conflicts. This fundamental motivation for peaceable, close relationships is reflected in the life stories told by Agreeable individuals; in life narratives provided by college students and adults, higher Agreeableness is associated with themes of love/friendship, caring for others, and unity (McAdams et al., 2004).

Does the motivation to maintain positive relationships translate into distinct approaches to handling conflict among high-Agreeable children and adults? A variety of studies yield an affirmative answer to this question. First, low-Agreeable children, adolescents, and adults are more likely than high-Agreeable individuals to endorse destructive tactics for handling conflict, such as manipulation, coercion, and power assertion, although even low-Agreeable individuals acknowledge that better tactics could be used (D. Buss, 1992; Graziano, Jensen-Campbell, & Hair, 1996; Jensen-Campbell, Gleason, Adams, & Malcolm, 2003; Jensen-Campbell, Graziano, & Hair, 1996). Agreeableness is also positively associated in children and adolescents with stronger endorsement of constructive conflict tactics, such as negotiation and compromise (Jensen-Campbell & Graziano, 2001; Jensen-Campbell et al., 2003). Second, Agreeableness predicts more effective handling of actual conflicts. Teachers and parents describe high-Agreeable children as negotiating conflict better (Jensen-Campbell et al., 2003), whereas peers describe low-Agreeable adolescents as more aggressive (Gleason, Jensen-Campbell, & Richardson, 2004). When children are observed in conflict situations in the lab, low Agreeableness is associated with higher levels of conflict and tension, as well as more destructive conflict tactics such as stand-offs, name-calling, and withdrawals (Jensen-Campbell et al., 2003). In similar lab-based situations with college students, low Agreeableness is likewise predictive of greater conflict (Graziano et al., 1996). Interestingly, greater Agreeableness does not predict more observed submissive behavior in children and adults (Cote & Moskowitz, 1998; Jensen-Campbell et al., 2003); apparently, Agreeable people do not simply solve their interpersonal problems by giving in to other people. In short, more Agreeable youths and adults appear to generate fewer conflicts for themselves and have a greater capacity for handling the interpersonal conflicts that do arise.

There is increasing research interest in understanding the biological systems underlying individual differences in Agreeableness. Differences in empathy,

warmth, and nurturance may arise from a biological system designed to promote parental investment in offspring and close family bonds. Some researchers (e.g., MacDonald, 1992, 1995) have argued that evolution yielded a human biological system that typically ensures that an intimate relationship and the care of close others is inherently rewarding and pleasurable and that the loss of such relationships is painful and distressing. Such a system would confer adaptive benefits because it would promote successful care of offspring through the establishment of strong attachment relationships between infants and their caregivers. Some evolutionary theorists have argued that the primary purpose of this evolved system was to promote parent-child attachment and that the system only secondarily began to serve the role of facilitating pair-bonding between reproductive partners (Diamond, 2004). In their tend-and-befriend model, Taylor et al. (2000) have argued that a biological affiliation system is likely to be especially important for understanding the ways that females respond to stress and threat. According to this model, females may be evolutionarily primed to respond to stress by “tending” (caring for others, particularly offspring) and “befriending” (seeking and offering support). Research with animals has pointed to several potential biological substrates of this affectional system, including endogenous opioids and the neuropeptide oxytocin (Carter, 1998; Taylor et al., 2000). Further, there is some preliminary evidence in humans that affectional bonds may activate brain areas that support positive emotions and deactivate brain areas that are linked with aggression, fear, and sadness (Diamond, 2004); this finding is consistent with the emotional profile associated with Agreeableness.

### Openness to Experience/Intellect

Openness to Experience/Intellect is perhaps the most debated and least understood of the Big Five traits, yet it includes a number of potentially important characteristics. This trait does not appear in temperament models, despite parents from a number of countries spontaneously using words from this domain of individual differences to describe their children (Mervielde, De Fruyt, & Jarmuz, 1998). In the Big Five studies, children who are high on this trait are described as eager and quick to learn, clever, knowledgeable, perceptive, imaginative, curious, and original. In previous reviews (Shiner, 1998; Shiner & Caspi, 2003), we argued that the

evidence for the existence of this trait in children was equivocal. More recently, the accumulating data provide convincing evidence that this trait can be measured reliably by at least age 6 or 7 years. The childhood trait does not appear to be as broad as some adult conceptualizations of the trait, however. For example, in Costa and McCrae's (1992) influential version of Openness to Experience, the trait includes openness to ideas, fantasy, aesthetics, actions, feelings, and values. In most childhood Big Five studies, the Openness trait focuses more narrowly on openness to ideas and actions and tends to emphasize intellectual capacities and creativity. In some studies with children, when the trait is measured with a broader range of items, it does not form an internally coherent trait (Lamb et al., 2002; Markey et al., 2002). By high school, adolescents can reliably describe themselves on most aspects of the broader Openness trait (McCrae & Costa, 2004; McCrae et al., 2002). Thus, it is safe to say that some form of Openness emerges as an individual difference by middle childhood, but the trait is likely to undergo significant developmental elaboration across the years from early childhood through adolescence.

The lower-order components of Openness in childhood are not yet clear, but *intellect* (Halverson et al., 2003; Mervielde & De Fruyt, 1999, 2002) and *curiosity* and *creativity* (Goldberg, 2001; Mervielde & DeFruyt, 1999, 2002) have received some support. In international lexical studies with adults, Openness also appears to include components of unconventionality (Ashton et al., 2004).

#### ***Openness to Experience: Early Childhood Antecedents***

The developmental precursors of Openness are unknown, but there is suggestive evidence from three lines of research. First, in one study, full-face positive emotions in the Strange Situation at 18 months (a presumed marker of high-intensity positive emotions) predicted Openness at 3.5 years (Abe & Izard, 1999). Second, early signs of Openness may include curiosity and exploration of new situations; these behaviors are markers of an Openness-like trait in a number of animal species (Gosling & John, 1999). Indirect evidence for this possibility comes from longitudinal studies showing that the tendency to seek stimulation and to explore new environments actively in early childhood predicts later academic achievement and IQ (Guerin et al., 2003; Raine, Reynolds, Venables, & Mednick, 2002). High-intensity

positive emotions and active exploration are likely precursors of both Openness and Extraversion. Openness and Extraversion tend to covary across the life span (Digman, 1997; Markon et al., 2005); the two traits may stem from some of the same underlying early processes. Third, orienting sensitivity, which includes the tendency to be sensitive to internal and external sensory stimulation, is concurrently related to Openness in adulthood (Rothbart, Ahadi, et al., 2000). Thus, the extant data on the antecedents of Openness are limited but suggest several potentially interesting early manifestations of the trait.

#### ***Openness to Experience: Underlying Processes***

McCrae and Costa (1997) suggested that Openness includes two particularly important processes: Openness as a psychic structure and Openness as a motivation to pursue new, complex experiences. First, "open individuals have access to more thoughts, feelings, and impulses in awareness, and can maintain many of these simultaneously" (McCrae and Costa, 1997, p. 838). Openness is associated with numerous indicators of greater access to varied inner experiences in adults: more differentiated self-reports of emotions (Terracciano, McCrae, Hagemann, & Costa, 2003), reduced tendencies to screen out previously irrelevant stimuli (Peterson, Smith, & Carson, 2002), greater dissociation and perceptual aberration (McCrae & Costa, 1997), and heightened experiences of inspiration (Thrash & Elliot, 2003). This greater access to inner experience may be a mixed blessing; for example, in one study of women undergoing a major move, greater Openness predicted both heightened self-esteem and increased depression (Kling, Ryff, Love, & Essex, 2003). More highly open adults are more creative, at least in supportive circumstances (George & Zhou, 2001); it seems likely that a very important source of this creativity is access to a complex world of inner ideas and emotions. Second, open individuals are motivated to seek out interesting new experiences. This view of Openness is consistent with some of the markers of Openness in children, including eagerness to learn new things (both academic and nonacademic).

Among adults, Openness expresses itself in a wide variety of observable behaviors and attitudes. More open adults tend to be more politically liberal, less authoritarian in their attitudes, and less traditional in their beliefs (Jost, Glaser, Kruglanski, & Sulloway, 2003; McCrae, 1996). They produce more structurally com-

plex narratives about their lives (McAdams et al., 2004), have more distinctive offices and bedrooms (Gosling, Ko, Mannarelli, & Morris, 2002), and possess more varied collections of books (Gosling et al., 2002). In contrast, we know strikingly little about the behaviors associated with Openness in children. It will be important to look in the right contexts to find the behavioral signatures of Openness in children. Adult Openness is accurately observed in some contexts and not others; for example, it is more accurately inferred from adults' pantomimes and conversations on hobbies than from their role playing of various social scenarios (Borkenau, Mauer, Riemann, Spinath, & Angleitner, 2004).

### Directions for Future Developmental Research on Personality Structure

In this section, we have reviewed a proposed taxonomy of individual differences in personality. A personality taxonomy is an *evolving* classification system whose purpose is to integrate and guide research. This also means that any such system must be open to empirical refutation and requisite modification. There are historical parallels between the use of structural models in personality psychology and the use of a standardized model for describing and diagnosing mental illness in psychiatry. Prior to the advent of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders III (DSM-III)*, clinicians and researchers did not have available explicit criteria to define the boundaries of diagnostic categories. Clinical diagnoses were difficult to compare and cross-sample replications were hard to conduct. The development of *DSM-III* was a big improvement because it provided a common language with which clinicians and researchers could communicate about the disorders they were treating or investigating. *DSM-III* had its share of problems, and subsequent modifications (*DSM-III-R*, *DSM-IV*) testify to the need for a flexible and evolving system that can accommodate new empirical information, as do recommended modifications in anticipation of *DSM-V* (Kupfer, First, & Regier, 2002). We can similarly hope that the use of a generally accepted trait taxonomy will help to impose structure on unintegrated research findings, reduce the likelihood that old traits will be reinvented under new labels, and advance the study of personality development across the life course.

Toward these goals, we suggest four ways to build on the current success of elucidating the structure of per-

sonality differences across the life course. First, much more work is needed to specify lower-order traits. We have highlighted some potential lower-order traits that warrant consideration in children and adults; other lower-order traits undoubtedly exist as well.

Second, the fields of child development and personality psychology will continue to benefit from creative measurement of individual differences, beyond the sole use of questionnaires. A strength of the temperament field has been its use of multiple measures of temperament traits, including behavior observations and structured laboratory tasks. Additional types of measures can be explored. For example, implicit measures have been used to assess anxiety and shyness in adults (Asendorpf, Banse, & Mucke, 2002; Egloff & Schmukle, 2002); rather than directly inquiring about a person's self-view of personality, these instruments measure indirectly an individual's automatic associations between trait descriptors and the self. Physiological measures can be used to parse groups of individuals into more homogeneous subtypes (Kagan, Snidman, McManis, Woodward, & Hardway, 2002). Puppet interviews have been used to assess self-views of traits in children as young as age 5 years and could be used to measure a wide range of traits early in childhood (Arseneault, Kim-Cohen, Taylor, Caspi, & Moffitt, 2005; Measelle, Ablow, Cowan, & Cowen, 1998; Measelle et al., 2005).

Third, more research is needed about the cross-cultural generalizability of the taxonomic system reviewed here for children and adolescents. Parents from the United States, China, and several European countries consider the Big Five traits to be important in describing their children (Kohnstamm, Halverson, Mervielde, & Havill, 1998). Cross-cultural studies of adult personality structure have been pursued vigorously over the past decade (Church, 2001). There is some research on childhood temperament and personality structure in countries outside the United States and Europe, such as China, Japan, and Russia (Digman & Shmelyov, 1996; Halverson et al., 2003; Rothbart, Ahadi, et al., 2001), but it will be important to explore the structure of childhood personality in other countries. Another crucial task will be to determine when in the life course mean-level cross-cultural differences in personality emerge.

Fourth, it will be important to chart the development of sex differences in mean levels of personality traits. Although there do not appear to be any sex differences in the structure of personality, there are some differences in the mean levels of personality traits (Feingold,

1994). A deeper understanding of the causes of such sex differences will be important for explaining both personality development and the development of psychopathology (Rutter, Caspi, & Moffitt, 2003).

THE DEVELOPMENTAL ELABORATION OF PERSONALITY TRAITS

The process of developmental elaboration refers to the mechanisms by which those temperament attributes that are part of each individual’s genetic heritage accumulate response strength through their repeated reinforcement and become elaborated into cognitive and affective representations that are quickly and frequently activated—into personality traits. This elaboration may involve at least six processes (Table 6.3), which we now describe in the order of their hypothesized emergence. For example, learning processes and environmental elicitation are hypothesized to influence the course of personality development in the first few months of life; environmental construal and social comparison processes can influence personality development only following the emergence of necessary cognitive functions in early and middle childhood; and environmental selection and manipulation generally require the emergence of self-regulatory functions in childhood and are likely to become particularly important as youths move into adolescence.

Before describing these six processes, we hasten to remind the reader that examples of these processes ap-

pear in nearly all sections of this chapter. The ubiquitous presence of process-focused personality analysis in this chapter is not an accident. As we noted in our chapter introduction, personality research is increasingly based on the recognition that traits are not merely semantic labels but rather reflect organizing and motivating biological and psychological processes (Derryberry, Reed, & Pilkenton-Taylor, 2003; Tellegen, 1991). The purpose of this section is to provide an organizing framework for thinking about and studying the processes by which personality traits develop and increasingly shape behavior.

Learning Processes

Temperament differences may influence several learning mechanisms that are involved in the elaboration process, including positive and negative reinforcement, punishment, discrimination learning, and extinction. In the second section, we described current models positing that Extraversion and Neuroticism reflect individual differences in a BAS and BIS, respectively (Gray, 1987, 1990). In essence, proponents of these models argue that Extraversion and Neuroticism reflect differences in various learning mechanisms (i.e., Extraversion indexes sensitivity to potential rewards and Neuroticism indexes sensitivity to potential threats). If these formulations of Extraversion and Neuroticism are correct, the two traits should correlate with different patterns of learning. There is some evidence for this in adults (Avila, 2001).

TABLE 6.3 Processes through Which Early Temperament/Personality Shapes the Development of Later Personality, Adaptation, and Psychopathology

Process	Definition	Example
Learning processes	Temperament shapes the child’s experience of classical and operant conditioning.	Children high on Openness may find complex and novel stimuli to be reinforcing.
Environmental elicitation	Temperament shapes the response of adults and peers to the child.	Children high on Extraversion may attract peers to play with them.
Environmental construal	Temperament shapes the ways that children interpret the environment and their experiences.	Children low on Agreeableness may interpret requests from adults as hostile impositions on their freedom.
Social and temporal comparisons	Temperament shapes the ways children evaluate themselves relative to others and to themselves across time.	Children high on Neuroticism may wrongly view themselves as inadequate relative to their peers.
Environmental selection	Temperament shapes children’s choices about their everyday environments.	Children high on Conscientiousness may pursue challenging activities.
Environmental manipulation	Temperament shapes the ways that children alter, modify, and manipulate their environments.	Children high on Extraversion may actively persuade other children to choose them as leaders of school groups.

Differences in sensitivity to rewards and threats should also predict biases in perception, memory, or attention (Canli, 2004). We previously reviewed some evidence that this is indeed the case (e.g., anxiety predicts selective attention to threats). Other traits in addition to Extraversion and Neuroticism should affect learning processes as well. For example, as we have reviewed, children differ strikingly in their persistence and attention, two temperament traits that are likely to influence learning. Agreeableness may be related to sensitivities to anger- or frustration-inducing stimuli, whereas Openness may be associated with attraction to complex or novel stimuli. All of these differences in learning processes should be amenable to investigation through behavioral and neuroscience methods.

More generally, different parental socialization processes are likely to interact with childhood temperament in the development of personality (for recent reviews, see Bates & McFadyen-Ketchum, 2000; Gallagher, 2002; Putnam, Sanson, & Rothbart, 2002). One example may serve to illustrate how children's temperament differences in learning interact with parental socialization. Kochanska (1997) demonstrated that fearful children (i.e., those with greater sensitivity to threats) show more positive conscience development when mothers use subtle, gentle, psychological discipline than when mothers use strongly power-assertive discipline. For such fearful children, their own internal experiences of distress may facilitate the feeling of guilt when they do something wrong, which appears to promote greater compliance (Kochanska et al., 2002). In contrast, gentle maternal discipline does not predict conscience development among fearless children, most likely because gentle discipline does not create enough discomfort; fearless children instead tend to develop stronger internalization when they are securely attached to their mothers and when their mothers are more responsive to them. Identification of other family moderators of temperament outcomes should be a high priority for research on children's individual differences. A better understanding of how temperament influences basic learning processes should help researchers identify which moderators to examine.

### Environmental Elicitation

Temperament differences also elicit different reactions from the environment and influence how other people react to children, beginning in the first few months of

life (Bell & Chapman, 1986). Research on evocative effects of children's temperament on parents is especially well developed in relation to infants and young children with "difficult" temperaments (i.e., children who are irritable, hostile, prone to cry, and hard to soothe). Many studies have documented that mothers of difficult infants experience lower confidence, greater depression, and lower self-efficacy than do mothers of more temperamentally easy infants (Crockenberg & Leerkes, 2003). Children's intense irritability has rippling negative effects on fathers and the family system more broadly (Crockenberg & Leerkes, 2003), including detrimental immediate and short-term effects on mothers' work outcomes (Hyde, Else-Quest, Goldsmith, & Biesanz, 2004). Children's negative emotions also predict differential negative treatment by parents; more emotionally negative children evoke more negative parental responses than less emotionally negative children in the same family (Jenkins, Rasbash, & O'Connor, 2003).

The evidence for child effects on parents is the most robust in relation to individual differences in negative emotions, but other temperament traits appear to predict parental responses as well (Crouter & Booth, 2003; Parke, 2004; Putnam et al., 2002). In addition, it is important to recognize that the effects of children's temperaments extend beyond the family environment to other caregivers, teachers, and peers. For example, children who express more positive affect are liked by peers and are seen by teachers as friendly and cooperative, whereas children who express high levels of anger are disliked by peers and are viewed as unfriendly, aggressive, and uncooperative by teachers (reviewed in Denham et al., 2001). Thus, children's temperaments play an important role in shaping the interpersonal experiences they encounter in multiple settings. In turn, the responses that children evoke from others are likely to be internalized as part of children's emerging self-concepts.

Research has begun to uncover some of the micro-processes through which children's temperament elicits responses from others. Individual differences in temperament and personality traits are reliably expressed in unique verbal and nonverbal behaviors, and other persons in the immediate environment react to these behaviors and use this information to make inferences and attributions (Borkenau & Liebler, 1995; Gifford, 1994). Perhaps most striking is evidence linking individual differences in adolescent personality and psychopathology to facial expressions of discrete emotions. For example,

Extraversion predicts facial expressions of social approach, Agreeableness is negatively correlated with facial expressions of anger, and Conscientiousness is associated with reduced facial expressions of negative emotion and with embarrassment (Eisenberg et al., 1989; Keltner, 1998; Keltner, Moffitt, & Stouthamer-Loeber, 1995). Such facial expressions of emotions help to coordinate social interactions: These expressions convey information about the motivations and personality of the sender, evoke complementary or similar emotions from others, and provide incentives for particular responses (e.g., positive emotions reinforce desired social behaviors; Keltner, Ekman, Gonzaga, & Beer, 2003). In addition to the facial expression of emotion, children's other individuating characteristics (e.g., vocal properties; Lin, Bugental, Turek, Martorell, & Olsner, 2002) are likely to provoke particular interpersonal responses as well.

Temperament characteristics elicit not only behaviors on the part of others but also expectations. Adults have implicit theories about developmental trajectories that they associate with particular temperament attributes. As such, children's temperament-based behaviors may elicit expectancy-based reactions from adult caregivers (Graziano, Jensen-Campbell, & Sullivan-Logan, 1998).

Finally, it is important to recognize that children's effects on others are likely to be moderated by the characteristics of the interaction partner. Even among parents of emotionally negative children, there are some parents in some contexts who respond with heightened attention and sensitivity (Crockenberg & Leerkes, 2003), which suggests the presence of important moderators of parental responses. Parents' beliefs and attitudes moderate how parents respond to children with particular temperaments (Bugental & Johnston, 2000). Parents' own personalities and moods are likely to moderate child effects as well, given the evidence discussed in the sixth section that parental personality predicts parenting styles. Future research on moderators of child effects will help to spell out more clearly how transactions between children's temperaments and their contexts shape their developing personalities.

### Environmental Construal

With the emergence of belief systems and expectations, temperament differences may also begin to influence how environmental experiences are construed, thus shaping each person's effective experience of the envi-

ronment (Hartup & van Lieshout, 1995). Research about the construal process stems from the cognitive tradition in personality psychology, which emphasizes each person's subjective experience and unique perception of the world. This research focuses on what people "do" mentally (Cervone & Mischel, 2002), demonstrating that social information processing—including attention, encoding, retrieval, and interpretation—is a selective process shaped by individual differences in temperament and personality (Derryberry & Reed, 2003; Matthews, Derryberry, & Siegle, 2000).

The role of cognitive factors in personality and psychopathology has been detailed by Crick and Dodge (1994), whose social information-processing model of children's social adjustment includes six steps: (1) to encode information about the event, (2) to interpret the cues and arrive at some decision about their meaning and significance, (3) to clarify goals, (4) to search for possible responses to the situation, (5) to consider the consequences of each potential response and to select a response from the generated alternatives, and (6) to carry out the selected response. Temperament and personality have the potential to shape social information processing at each of these steps.

One of the most important reasons that temperament is likely to influence cognitive processing is that temperament involves emotional processes that are known to shape cognition (Derryberry & Reed, 2003). Lemerise and Arsenio (2000) presented a reformulation of Crick and Dodge's social information-processing model that amplifies the crucial role of emotional processes. These authors argue that children's individual differences in emotionality and emotion regulation affect processes at each of the six stages of social information processing (see also Arsenio & Lemerise, 2004). For example, children's differences in positive and negative emotions will affect the cues they notice in the environment, the goals that are salient to them, and the types of potential responses they generate. Children's differences in self-regulation will help to determine the responses they select and their ability to enact those responses. Although personality influences cognitive processes, cognitive processes likewise influence ongoing emotional experiences (Matthews et al., 2000); thus, there are bidirectional effects between cognitive/perceptual and emotional processing (Derryberry & Reed, 2003).

Throughout our personality taxonomy section, we presented examples of how personality shapes social-cognitive processing. Two other examples illustrate how

such processes occur. As noted, Neuroticism in adults is associated with a variety of cognitive biases. Recent research has demonstrated that higher Neuroticism is associated with specific detrimental ways of appraising and coping with difficult situations. Children who are higher on negative emotionality (including both neuroticism and irritability) are more likely to appraise negative life events as threatening and to use avoidant coping as a way of dealing with these life events, which leads to poorer adjustment (Lengua & Long, 2002). Similarly, Neuroticism in adults predicts heightened distress and worry in response to experimentally induced stress in the lab; this link between Neuroticism and distress is, in part, mediated by threat appraisals and by emotion-focused coping (Matthews et al., 2000). These studies demonstrate that one of the reasons that Neuroticism is so robustly associated with poor adjustment is because it is linked with specific social-cognitive biases.

Social-cognitive processes are also implicated in aggression. Children who are high in reactive aggression (aggression aimed at retaliation against someone) are those who show both high frustration/anger and a tendency to assume hostile intentions on the part of others (Dodge, Lochman, Harnish, Bates, & Pettit, 1997). An interesting, similar pattern predicts aggression and hostility in adults. In one study (Meier & Robinson, 2004), adult participants were asked to categorize words as blameworthy (e.g., murder or adultery) or not (e.g., baldness or hurricane). Among participants low on Agreeableness, greater speed at categorizing words as blameworthy predicted greater hostility and arguments in daily life. Thus, for both children and adults, a heightened bias toward assuming and assigning blame predicts greater hostility and aggression among some individuals.

As these examples illustrate, although social-cognitive and trait approaches to personality are often portrayed as antagonistic, they are perfectly complementary and mutually informative. Future work can aim to explore further the ways that children's early temperaments influence the ways that children construe and make sense of their worlds.

### Social and Temporal Comparisons

With increased cognitive sophistication (e.g., role-taking skills), two social-psychological processes are hypothesized to influence self-evaluations and identity development: Children learn about themselves by com-

paring and contrasting themselves to others (social comparisons) as well as to themselves over time (temporal comparisons). The salience and relative importance of social and temporal comparisons may change across the life course (Suls & Mullen, 1982). Age-related changes in social cognition and social roles make it likely that social comparisons may be especially influential from childhood to adolescence and into adulthood and that temporal comparisons may become increasingly important during the adult years.

The microprocesses through which personality may shape social and temporal comparisons also deserve attention. Temperament and personality may shape a range of relevant processes (Cassidy, Ziv, Mehta, & Feeney, 2003; Derryberry & Reed, 2003), including (a) the kinds of feedback that people deliberately seek out about themselves, (b) attentional biases to comparison information, (c) standards used for comparison, and (d) emotional responsivity to comparison information. Extant research offers some hints about the ways in which personality differences may shape comparison processes. For example, greater anxiety and sadness in children predict negative self-views, which predict poorer estimates of competence relative to actual competence over time (Pomerantz & Rudolph, 2003). Other research suggests that subsets of aggressive children have extremely high or extremely low views of their competence relative to others (Brendgen, Vitaro, Turgeon, Poulin, & Wanner, 2004). More systematic research is needed regarding these processes.

### Environmental Selection

As self-regulatory competencies increase with age, individuals begin to make choices and display preferences that may reinforce and sustain their characteristics. Children's emerging personalities shape the environments they select, whether consciously or unconsciously. Processes of environmental selection are likely to become increasingly important across the years from childhood to adulthood (Scarr & McCartney, 1983). Even among very young children, temperament is likely to shape the spheres children occupy in the environments chosen for them by adults (e.g., inhibited toddlers may avoid interactions with other children in child care, or children high on intellect may choose more stimulating activities at home). As children move into middle childhood, they are given greater freedom to choose the environments in which they spend their time (Cole & Cole,

1996). During childhood and adolescence, youths' personalities may help determine the activities in which they participate and the ways in which they choose to spend their free time (McHale, Crouter, & Tucker, 2001; Shanahan & Flaherty, 2001). Personality effects on children's peer relationships may be particularly important; particular traits appear to predict the peer groups children join (Denham et al., 2001), children's experiences of peer rejection and acceptance (Hay, Payne, & Chadwick, 2004), and the quality of children's friendships (Pike & Atzaba-Poria, 2003). Children's individual differences also predict the life events they experience; for example, children with externalizing behavior problems experience a greater number of controllable negative life events than children without these problems (Masten, Neeman, & Andenas, 1994).

In adulthood, individuals make personality-based choices regarding education, occupation, and intimate relationships (reviewed in a later section); all of these choices shape individuals' everyday environments. Indeed, by adulthood the most striking personality differences between individuals are to be found not by studying their responses to the same situation but by studying how they choose and construct new situations (Wachtel, 1973). A person's selection and creation of environments is thus one of the most individualizing and pervasive expressions of his or her personality.

The process of environmental selection may also account for the empirical observation that measures typically used to study the environment are subject to substantial genetic influence (Plomin & Bergeman, 1991). A key issue for personality researchers is the extent to which personality contributes to genetic influences on measures of the environment. So far, genetic effects on the Big Five personality traits have been reported to explain genetic influences on some life events (Saudino, Pedersen, Lichtenstein, McClearn, & Plomin, 1997), and personality traits account for about 30% of the genetic influence on divorce risk (Jockin, McGue, & Lykken, 1996). The main implication from these results, as discussed later, is that associations between environmental measures and personality cannot be assumed to be caused environmentally, and, in some instances, the likely direction of effects is the other way around: Individuals differentially select and are differentially exposed to environments (e.g., divorce or stressful life events) as a result of their genetically influenced personality traits.

## Environmental Manipulation

Once the self-concept is firmly established, and with the development of more sophisticated self-regulatory capacities, individuals also begin to alter, modify, and manipulate the environments in which they find themselves (D. Buss, 1987). These processes may become particularly important as children become more skilled in regulating their own behavior and more insightful into the causes of others' behaviors. Like adults, children vary in the goals that they pursue in various circumstances (Rose & Asher, 1999), and these goals are likely to influence the ways that children attempt to modify their environments. The ways that individuals select and shape their environments may be especially relevant for self-regulation. Individuals regulate their behavior in the midst of an ongoing emotional experience. But individuals also regulate their behavior and others' behavior proactively by anticipating potential situations and selecting how to handle those situations according to their goals (Eisenberg, 2001; Gross, 1999).

We have described six processes through which an initial disposition is elaborated so that it increasingly organizes emotion, thought, and action. Research is now needed about each of these processes in relation to different temperament and personality traits.

## THE ORIGINS OF INDIVIDUAL DIFFERENCES IN PERSONALITY

In this section, we review what is known about genetic influences on personality variation between people, and discuss how measured genes can be incorporated into research on personality development.

### Genetic and Environmental Influences on Personality Development across the Life Span

To estimate the relative roles that genes and environments play in personality development, behavioral geneticists employ two basic research designs: (1) twin studies and (2) adoption studies. The logic behind using the twin method to estimate heritable influences is straightforward, and it has three parts. First, a genetic contribution to personality is indicated when the similarity of monozygotic (MZ) twins' personalities is greater than the similarity of dizygotic (DZ) twins' per-

personalities. This inference is based on the fact that MZ twins share all their genes, but DZ twins, like all siblings, share on average only half of their polymorphic genes. Quantitative model fitting usually labels this “A,” for additive genetic effects. To use this logic, researchers must test the critical assumption that all of the greater similarity between MZ and DZ twins can safely be ascribed to MZ twins’ greater genetic similarity. This is called the “equal environments assumption.” In other words, researchers must show that MZ twins have not been treated more alike than DZ twins in ways that are related to their personality outcomes. Research into this question suggests that MZ and DZ twins are not perfectly equal on some environmental experiences. However, some part of the greater MZ than DZ twin similarity in treatment arises because MZ twins’ genetically influenced similar behavior evokes similar treatment. Evoked similar treatment does not violate the assumption unless it further exacerbates MZ twin similarity. Moreover, despite the fact that such inequality may have inflated some heritability estimates by a small amount, it has not done so enough to invalidate the inference that genes influence personality differences.

Second, twin studies can show whether environmental experiences influence twin similarity over and above genetic influences. MZ twins’ genetic similarity is twice that of DZ twins, and therefore, if nothing more than genes were influencing their personalities, MZ twins’ personalities should be at least twice as similar as DZ twins’. If not, this indicates that something more than genes has made the twins similar (i.e., environments that the siblings share in common must have enhanced their similarity). In model fitting, this yields a significant variance component called family wide, shared, or common environmental variance, often labeled “C.” It indexes environmental effects on personality that can be detected because they have increased the personality similarity between family members in the study and because the family members shared the experience for reasons completely apart from their genetic similarity.

Third, twin studies also address the perennial question of why family members differ from each other (Plomin & Daniels, 1987), by using the following logic. If MZ twins, despite sharing all their genes, are not perfectly identical in their personality, this indicates that nonshared experience unique to each family member has reduced their similarity. In model fitting, this yields a

significant variance component called child-specific, nonshared, or unique environmental variance, often labeled “E.” It indexes environmental effects on personality that can be detected because they have created differences between family members in the study. Phenotype measurement errors can produce such effects, too, because errors in measurement produce scores that look different for twins in a pair.

The fundamental logic behind using the adoption method to estimate heritable influences is also straightforward. The correlation between adoptee and biological parent personality represents genetic transmission, whereas the correlation between adoptee and adoptive parent personality represents social (i.e., environmental) transmission. To use this logic researchers must test the critical assumptions that adoptees share no more than random genes with their adoptive parents (i.e., adoption was extrafamilial and the adoption agency did not try to match the adoptive and birth family’s characteristics), and adoptees share not more than random environments with their biological parents (e.g., the quality of prenatal and orphanage care were uncorrelated with adoptees’ biological backgrounds). Like twin data, adoption data can be modeled to ascertain A, C, and E components of variance.

With data from large studies throughout the world (Boomsma, Busjahn, & Pelttonen, 2002), research has uncovered increasingly reliable and robust evidence that personality traits are substantially influenced by genetic factors. Bouchard and Loehlin (2001; Bouchard, 2004) provide a comprehensive review of this research, pointing to heritability estimates across the Big Five factors in the range of  $.50 \pm .10$ . There are some fluctuations from study to study, but in general (a) all five superfactors appear to be influenced by genetic factors to the same extent and (b) genetic and environmental factors also affect individual differences in men’s and women’s personalities to the same extent.

Three clarifications and qualifications deserve special notice. First, twin studies using peer ratings of personality, rather than self-report personality questionnaires, show genetic influences similar to those found in self-report studies (Reimann, Angleiter, & Strelau, 1997). Moreover, multivariate genetic analyses indicate that the same genetic factors are largely involved in self-reports and peer ratings of personality, which provides strong evidence for the genetic validity of self-report ratings. It does not appear to be the case

that heritability estimates derived from twin studies are simply an artifact of self-report methodologies in which MZ and DZ twins are asked to rate themselves. Some studies using observational measures of behavior (e.g., empathy; Emde & Hewitt, 2001) yield lower heritability estimates than have been found using questionnaire measures. However, there are still too few such observational studies to know if this is a robust methodological difference.

A second, related methodological challenge has been levied at temperament and personality research with children. Twin studies of younger age groups have relied primarily on ratings by parents, which have yielded an odd result: Correlations for identical (MZ) twins are high, and correlations for fraternal (DZ) twins are very low, sometimes even negative (Saudino & Cherny, 2001). The suggestion is that parents may provide biased ratings of their twins and that behavioral genetic studies that rely on parents for data may not yield valid estimates of genetic and environmental influences on personality functioning. However, the situation is rather less alarming than often claimed. Parents sometimes contrast their twins in ways that generate greater than expected differences between MZ versus DZ twins, but this problem may be restricted to some traits (e.g., symptoms of hyperactivity, temperament ratings of activity level; Simonoff et al., 1998) and may be attenuated by different rating measures (Goldsmith, Buss, & Lemery, 1997).

Third, family and adoption studies of personality yield lower estimates of genetic influences than twin studies (Martin et al., 2000; Plomin, Corley, Caspi, Fulker, & DeFries, 1998). Specifically, parent-child and biological sibling correlations for personality traits average about .1 to .2, with corresponding heritabilities of .3 that are considerably lower than the heritabilities of .5 obtained in twin studies. One possibility is that the discrepant findings result from the fact that parent-offspring and sibling-sibling correlations are derived from different-age pairs and thus (dis)similarity is confounded by age and cohort differences. Another possibility is that nonadditive genetic effects play a larger role in personality than suggested by MZ and DZ correlations. Nonadditive genetic effects refer to effects of genes that interact to influence a trait, in contrast to additive genetic effects in which genes “add up.” Nonadditive effects only contribute slightly to the resemblance of DZ twins and other first-degree relatives, whereas MZ twins are identical for all (additive and nonadditive) genetic

effects. Although adoption studies are far fewer and much smaller than twin studies of personality, it is noteworthy that they suggest less genetic influence than twin studies, and the lack of correspondence, at least in relation to personality research, between the results of twin and adoption/family studies merits further scrutiny.

Four novel findings in behavioral genetics research on personality merit mention. First, measures of personality that incorporate multiple viewpoints or perspectives (e.g., by consolidating information from multiple reporters or across multiple situations) yield larger estimates of genetic influences (as well as smaller, but more reliable, estimates of nonshared environmental influences) than measures based on a single viewpoint (e.g., Arseneault et al., 2003; Phillips & Matheny, 1997; Scourfield, van den Bree, Martin, & McGuffin, 2004). This finding has been uncovered in studies of young children, adolescents, and adults. It has been suggested that “consensus trait measures,” which eliminate specificities or idiosyncracies in different viewpoints about a person, could be used to better identify both specific genes and specific experiences that are correlated with personality (Bouchard & Loehlin, 2001).

Second, as noted earlier, behavioral genetic studies have been used to examine whether there is etiological differentiation in the lower-order traits (or narrow facets) that make up the broader personality superfactors such as the Big Five. The question is whether higher-order dimensions, or superfactors, represent the best level of analysis for research in genetics. Analyses at the lower-order levels of the personality hierarchy offer additional, useful information about the origins of individual differences in personality. For example, analyses at the lower-order trait level suggest that siblings resemble each other in their altruism and prosocial behavior (facets of Agreeableness), in part, because of the rearing environments they share (Jang, McCrae, Angleitner, Riemann, & Livesley, 1998, Sample 1; Krueger et al., 2001), but analyses of the Agreeableness superfactor (which includes many other facets) may conceal this shared environmental influence. Earlier we noted that, for behavioral prediction, it is often a short-sighted strategy to rely exclusively on measures of broad superfactors. Likewise, such exclusive reliance may limit research into the etiology of personality differences.

Third, although it is often said disparagingly that behavioral genetics is adevelopmental and static, recent findings in three different areas of research demonstrate that behavioral genetic methods are ideal for application

to questions about age-related changes in etiology, in relation to both normal and abnormal development. First, research on cognitive development shows that the heritability of IQ increases from early childhood through late adolescence (McGue, Bacon, & Lykken, 1993; Plomin, Fulker, Corley, & DeFries, 1997). In this instance, one can think of a heritability estimate as an outcome variable. When it changes with age, this suggests that the balance of genetic versus environmental causal processes differs at successive developmental stages. In the case of IQ, the findings suggest that the effect on IQ of environmental factors shared by siblings dissipates with age, as each child increasingly seeks out environments that are correlated with his or her genetic endowments. Second, research on the development of drug dependence suggests that the causes of initiation and of dependence are not identical so that the factors that lead adolescents to sample drugs are not necessarily the same factors that lead to drug dependence (Kendler et al., 1999). Third, research in developmental psychopathology suggests that the pattern of antisocial behavior that begins early in life, is pervasive across settings, and persists into adulthood is more likely to be influenced by genetic factors than is the pattern of late-onset, situational, transient delinquency (Taylor et al., 2000). In combination, these three sets of findings illustrate how quantitative genetic studies can play an important role in illuminating developmental processes.

Fourth, behavioral genetic methods are also being used to address the processes of continuity and change in personality development. The quantitative methods that behavioral geneticists use to estimate genetic and environmental components of phenotypic variance at a given point in time can be extended to estimate genetic contributions to continuity and change across time by analyzing cross-twin correlations across different times. Longitudinal personality data from twins show that such MZ cross-twin correlations are consistently and significantly larger than DZ cross-twin correlations, providing evidence that a major source of personality continuity in individual differences is attributable to genetic factors (McGue et al., 1993; Pedersen & Reynolds, 1998; Viken, Rose, Kaprio, & Koskenvuo, 1994). This does not mean that genes “fix” personality but rather that genetic factors contribute to the preservation of individual differences over long stretches of the life span, at least from adolescence onwards. A possible interpretation of these findings is the set-point model (Carey, 2003), which argues that environmental fluctuations

may produce short-term changes in personality phenotypes but that genetic factors contribute to individual set-points to which individuals will regress (Lykken & Tellegen, 1996). Longitudinal data with multiple, repeated measurements—over both short and long intervals—are needed to fully test the predictions derived from the model.

### Molecular Genetic Analysis of Personality

One of the most exciting directions for genetic research on personality involves the use of molecular genetic techniques to identify some of the specific genes responsible for genetic influences on personality. Quantitative genetic studies are widely seen as a necessary preliminary to identifying heritable phenotypes that can be usefully examined at the molecular genetic level (Martin, Boomsma, & Machin, 1997), and finding genes for personality will revolutionize psychological research by providing direct measures of specific genotypes for individuals.

The search for genes for personality is difficult because, unlike classical single-gene disorders in which a single gene is necessary and sufficient to produce the disorder, there is no evidence for such major effects of genes for personality. For quantitative traits like personality, genetic influence is much more likely to involve multiple genes of varying but small effect size, which greatly increases the difficulty of detecting such genes. Genes for complex traits influenced by multiple genes and multiple environmental factors are known as quantitative trait loci (QTLs; Plomin & Crabbe, 2000). The goal is not to find the gene for a personality trait but rather some of the many genes that make contributions of varying effect sizes to the variance of the trait.

Researchers attempting to find QTLs for personality have investigated allelic association using DNA markers that are in or near genes thought to be relevant to the trait. Allelic association refers to a correlation between alleles of a DNA marker and trait scores across unrelated individuals: Allelic association occurs when individuals with a particular allele for the marker have higher scores on the trait. Genes thought to be relevant to a particular trait are often called candidate genes, which is something of a misnomer. For example, for cardiovascular disease, several cholesterol-related genes were good candidate genes because it was known that cholesterol is involved in the process leading to heart disease. However, for personality, much less is known

about relevant physiological mechanisms, which means that few specific genes can be suggested as candidates. The phrase *candidate gene* has thus been corrupted to include any genes that might conceivably be related to personality. The problem with this loose use of this phrase is that any gene expressed in the brain could be considered as a candidate gene, so the phrase loses its meaning (Plomin & Caspi, 1999).

A meta-analysis of studies reporting data on associations between candidate genes and personality traits concluded there were few replicable associations (Munafò et al., 2003). Much of the initial excitement about research on molecular genetics and personality has given way to a more sober appreciation of the pitfalls involved in this kind of research (Benjamin, Ebstein, & Belmaker, 2002). The situation is not much better in psychiatric genetics (Plomin & McGuffin, 2003). Several explanations have been invoked to explain some of the failures to find psychiatric genes that withstand replication over time, including but not limited to publication bias, phenotypic heterogeneity, allelic heterogeneity, weak prior probabilities of association, multiple testing, population stratification, and inadequate sample size (Cardon & Palmer, 2003; Colhoun, McKeigue, & Smith, 2003; Lohmueller, Pearce, Pike, Lander, & Hirschhorn, 2003; Merikangas & Risch, 2003; Sullivan, Eaves, Kendler, & Neale, 2001; van den Oord & Sullivan, 2003). These same explanations may account for the slow pace of discovering, and replicating, genes for personality. It may be useful to step back and reflect on the surge of interest in the search for personality genes, which was stimulated by psychiatrists for two reasons. First, it was hoped that the use of quantitative personality traits (rather than categorical psychiatric diagnoses) would offer greater statistical power and thus facilitate the identification of genetic effects of very small effect size. So far, more power has not proven to be a panacea. Second, personality traits were thought to represent endophenotypes for psychiatric disorders—variables that are intermediate on a causal chain from genes to disorder. There was hope that gene associations would be found more successfully with endophenotypes than has been the case with diagnosed disorders because the former are thought to have simpler genetic underpinnings than disorders themselves. Whether personality traits fulfill the criteria for endophenotypes is debatable (Gottesman & Gould, 2003).

It is also likely that genes do not directly encode for personality traits. In fact, it is now recognized that the

heritability coefficient indexes not only direct effects of genes but also effects of interactions between genes and environments (Rutter & Silberg, 2002). Gene-environment interactions (GxE) occur when the effect on a person of exposure to a particular environment is conditional upon their genotype (or conversely, when environmental experiences moderate gene expression). Because interactions are independent of main effects, it is possible that even genome-wide scans of very large numbers of people whose personalities are carefully measured will fail to detect genes whose effects are conditional on environmental risk.

In various branches of medicine that deal with complex multifactorial outcomes (e.g., cardiovascular disease), GxE are being discovered and replicated. In the behavioral sciences, several studies also suggest the possibility that some complex traits, instead of resulting from many genes of small effect, result from relatively fewer genes whose effects are conditional on exposure to environmental risk. One study showed that a functional polymorphism in the promoter region of the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) moderated the effect of child maltreatment in the cycle of violence (Caspi et al., 2002). Specifically, maltreated children whose genotype conferred low levels of MAOA expression more often developed conduct disorder than children whose genotype conferred high levels of MAOA. A second study showed that a functional polymorphism in the promoter region of the serotonin transporter gene moderated the influence of stressful life events on depression (Caspi, Sugden, et al., 2003). Specifically, individuals with one or two copies of the short allele exhibited more depression following stressful life events than individuals homozygous for the long allele. Both studies received initial, independent replication (Foley et al., 2004; Kaufman et al., 2004; Kendler, Kuhn, Vittum, Prescott, & Riley, 2005; but this is a fast-moving field, and readers are encouraged to monitor developments that will have no doubt occurred since this writing).

It is possible that bringing together measured genotypes and measured environments to study personality traits and psychiatric disorders more accurately reflects the processes by which personality phenotypes develop than does the study of genetic main effects. However, such GxE research requires careful, deliberate, theory-guided hypothesis testing. Moffitt, Caspi, and Rutter (2005) have outlined several strategic steps for GxE tests in developmental psychopathology, which may be

extended to study personality phenotypes. Up to now, developmental psychologists have played a limited role in molecular genetics research. We suggest that they may contribute in two fundamental ways. First, they can help refine the measurement of psychological phenotypes for inclusion in genetic research. Second, they can help to measure developmental contexts and correlated environmental risks that may interact with genetic factors to shape personality development. It may be that ignoring nurture has handicapped the ability of the psychological sciences to better understand nature, and developmental psychologists may be able to rectify the situation.

## PERSONALITY CONTINUITY AND CHANGE

The assertion that an individual's personality has changed or remained the same over time is ambiguous. The boy who has daily temper tantrums when he is age 2 but weekly tantrums when he is age 9 has increased his level of emotional control; he has changed in absolute terms. But if he ranks first in temper tantrums among his peers at both ages, he has not changed in relative terms. Further ambiguity arises if the form of the behavior changes. If this boy emerges into adulthood as a man who is irritable and moody, we may grant that the phenotype has changed but claim that the underlying personality has not. A third ambiguity arises when a claim of continuity rests on observations not of an individual but of a sample of individuals. The continuity of an attribute at the group level may be masking large but mutually canceling changes at the individual level. There are several meanings denoted by the term *continuity*. The purpose of this section is to disentangle those meanings. First, we review evidence about three types of continuity and change observed in longitudinal research: differential, mean-level, and ipsative. Second, we review the conceptual challenge of testing and documenting coherence in personality functioning across time and in diverse circumstances.

### Types of Continuity Observed in Longitudinal Research

#### *Differential Continuity and Change*

Continuity and change are most often indexed by correlations between personality scores across two points in time (i.e., test-retest correlations). These differential, or rank-order stability correlations, reflect the degree to

which the relative ordering of individuals on a given trait is maintained over time. Two contradictory predictions have been proposed about the rank-order stability of personality traits. The classical trait perspective argues that personality traits in adulthood are biologically based temperaments that are not susceptible to the influence of the environment and thus do not change over time (McCrae et al., 2000). From this *essentialist* perspective, we would expect the test-retest correlations to be high, even early in life. In contrast, the radical contextual perspective emphasizes the importance of life changes and role transitions in personality development and suggests that personality should be fluid and prone to change and should yield low test-retest correlation coefficients, especially during developmental periods characterized by rapid physical, cognitive, and social changes (Lewis, 2001).

Existing longitudinal studies do not support either of these positions. A meta-analysis of the rank-order stability of personality (organized according to the five-factor model) revealed six major conclusions (Roberts & DelVecchio, 2000):

1. Test-retest correlations over time are moderate in magnitude, even from childhood to early adulthood.
2. Rank-order stability increases with age. Test-retest correlations (unadjusted for measurement error) increased from .41 in childhood to .55 at age 30, and then reached a plateau around .70 between ages 50 and 70.
3. Rank-order stability decreases as the time interval between observations increases.
4. Rank-order stability does not vary markedly across the Big Five traits.
5. Rank-order stability does not vary markedly according to assessment method (i.e., self-reports, observer ratings, and projective tests).
6. Rank-order stability does not vary markedly by gender.

Several implications can be drawn from this meta-analysis. First, the level of continuity in childhood and adolescence is much higher than originally expected (Lewis, 2001), especially after age 3. Even more impressive is the fact that the level of stability increases in a relatively linear fashion through adolescence and young adulthood. Young adulthood has been described as demographically dense, in that it involves more life-changing roles and identity decisions than any other period in the life course (Arnett, 2000). Despite these dramatic

contextual changes, personality differences remain remarkably consistent during this time period. Second, personality continuity in adulthood peaks later than expected. According to one prominent perspective, personality traits are essentially fixed and unchanging after age 30 (McCrae & Costa, 1994). However, the meta-analytic findings show that rank-order stability peaks some time after age 50, but at a level well below unity. Thus, individual differences in personality traits continue to change throughout adulthood, but only modestly after age 50. Third, the magnitude of differential stability of personality traits, although not as high as essentialists would claim, is still remarkably high. In this regard, it is interesting to compare personality traits to two overlapping trait domains, which show even higher differential stability: (1) cognitive abilities and (2) interests. Measures of cognitive ability exhibit more longitudinal consistency than measures of personality traits. It is unlikely that this difference is simply a function of the differential reliability of the two kinds of measures because this difference holds up even when the measures are corrected for unreliability. However, a related methodological consideration is that ability measures show greater continuity because ability tests demand maximal performance, whereas personality questionnaires assess representative, typical performance; the former test format may yield evidence of greater continuity (Ackerman & Heggestad, 1997). Measures of interests also exhibit more longitudinal consistency than measures of personality traits, especially during the 20-year period from early adolescence through early adulthood (Low, Yoon, Roberts, & Rounds, 2005). Interests may stabilize at an earlier age because, relative to personality traits, they are more likely to involve motivational processes that lead individuals to select congruent and reinforcing experiences.

### *Mean-Level Continuity and Change*

Mean-level change refers to changes in the average trait level of a population. This type of change is thought to result from maturational processes shared by a population and is typically assessed by mean-level differences in specific traits over time, which indicate whether the sample as a whole is increasing or decreasing on a trait.

Contradictory perspectives—similar to those guiding predictions about differential stability—have also guided expectations about mean-level changes in personality traits. Proponents of the five-factor model of personality argue that personality traits do not demon-

strate mean-level changes after adulthood is reached (Costa & McCrae, 1997). In contrast, proponents of a life-span developmental perspective emphasize the importance of life changes and role transitions in personality development and suggest that mean-level changes do occur and often at ages much later than young adulthood (Helson, Kwan, John, & Jones, 2002).

A meta-analysis synthesized and organized (according to the five-factor model) data from 87 longitudinal studies spanning the period from age 10 to 101 years (Roberts, Walton, & Viechtbauer, in press). The pattern of change in the first domain of the Big Five, Extraversion, was complex until this superfactor was divided into constituent elements of social dominance (assertiveness, dominance) and social vitality (talkativeness, sociability). Traits associated with social dominance increased from adolescence through early middle age, whereas traits associated with social vitality increased in adolescence and then showed decreases in young adulthood and old age. Consistent with evidence from cross-sectional comparisons of different age groups (McCrae et al., 2000), traits belonging to the domains of Agreeableness and Conscientiousness increased in young adulthood and middle age. Traits belonging to the domain of Neuroticism decreased mostly in young adulthood. Finally, traits from the Openness to Experience domain showed increases in adolescence and young adulthood and a tendency to decrease in old age.

In general, the longitudinal evidence documents that, at least from adolescence through adult life, most people become more psychologically mature. Two distinct definitions of maturity prevail in developmental theories (Hogan & Roberts, 2004). The first, humanistic definition equates maturity with self-actualization and personal growth and with the process of becoming less defensive and rigid and more creative and open to feelings. According to the longitudinal evidence (Roberts et al., in press), the data do not support this developmental progression; after young adulthood, people do not grow increasingly open to experience and toward old age they actually exhibit declines on traits related to Openness to Experience. The second, functional definition equates maturity with the capacity to become a productive and involved contributor to society, with the process of becoming more planful, deliberate, and decisive, but also more considerate and charitable (traits encompassed by higher levels of Emotional Stability, Conscientiousness, and Agreeableness). According to the longitudinal data, most people do appear to become

more functionally mature with age, and those who develop the cardinal traits of psychological maturity earliest are more effective in their love, work, and health (as reviewed later).

Three additional aspects of these longitudinal findings deserve note. First, there are no discernible sex differences in patterns of mean-level continuity and change across the Big Five. Apparently, men and women change in the same ways over the life course, although mean-level differences between the sexes are maintained over time. This suggests that the causes of personality continuity and change across the life course are likely to be the same for the sexes. Second, the majority of mean-level personality change occurs in young adulthood not in adolescence, as we might suspect given traditional theories of psychological development. This pattern of change is not simply a recent historical phenomenon because it was observed in different cohorts across the twentieth century. This finding suggests that the causes of normative personality change are likely to be identified by narrowing research attention to the study of young adulthood. Third, for select trait categories, change occurs well past young adulthood, demonstrating the continued plasticity of personality well beyond typical age markers of maturity.

The evidence base about continuity and change still has several important gaps. First, the best data about personality continuity and change—and hence the most reliable conclusions—continue to be restricted to adult samples. Relatively few studies have used a comprehensive set of personality variables to characterize young children and to track continuities and changes in their personalities over time. Second, most longitudinal studies continue to estimate continuity and change over only two waves of assessment, despite the advent of new methodological approaches that are appropriate for answering more nuanced questions about both short- and long-term temporal dynamics (Biesanz, West, & Kwok, 2003). Finally, and most important, the next generation of studies should move beyond description and attempt to explain patterns of continuity and change (Mroczek & Spiro, 2003).

### *Ipsative Continuity and Change*

Differential and mean-level continuities are indexed by statistics that characterize a sample of individuals. However, continuity at the group level may not mirror continuity at the individual level. For this reason, some researchers examine ipsative continuity, which explic-

itly refers to continuity at the individual level. Ipsative continuity denotes continuity in the configuration of variables in an individual across time. Ipsative continuity could also be called *person-centered continuity*. The latter term derives from Block's (1971) distinction between a variable-centered approach to personality, which is concerned with the relative standing of persons across variables, and a person-centered approach, which is concerned with the salience and configuration of variables in the person (see the first section). An ipsative approach to the study of development seeks to discover continuities in personality functioning across development by identifying each person's salient attributes and their intraindividual organization.

Relatively little longitudinal research has been conducted from an ipsative point of view. An exception is Block's (1971) *Lives Through Time* in which he employed the Q-sort technique of personality description to analyze continuity and change. Continuity and change were indexed by computing correlations across the set of attributes—Q-correlations—between an individual's Q-sort profiles from different measurement occasions; the higher the correlation, the more the configuration of attributes in the individual remained stable across time. Block's analysis showed that aggregate indices of continuity masked large individual differences in personality continuity. For example, the average Q-correlations between early and late adolescence exceeded .70 and those between late adolescence and adulthood exceeded .50, but the intraindividual Q-correlations ranged from moderately negative to the maximum imposed by measurement error. Other studies of personality continuity and change between childhood and adolescence report average Q-correlations ranging from .43 to .71, with considerable variability in the distribution of these scores; intraindividual Q-correlations ranged from  $-.44$  to .92, indicating that from childhood to adolescence people vary widely in how much continuity or change they exhibited (Asendorpf & van Aken, 1991; Ozer & Gjerde, 1989).

An interesting discovery is that there are meaningful individual differences in intraindividual continuity. In a longitudinal American study, Block (1971) originally reported that those persons whose personalities remained stable from adolescence to adulthood (non-changers) were more intellectually, emotionally, and socially successful as adolescents than the changers, and a measure of adjustment also showed them to be better adjusted. In European samples, Asendorpf and van

Aken (1991) also found that the most resilient children showed the most continuity of personality patterns across time. In a New Zealand sample, Roberts, Caspi, and Moffitt (2001) reported that traits associated with the domains of Agreeableness, Conscientiousness, and Emotional Stability were positively correlated with increased personality consistency: People who were interpersonally effective, planful, decisive, and considerate were less likely to change over time. Although there is no obvious explanation for this replicated finding, one possibility is that Agreeable, Conscientious, and Emotionally Stable people are better equipped to deal with social-developmental challenges across the life course. They have more personal capital in the form of increased resilience, which allows them to master more efficiently the life challenges that they face and to recuperate more quickly from aversive and disappointing life events that they encounter. In contrast, their more brittle counterparts may be more susceptible to the influence of their environment. The robust finding that some people are more prone to change than others calls for research that systematically tests for an explanation.

### Personality Coherence

The kinds of continuity discussed so far refer to *homotypic* continuity—continuity of similar behaviors or phenotypic attributes over time. The concept of coherence enlarges the definition of continuity to include *heterotypic* continuity—continuity of an inferred attribute presumed to underlie diverse phenotypic behaviors. Specific behaviors in childhood may not predict phenotypically similar behavior later in adulthood but may still be associated with behaviors that are conceptually consistent with the earlier behavior (Livson & Peskin, 1980). Kagan (1969) noted that heterotypic continuities are most likely to be found from the earlier years of life, when children go through numerous rapid changes. In contrast, homotypic continuities are more likely to be found after puberty, when psychological organization nears completion.

With the coming of age of various longitudinal samples, examples of heterotypic continuities now abound in the psychological literature, as we see in the following section. But it is important to emphasize that coherence and heterotypic continuity refer to conceptual rather than a literal continuity among behaviors: “The notion of coherence refers to a pattern of findings where a construct, measured by several different methods, retains

its psychological meaning as revealed in relationships to a variety of other measures” (Ozer, 1986, p. 52) across time and in different contexts. Accordingly, the investigator who claims to have discovered coherence must have a theory—no matter how rudimentary or implicit—that specifies the basis on which the diverse behaviors and attributes can be said to belong to the same equivalence class. The theories behind claims of coherence often amount to appeals to the reader’s intuition. In the personality taxonomy that we presented earlier in this chapter, we described current theories about the processes underlying the Big Five traits. As researchers develop richer and more comprehensive theories about the nature of particular individual differences, the task of making theory-based predictions about coherence should become easier. We now review three conceptual approaches to the problem of studying personality coherence across the life course. Each of these social-developmental approaches provides a framework for understanding coherence by focusing on the distinctive ways in which individuals organize their behavior to meet new environmental demands and developmental challenges.

### *An Organizational-Adaptational Perspective*

An organizational-adaptational perspective focuses on tasks and milestones that are encountered during the course of development and on how these are met by different personalities (Masten & Coatsworth, 1995; Masten et al., 1999; van Lieshout, 2000). According to this perspective, personality traits influence problem-solving modalities that individuals use when meeting new developmental challenges at different points in the life course (e.g., developing competent peer relationships in childhood, establishing appropriate cross-sex relationships in adolescence, learning to parent in early adulthood, or providing for dependent parents in middle age). Some of these developmental tasks are universal, whereas others are specific to a sociocultural context and historical period. A useful example of the organizational-adaptational perspective comes from Sroufe and colleagues’ work on the links between children’s early attachment to mothers and the children’s adaptational profiles during later developmental phases. This general approach enabled Sroufe and his colleagues to confer conceptual coherency on their findings that individuals who were securely attached as infants later explored their environments as toddlers (Matas, Arend, & Sroufe, 1978), were less dependent on their teachers in the preschool years (Sroufe, Fox, & Pancake, 1983), attained

higher sociometric status and displayed greater competence in peer relations in late childhood (Urban, Carlson, Egeland, & Sroufe, 1991), and appeared to establish appropriate cross-sex relationships in adolescence (Sroufe, Carlson, & Shulman, 1993).

### *A Sociological Perspective*

Beyond childhood the search for coherence becomes more complicated, and it may be that a purely psychological approach is insufficient for the analysis of personality continuity and change as the individual increasingly negotiates social roles defined by the culture (Settersten, 2003). Some researchers have found it useful to adopt a sociocultural perspective and to conceive of the life course as a sequence of culturally defined, age-graded roles (e.g., marriage, work, and parenting) that the individual enacts over time (Caspi, 1987; Helson, Mitchell, & Moane, 1984). In this fashion, the life course can be charted as a sequence of age-linked social roles, and personality coherence can be explored by investigating consistencies in the ways different persons select and perform different sociocultural roles; for example, in whether they opt for conventional or unconventional career paths or in whether they are “off-time” in relation to normative, age-graded tasks such as getting married.

### *An Evolutionary Psychology Perspective*

Bouchard (1995) correctly argued that a purely sociocultural perspective on the life course “ignores the fact that life-histories themselves are complex evolved adaptations” (p. 91). An evolutionary perspective on the life course complements the sociocultural perspective by exploring how personality variation is related to those adaptively important problems with which human beings have had to repeatedly contend: It focuses research on the genetically influenced strategies and tactics that individuals use for survival and reproduction. Evolutionary psychology thus focuses attention on the coherence of behavioral strategies that people use in, for example, mate selection, mate retention, reproduction, parental care, kin investment, status attainment, and coalition building (D. Buss, 1999). Although these ideas have not yet been tested in the context of long-term longitudinal studies, they show the promise of evolutionary psychology for organizing longitudinal-developmental data on personality coherence.

These three approaches, or road maps for studying personality across the life course, share an important assumption: Continuities of personality across the life

course are expressed not only through the constancy of behavior across time and in diverse circumstances but also through the consistency over time in the ways that persons characteristically modify their changing contexts as a function of their behavior. We now turn to review evidence of such continuities across the life course.

## **PERSONALITY AND THE LIFE COURSE: HOW EARLY-EMERGING PERSONALITY DIFFERENCES SHAPE DEVELOPMENTAL PATHWAYS**

Two events have served to make research on personality trait development more vibrant over the past 10 years. First, developmental psychologists have begun to measure personality traits rather than ignore them. Second, personality psychologists have become increasingly interested in relating measures of personality traits to something besides other personality measures. The result is robust evidence that early-emerging individual differences in personality shape how individuals experience, interpret, and respond to the developmental tasks they face across the life course. In this section, we review longitudinal evidence about how personality traits shape (a) the cultivation of social relationships, (b) the mastery of educational and work tasks, and (c) the promotion and maintenance of physical health. For each developmental task, we identify the most relevant personality variables and outline the mechanisms by which these personality traits are hypothesized to exert their influence.

### **Cultivating Relationships: How Personality Shapes Friendships, Intimate Relationships, and Parenting**

One of the most important tasks faced by children and adolescents is the establishment of friendships and acceptance among peers (Hartup & Stevens, 1999; Masten & Coatsworth, 1998). Among children, all of the higher-order Big Five traits except Openness are important predictors of social competence. Perhaps so many aspects of personality predict social competence because social functioning requires a wide array of skills, including emotional expression, emotional understanding, and emotional and behavioral regulation (Rubin, Bukowski, & Parker, Chapter 10, this *Handbook*, this volume). Agreeable and Extraverted children show better social competence concurrently and across time and experience growth in perceived social support from early to

late adolescence (Asendorpf & van Aken, 2003a; Branje, van Lieshout, & van Aken, 2004; Shiner, 2000; Shiner et al., 2003). Children high on Negative Emotionality or low on aspects of Conscientiousness (e.g., attention and self-control) have a variety of social difficulties concurrently and across time (Eisenberg et al., 2000); the interaction of high Negative Emotionality and low self-regulation may be especially problematic for social functioning (Eisenberg et al., 2000).

Personality continues to be an important predictor of relationships in adulthood. Extraversion predicts positive relationships (Shiner et al., 2002), whereas Neuroticism and Disagreeableness are the strongest and most consistent personality predictors of negative relationship outcomes—including relationship dissatisfaction, conflict, abuse, and, ultimately dissolution (Karney & Bradbury, 1995; Shiner et al., 2002). These effects of Neuroticism and low Agreeableness have been uncovered in long-term studies following samples of children into adulthood and in shorter-term longitudinal studies of adults. The potential contribution of personality differences to shaping abusive relationships has been further underscored by longitudinal studies that find associations between early developing aggressive traits in childhood and subsequent abusive behavior in adult romantic relationships (Andrews, Foster, Capaldi, & Hops, 2000; Ehrensaft, Moffitt, & Caspi, 2004). One study that followed a large sample of adolescents across their multiple relationships in early adulthood discovered that the influence of Neuroticism and low Agreeableness on relationship quality showed cross-relationship generalization: It predicted the same abusive relationship experiences across relationships with different partners (Robins, Caspi, & Moffitt, 2002). Increasingly, sophisticated studies that include dyads (not just individuals) and multiple methods (not just self reports) demonstrate that the link between personality traits and relationship processes is more than simply an artifact of shared method variance in the assessment of these two domains (Donnellan, Conger, & Bryant, 2004; Watson, Hubbard, & Wiese, 2000).

An important research goal is to uncover the proximal relationship-specific processes that mediate these personality effects on relationship outcomes (Reiss, Capobianco, & Tsai, 2002). Personality traits affect relationships by influencing and altering microinteractional processes. First, individuals select their interactional contexts by choosing partners who resemble them. The tendency to form unions with similar others has im-

plications for the course of personality development because similarities between couple members create interpersonal experiences that reinforce initial tendencies (Alwin, Cohen, & Newcomb, 1991; Caspi & Herbener, 1990). Second, personality differences influence people's exposure to relationship events. For example, people high in Neuroticism are more likely to be exposed to daily conflicts in their relationships (Bolger & Zuckerman, 1995). Third, personality differences shape people's reactions to the behavior of their partners. For example, high-Disagreeable individuals may escalate negative affect during conflict (e.g., Gottman, Coan, Carrere, & Swanson, 1998). Similarly, high-Agreeable people are better able to regulate emotions during interpersonal conflicts (Jensen-Campbell & Graziano, 2001). Cognitive processes also come online in creating trait-correlated experiences (Snyder & Stukas, 1999). For example, highly neurotic individuals may overreact to minor criticism from their partner, believe they are no longer loved when their partner does not call, or assume infidelity on the basis of mere flirtation. Fourth, personality differences evoke behaviors from partners that contribute to relationship quality. For example, people high in Neuroticism and low in Agreeableness may be more likely to express four behaviors identified as detrimental to relationships: criticism, contempt, defensiveness, and stonewalling (Gottman, 1994).

Whereas a great deal of research has investigated the influence of personality on friendships and intimate relationships, fewer studies have considered the possibility that parents' personalities shape their parenting styles and relationships with their children (Belsky & Barends, 2002). This is a curious omission. Although researchers interested in psychiatric disorders have documented that maternal psychopathology can compromise effective parenting (Goodman & Gotlib, 2002), developmental researchers have been slower to recognize that parental personality forms a critical part of children's developmental context (Goldsmith, Losoya, Bradshaw, & Campos, 1994). Moreover, behavioral genetic studies suggest that some parenting behaviors may be heritable (Spinath & O'Connor, 2003). This does not mean that there is a gene for parenting styles. Rather, it suggests that individual differences in parenting behaviors may be related to personality characteristics that are influenced by genetic factors.

The handful of studies that have examined personality → parenting associations—using self-reports as well as observations of parenting—suggest that Extraversion

and Agreeableness are related to sensitive and responsive parenting, whereas aspects of Neuroticism, such as anxiety and irritability, are related to less competent parenting (e.g., Belsky, Crnic, & Woodsworth, 1995; Clark, Kochanska, & Ready, 2000; Kochanska, Clark, et al., 1997; Kochanska et al., 2004; Losoya, Callor, Rowe, & Goldsmith, 1997; Metsapelto & Pulkkinen, 2003; Prinzie et al., 2004). Much more work needs to be done: First, most of the research to date has focused on parents of very young children to the virtual exclusion of adolescents. Second, most of the research has not tested mediators (e.g., parental attributions) of personality → parenting associations. Third, most of the research has focused on the main effects of personality and has not addressed the conditions under which particular personality attributes are more or less important in explaining parenting behavior (e.g., Are personality main effects moderated by qualities of the marital relationship or by the child's temperament?). For example, there is some evidence that difficult children are particularly likely to be rejected by highly Conscientious mothers during problem-solving tasks (Neitzel & Stright, 2004). Fourth, to our knowledge, no study has examined personality effects on parenting behavior in relation to multiple children in the same family, and this is a design that has the power to test the cross-situational generalizability of personality effects (across offspring) and to estimate the influence of parental personality on family life independently of other family-wide environmental effects.

The study of personality effects on social relationships is exciting territory where hypotheses about personality dynamics can be tested using multiple and creative methodologies. These approaches need not be confined to close relationships. Bugental (2000) proposed a taxonomy of social relationships that offers the promise of helping to coordinate personality research by focusing attention on how personality variables shape behaviors in five domains of social life: (1) attachment relations, (2) mating relations, (3) hierarchical power relations between persons of unequal status, (4) reciprocal relations among persons of equal status, and (5) coalitional-group relations.

### Striving and Achieving: How Personality Shapes Performance in School and Work Settings

During the life course, individuals assume multiple performance tasks (e.g., pursuing an education, assuming a job, or managing and allocating resources). Personality

traits from the domain of Conscientiousness are the most important noncognitive predictors of educational achievement and occupational attainment (Judge et al., 1999; Shiner, in press). In fact, childhood Conscientiousness predicts improvements in academic achievement across time into adulthood (Shiner, 2000; Shiner et al., 2003). Similarly, adult Conscientiousness predicts job performance across a wide variety of measures and across nearly all types of jobs (Barrick, Mount, & Judge, 2001). Conscientiousness encompasses many traits that are necessary for completing work effectively: the capacities to sustain attention, to strive toward high standards, and to inhibit impulsive behavior. In contrast, childhood Neuroticism predicts lower adult occupational attainment (Judge et al., 1999). Adult Neuroticism appears to have small negative effects on job performance (Barrick et al., 2001; Hurtz & Donovan, 2000) and is associated with lower academic attainment (Shiner et al., 2002).

Links between the other Big Five traits and academic and work achievement are less consistent and robust but are still found. Openness to Experience/Intellect predicts academic achievement in samples of school-age children, adolescents, and college students (Farsides & Woodfield, 2003; Graziano, Jensen-Campbell, & Finch 1997; John et al., 1994), and child and adult Agreeableness sometimes do as well (Shiner, 2000; Shiner et al., 2002). Meta-analyses reveal that Extraversion, Agreeableness, and Openness predict some more limited aspects of work performance in a subset of occupations (Barrick et al., 2001). Research with children, adolescents, and adults demonstrates that many of the links between personality traits (especially Conscientiousness) and various indices of achievement remain significant after controlling for individual differences in ability (Judge et al., 1999; Shiner, 2000; Shiner et al., 2003), but sometimes the links disappear (Schmidt & Hunter, 2004). The predictive associations between temperament and personality traits and achievement are apparent early in life, at the time that children first enroll in school (Miech, Essex, & Goldsmith, 2001). The finding that personality effects on achievement emerge early in life is important because school adjustment and academic performance have cumulative effects over time (Entwistle & Alexander, 1993).

The personality processes involved may vary across different stages of development, and at least four candidate processes deserve research scrutiny (see Schneider, Smith, Taylor, & Fleenor, 1998). First, the personality

→ achievement associations may reflect “attraction” effects, or “active niche-picking,” whereby people actively choose educational and work experiences whose qualities are concordant with their own personalities. For example, people who are more conscientious prefer conventional jobs such as accounting and farming (Gottfredson, Jones, & Holland, 1993). People who are more extraverted prefer jobs that are described as social or enterprising such as teaching or business management (Ackerman & Heggestad, 1997). Moreover, extraverted individuals are more likely to assume leadership roles in multiple settings (Anderson et al., 2001). All of the Big Five have substantial relations with better performance when the personality predictor is appropriately aligned with work criteria (Hogan & Holland, 2003). This indicates that if people find jobs that fit with their dispositions they will experience greater levels of job performance, which should lead to greater success, tenure, and satisfaction across the life course (Judge et al., 1999).

Second, personality → achievement associations reflect “recruitment” effects, whereby people are selected into achievement situations and are given preferential treatment on the basis of their personality characteristics. These recruitment effects begin to appear early in development. For example, children’s personalities influence their emerging relationships with teachers at a young age (Birch & Ladd, 1998). In adulthood, job applicants who are more extraverted, conscientious, and less neurotic are liked better by interviewers and are more often recommended for the job (Cook, Vance, & Spector, 2000).

Third, some personality → achievement associations emerge as consequences of “attrition” or “deselection pressures,” whereby people leave achievement settings (e.g., schools or jobs) that do not fit with their personality or are released from these settings because of their trait-correlated behaviors (Cairns & Cairns, 1994). For example, longitudinal evidence from different countries shows that children who exhibit a combination of high irritability/antagonism and poor self-control are at heightened risk of unemployment (Caspi, Wright, Moffitt, & Silva, 1998; Kokko, Bergman, & Pulkkinen, 2003; Kokko & Pulkkinen, 2000).

Fourth, personality → achievement associations emerge as a result of direct, proximal effects of personality on performance. Personality traits may promote certain kinds of task effectiveness; there is some evi-

dence that this occurs in part via the processing of information. For example, higher positive emotions facilitate the efficient processing of complex information and are associated with creative problem solving (Ashby, Isen, & Turken, 1999; Fredrickson, 2003). In addition to these effects on task effectiveness, personality may directly affect other aspects of work performance such as interpersonal interactions (Hurtz & Donovan, 2000). Personality traits may also directly influence performance motivation (e.g., Conscientiousness consistently predicts stronger goal setting and self-efficacy, whereas Neuroticism predicts these positive motivations negatively; Erez & Judge, 2001; Judge & Ilies, 2002).

Personality traits not only affect performance in school and at work; they are also influenced by these experiences. The “corresponsive principle” summarizes the empirical observation that the most likely effect of achievement-setting experiences on personality development is to deepen the characteristics that lead people to those experiences in the first place (Roberts, Caspi, & Moffitt, 2003). For example, if people assume leadership positions because they are socially dominant, they will become more socially dominant through their experience as leaders. Similarly, some individuals may perform less well in educational settings as a function of their high irritability and aggressiveness. In turn, they are at a heightened risk of becoming increasingly antagonistic and alienated over time through their failure experiences (Shiner et al., 2002). The corresponsive principle thus links two mutually supportive life-course dynamics: “social-selection,” wherein people select environments that are correlated with their personality traits, and “social-influence,” wherein environmental experiences shape personality functioning. According to longitudinal data, the traits that “select” people into specific experiences are the traits that are most “influenced” in response to those experiences. Life experiences do not impinge themselves on people in a random fashion causing widespread personality transformations; rather, the traits that people already possess are changed (i.e., deepened and elaborated) by trait-correlated experiences that they create in achievement settings.

### **Health Promotion and Maintenance: How Personality Shapes Health Trajectories**

The lifelong interplay between psyche and soma is nowhere more apparent than in research documenting

that personality traits contribute to the maintenance of physical integrity and health. Especially impressive are life-span studies documenting associations between personality traits related to Conscientiousness with longevity (Friedman et al., 1995). Individuals high in traits related to Disagreeableness (e.g., anger and hostility) appear to be at greatest risk of disease (e.g., cardiovascular illness; Miller, Smith, Turner, Guijarro, & Hallet, 1996). The evidence for the involvement of Neuroticism in ill health is more mixed, with some research pointing to links with increased risk of actual disease and other studies documenting links with illness behavior only (Smith & Spiro, 2002).

The study of health also serves to illustrate the utility of hierarchical structural models of personality in integrating and interpreting research findings. For example, some of the inconsistency that has been observed in studies of hostility and cardiovascular disease may be due to the fact that hostility is a facet or component of both Neuroticism and Agreeableness (versus Antagonism; Smith & Williams, 1992). Measures of hostility that reflect overt interpersonal expressions of anger are facets of Agreeableness that may be the lethal personality risk factor for coronary heart disease, whereas measures of hostility that tap irritation and self-focused negativity are facets of Neuroticism and may be better predictors of health complaints rather than actual health outcomes. A taxonomic model of personality can help researchers to make conceptual and measurement refinements in testing psychosomatic hypotheses.

Personality health associations may reflect at least three distinct processes (Contrada, Cather, & O'Leary, 1999; Rozanski, Blumenthal, & Kaplan, 1999). First, personality differences may be related to pathogenesis—mechanisms that promote disease. This has been evaluated most directly in studies relating various facets of Disagreeableness/hostility to greater reactivity in response to stressful experiences (Smith & Gallo, 2001). However, part of the complexity of testing hypotheses about the role of personality in the physiological processes of a disease involves the need for greater clarity about the disease processes involved and during which disease phases personality effects may be implicated.

Second, personality differences may be related to physical-health outcomes because they are associated with health-promoting or health-damaging behaviors. For example, individuals high in Extraversion may foster social relationships, social support, and social integra-

tion, which are positively associated with health outcomes (Berkman, Glass, Brissette, & Seeman, 2000). In contrast, individuals low in Conscientiousness engage in a variety of health-risk behaviors such as smoking, unhealthy eating habits, lack of exercise, unprotected sexual intercourse, and dangerous driving habits (Bogg & Roberts, 2004). The association between Conscientiousness-related traits and health-risk behaviors is especially robust and appears to be stronger among adolescents than adults, suggesting that this risky personality trait merits greater research and public-health attention. Future personality research could be usefully integrated with developmental research from a decision-theory perspective to better understand the decision-making processes that may mediate the links between traits from the Conscientiousness domain and health-risk behaviors (Hampson, Andrews, Barckley, Lichtenstein, & Lee, 2000). Such research has the potential to contribute to a psychology of public health.

Third, personality differences may be related to reactions to illness. This includes a wide class of behaviors, including the possibility that personality differences affect the selection and execution of coping behaviors (e.g., Scheier & Carver, 1993), modulate distress reduction, and shape treatment adherence (Kenford et al., 2002).

The previous processes linking personality traits to physical health are not mutually exclusive. Moreover, different personality traits may affect physical health via different processes. For example, facets of Disagreeableness may be most directly linked to disease processes, facets of low Conscientiousness may be more clearly implicated in health-damaging behaviors, and facets of Neuroticism may contribute to ill-health by shaping reactions to illness.

The study of personality and health has historically been confined to adults. However, this may well change as health psychologists turn their attention to earlier periods in development to understand public-health puzzles. Consider research on social inequalities in health, which has tended to focus on low socioeconomic status in adulthood as the main causal variable and on adults' stress experiences as the main mediating mechanism. However, mounting evidence from life-course research points to the contribution of early life experiences and to the cumulative impact of sustained social disadvantages on adult health, compelling health psychologists to turn their attention to examine the role

that personality factors may play in mediating the associations between early social experiences and poor health across the life course (Chen & Mathews, 2002; Gallo & Mathews, 2003).

### **Predicting All of Behavior All of the Time?**

Although personality traits have been shown to shape developmental outcomes in multiple domains and in different age groups, a common refrain is that these predictive associations only account for a fraction of the variance in outcomes of interest. This observation must be balanced by four considerations. First, it seems necessary to periodically reissue the reminder that even small effect sizes are of theoretical and practical significance (McCartney & Rosenthal, 2000). By way of comparison, epidemiological and clinical studies repeatedly uncover associations whose effect sizes range between .1 and .3 (e.g., the association between decreased bone mineral density and risk of hip fracture or between the nicotine patch and smoking abstinence), leading a recent expert panel to recommend rethinking conventional interpretations of psychological research. Given adequate attention to sampling considerations, researchers should be pleased with associations around .2 to .3 (Meyer et al., 2001). Second, debates about the size of personality effects are based on the implicit assumption that every behavior is the product of a single trait. This is implausible, because each individual is characterized by a personal pattern of multiple traits working additively and interactively to influence behavior. This multiple-trait perspective has important implications for effect-size estimates: Simulation studies demonstrate that it is unreasonable and statistically inconceivable in multiply determined systems for any single trait to explain much more than 10% of the variance (Ahadi & Diener, 1989). Further research on the interactions of personality traits may enhance our ability to predict particular outcomes (see, e.g., Witt, Burke, Barrick, & Mount, 2002, on the prediction of work performance from the interaction of Agreeableness and Conscientiousness). Third, social behavior is a product of multiple personalities acting in concert and influencing one another (Asendorpf, 2002). Consider the case of relationship outcomes. If personality effects are additive across partners, the true impact of a personality trait on a relationship should be regarded as the summed effect of two personalities not a single individual's trait (Moffitt, Robins, & Caspi, 2001). Fourth, because the effects of personality differ-

ences accumulate over a lifetime, a focus on a single outcome variable measured at a single point in time may underestimate the contribution of personality to the course of developmental trajectories. Abelson (1985) makes this point in noting that differences between baseball players are trivial if considered on the basis of a single at-bat but become meaningful over the course of a game, a season, and a career. These observations are not intended to breed smug self-satisfaction. Rather, they are meant to foster reasonable expectations and aspirations for research on personality development.

### **PERSONALITY AND THE EMERGENCE OF PSYCHOPATHOLOGY**

Just as individual differences in personality shape adaptation over time, childhood personality plays an important role in the development of psychopathology. One of the primary questions that has fueled scholarly and popular interest in temperament research is whether children with particular temperaments are at greater risk of developing psychiatric problems. Much of the early interest in temperament traits was generated by Thomas and Chess's suggestion that children's early individual differences could help set off a chain of transactions between the child and the environment that could lead eventually to the development of clinical disorders (Thomas, Chess, & Birch, 1968). In this section, we address links between temperament/personality and psychopathology. First, we survey several new directions in research about the association between personality and psychopathology. Second, we summarize what is known about the predictive correlations between childhood temperament/personality differences and later psychopathology. Third, we present a conceptual model of possible associations between temperament/personality and psychopathology and provide empirical examples.

#### **New Directions in Research on Personality and Psychopathology**

The links between personality and psychopathology are turning out to be complex, and recent research recognizes this complexity. Next we describe three new directions and advances taken in this area of research.

A first advance springs from evidence that clinical disorders often include subgroups of individuals characterized by different temperament or personality

profiles. These subgroups may differ from each other in at least four ways: They may (1) have developed the disorder through different pathways, (2) have different profiles of comorbidity and life adaptation, (3) have different prognoses, and (4) respond differently to different treatments. The presence of personality-based subgroups in some clinical disorders is consistent with the principle of equifinality (i.e., children who are following widely different life paths may eventually develop the same set of pathological symptoms). For example, the diagnosis of Anorexia Nervosa appears to contain a subgroup defined by high levels of perfectionism, obsessive-compulsive features, and rigidity as well as excessive inhibition and harm avoidance (Keel et al., 2004; see Westen & Harnden-Fischer, 2001, for a similar subgroup): Relative to other individuals with Anorexia, this subgroup appears to show poorer adaptive functioning and is likely to have a worse outcome.

A second example comes from work on callous-unemotional traits in children with conduct disorder; callous-unemotional traits include lack of empathy, self-serving use of manipulation, restricted emotional expression, and impoverished conscience. Conduct-disordered children with this constellation of traits show higher proactive (unprovoked) aggression, greater delinquency, and greater variety of conduct problems over time than conduct-disordered children without these traits (Frick, Cornell, Barry, Bodin, & Dane, 2003). This subgroup is also characterized by different patterns of social-information processing; for example, greater focus on positive aspects of aggression and lesser hostile attributional biases (Frick, Cornell, et al., 2003; Pardini, Lochman, & Frick, 2003). As these two examples demonstrate, personality research is helping to parse heterogeneous diagnostic groups into more homogeneous subgroups, which may eventually help clinicians in their treatment planning (Harkness & Lilienfeld, 1997).

A second direction followed in this area of research is the recognition that personality differences may help to explain patterns of comorbidity among disorders. Two of the most important patterns of comorbidity in both children and adults involve the co-occurrence of depression and anxiety—the internalizing disorders—and the co-occurrence of conduct problems and hyperactivity—the externalizing disorders. Several researchers have suggested that personality differences may account for patterns of comorbidity: Certain disorders may co-occur because

they spring in part from similar causes, including shared temperament/personality risk factors, whereas each disorder may also be related to other personality traits that are specific to that disorder (Lilienfeld, 2003; Weiss, Susser, & Catron, 1998). Specific models have been proposed to account for the comorbidity of internalizing and externalizing disorders. Watson and Clark (Clark & Watson, 1991; Watson et al., 1995) developed a tripartite model to account for co-occurring internalizing disorders in adults. According to this model, depression and anxiety tend to co-occur because both share high levels of Negative Affect (or Neuroticism); in addition, depression is specifically characterized by low Positive Affect (or Extraversion) and anxiety is specifically characterized by physiological arousal. There is general support for this model in both children and adults (reviewed in Laurent & Ettelson, 2001; also Lonigan, Phillips, & Hooe, 2003), but more recent research has added that social phobia is also specifically characterized by low Positive Affect (Brown, Chorpita, & Barlow, 1998). As for the externalizing disorders, there is evidence that personality traits associated with low Conscientiousness (often called disinhibition) may underlie the co-occurrence of substance dependence and antisocial behavior in adults; further, Conscientiousness appears to be linked with these disorders by virtue of shared genetic origins (Krueger et al., 2002).

A third prominent research question involves the extent to which normal-range personality traits can provide adequate coverage of individual differences relevant to psychopathology. In other words, can prominent trait models like the Big Five capture the relevant variation in abnormal functioning? This question has been particularly important in relation to personality disorders, where some research demonstrates that combinations of the Big Five traits can capture the symptoms of Borderline Personality Disorder (Trull, Widiger, Lynam, & Costa, 2003) and psychopathy (Miller, Lynam, Widiger, & Leukefeld, 2001), particularly when combinations of lower-order traits are used (Reynolds & Clark, 2001). Further, a meta-analysis demonstrated that abnormal personality traits appear to share a hierarchical structure with normal-range personality traits (Markon et al., 2005). However, normal-range personality measures may need to be refined somewhat to cover personality disorder variation more completely. Some normal-range personality measures may do better than others in tapping pathological personality functioning, and scales measuring some Big

Five traits (e.g., Agreeableness and Conscientiousness) include few negative descriptors at their extremes. Future work will need to investigate whether current personality measures could be strengthened by including more extreme depictions of certain traits (Haigler & Widiger, 2001).

The personality traits relevant to some disorders are, quite possibly, not part of typical personality models. Recent work on Obsessive-Compulsive Disorder (OCD) provides a good example. Among preschool-age children, obsessive-compulsive behaviors are highly heritable, but their genetic origins are largely separate from the genetic origins of other anxiety-related behaviors (Eley et al., 2003); OCD may be less related to general distress or Neuroticism than are many of the other anxiety disorders. Instead, OCD may have more specific associations with a particular psychological feature: a disturbance in the emotion-based system that typically enables individuals to feel that closure has been reached and safety has been secured (Szechtman & Woody, 2004). Although this deficit may be related to Big Five traits in some way, it also appears likely to capture an aspect of psychological functioning that is largely separate from the Big Five. The search for other individual differences outside the Big Five is likely to be important in future research linking personality and psychopathology, because such traits may interact with Big Five traits to give rise to specific disorders.

### **Empirical Evidence for Specific Associations between Personality Traits and Psychological Disorders**

Numerous studies have examined associations between temperament and personality differences and psychopathology, both concurrently and longitudinally. Two reviews (Shiner, in press; Tackett & Krueger, 2005; see also Rothbart & Bates, Chapter 3, this *Handbook*, this volume) surveyed the research on the predictive relations between childhood personality and disorders; the conclusions were as follows:

1. Extraversion appears to put children at risk of externalizing behaviors and aggression and protects against internalizing symptoms. In contrast, behavioral inhibition predicts heightened risk for anxiety, depression, and general internalizing symptoms.
2. Neuroticism predicts later internalizing difficulties, whereas early fearfulness appears to protect children

against the development of externalizing symptoms. Neuroticism also appears to be a risk factor for substance use problems. As we noted earlier, early anger and irritability predict externalizing problems such as aggression and conduct problems; later in life, these traits may also lead to greater internalizing symptoms.

3. Children's self-control and attention promote the development of rule-abiding behavior versus externalizing, antisocial behavior; in other words, children who are low on Conscientiousness are at risk of developing externalizing behaviors. Low Conscientiousness also predicts problems with later drug use.
4. Low Agreeableness (as well as low prosocial tendencies and high antagonism) is associated with later antisocial, externalizing behaviors, and boys who are chronically physically aggressive are at a heightened risk of serious delinquency and violence. Children with difficult temperaments (which is most akin to low Agreeableness) likewise develop greater externalizing problems than children with less difficult temperaments.
5. There is no evidence that childhood Openness is predictive of psychopathology, although it should be noted that Openness has been studied less often than the other childhood traits.

Research on personality and psychopathology is in need of significant improvement, as both design and measurement limitations continue to compromise the external and internal validity of many studies: Most samples are small or unrepresentative, reports of personality and psychopathology are often obtained from the same source, and measures of temperament and symptoms often overlap in content. Future research about personality and psychopathology can adopt the more general recommendations outlined by Kraemer and colleagues about how to define and measure risk factors for psychopathology (Jacobi, Hayward, de Zwaan, Kraemer, & Agras, 2004; Kraemer et al., 1997).

### **Processes Linking Personality Differences and Psychopathology**

Much of the current research on personality and psychopathology simply documents correlations between temperament or personality traits and aspects of psychopathology without articulating how the two domains may be connected. We present a conceptual model of possible associations between temperament/personal-

ity and psychopathology in childhood and adolescence. In laying out this conceptual model, we draw on models elaborated by others (Clark, Watson, & Mineka, 1994; Rothbart & Bates, 1998; Widiger, Verheul, & van den Brink, 1999). As much as possible, we borrow their terminology to describe the possible associations, to avoid unnecessarily introducing new labels. First, personality may set in motion processes that cause the development of psychopathology (vulnerability association). Second, psychopathology may represent the extreme end of a continuously distributed personality trait or cluster of traits (spectrum association). Third, personality may protect against the development of psychopathology in the face of stress and adversity (resilience association). Fourth, personality may influence the course and prognosis of a disorder, even if the personality trait is not a cause of the disorder (maintenance association). Fifth, psychopathology may influence the course of personality development itself (scarring association). We now elaborate on these five types of association from a developmental perspective.

***Vulnerability Association: Personality May Put Children at Risk for the Development of Psychopathology***

According to this model, which has garnered the most interest among researchers, personality traits set in motion the processes that lead to psychopathology. However, whereas there are numerous published reports of predictive associations between personality traits and psychiatric disorders, less empirical attention has been given to causal processes. Previously, we outlined six processes through which early temperament differences become elaborated into more broad personality dispositions (see Table 6.3). These same six processes are likely to be the ones through which temperament differences put children at risk for psychopathology as well.

Research on the development of conduct disorder serves to demonstrate how these six processes may operate. Longitudinal research shows that conduct disorder and severe antisocial behavior are predicted by an early history of high negative emotionality, poor self-control, and high unmanageability (Sanson & Prior, 1999). How might these temperament differences contribute to the development of severe antisocial behavior over time?

First, children with conduct disorder are especially sensitive to signals of reward (O'Brien & Frick, 1996) but are relatively insensitive to punishing stimuli (Lytton, 1990). Learning processes may be at work here;

these children may have temperament traits that lead to difficulty learning to inhibit behavior when faced with potential rewards. Second, observational studies show that adopted children who are at genetic risk for antisocial behavior receive more negative control and coercive parenting from their adoptive parents than do adopted children not at genetic risk (O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998). These findings point to environmental elicitation in which children's genetically influenced temperaments evoke coercive parenting behaviors.

Environmental construal may be seen in the way that aggressive children misinterpret the intentions of others. For example, such children seek less information about social situations and are more likely to assume hostile intent on the part of other persons (Dodge et al., Chapter 12, this *Handbook*, this volume). Related to the process of environmental construal are social comparison processes in which temperament shapes the way that individuals evaluate themselves in relation to others. In some studies, externalizing children overestimate their social competence relative to others (Hughes, Cavell, & Grossman, 1997; Patterson, Kuper-smidt, & Griesler, 1990).

Environmental selection may be seen in the ways by which some children "select" situations that can then reinforce particular behaviors. For example, children with poor self-control are more likely to form ties to delinquent peers who, in turn, promote their antisocial behavior (Wright, Caspi, Moffitt, & Silva, 2001). Through environmental manipulation, an individual's personality alters and shapes the environment. For example, disagreeable youth not only perceive more interpersonal conflict in their environment but also attempt to resolve conflict with destructive tactics (Jensen-Campbell & Graziano, 2001).

***Spectrum Association: Psychopathology May Be an Extreme Manifestation of Personality***

Although psychiatric disorders are typically measured categorically, it is possible that some disorders are not discrete conditions but represent extreme ends of continuously distributed personality dimensions or combinations of dimensions (Sonuga-Barke, 1998; Widiger & Clark, 2000). For example, some researchers have argued that ADHD may be an extreme variant of an underlying temperament or personality trait rather than a discrete condition that is clearly separable from normal functioning (Jensen et al., 1997). Children with ADHD

combined type and hyperactive-impulsive type may have a basic deficit in inhibiting a prepotent response when faced with potential reinforcement for that response (i.e., ADHD may represent the extreme low ends of the traits of attention and inhibitory control; Barkley, 1997). ADHD thus appears to be particularly associated with markers of low Conscientiousness (Nigg et al., 2002).

An understudied area where spectrum relationships are likely to be observed is childhood and adolescent personality disorders. Extensive research has linked dimensional personality traits with categorical personality disorders in adults: Some researchers have argued that adult personality disorders should be conceptualized as complex combinations of adaptive and maladaptive personality traits rather than as categorically distinct conditions (Costa & Widiger, 2002; Widiger et al., 1999; Widiger & Simonsen, 2005). Little is known, however, about how child and adolescent personality is related both to concurrent personality disorders and to later-appearing personality disorders in adulthood, although some recent theoretical work has elaborated on potential links (Cohen & Crawford, in press; Geiger & Crick, 2001; Kernberg, Weiner, & Bardenstein, 2000). Children's early personalities are likely to be important predictors of the processes through which personality functioning goes awry and becomes set into maladaptive, rigid patterns (Mervielde, De Clercq, De Fruyt, & van Leeuwen, 2005; Shiner, 2005).

Although we have presented vulnerability and spectrum associations as if they are distinct, the line between the two is blurry. Most of the associations that have been found between personality and psychopathology could be explained equally well by either the vulnerability or the spectrum model. Some disorders may be better described as discrete entities, whereas others may be better described as dimensional conditions. Further, some aspects of the same disorder may be discrete, whereas other aspects may be dimensional (Pickles & Angold, 2003).

Several research strategies can be harnessed to study the distinction between discrete disorders and spectrum associations. First, taxometric methods can be used to distinguish whether differences between groups of individuals (e.g., depressed versus not depressed persons) represent quantitative differences of degree or qualitative differences in kind (Cole, 2004). Taxometric methods are useful in addressing the issues that we raised in an earlier section (i.e., identifying subtypes in disor-

ders; Beauchaine, 2003) and addressing sources of comorbidity (Ruscio & Ruscio, 2004). Such methods also are highly relevant to developmental research because they can be used to identify children who are at risk for disorders and can help pinpoint sensitive periods when discrete disorders may emerge (Beauchaine, 2003).

Second, psychopharmacological studies can also be used to generate evidence about whether personality traits and psychiatric disorders exist on a continuum (e.g., Ekselius & von Knorring, 1999). For example, the antidepressant paroxetine has been shown to reduce negative affect levels in persons without a history of mental disorder (Knutson et al., 1998). Some treatments thought to be targeted at specific syndrome disorders may exert their influence via broader personality variables.

Third, methods in behavioral genetics research can be used to address the question of whether the heritability of a disorder (e.g., ADHD) is the same or different from that of individual differences in a trait (e.g., continuously distributed symptoms of hyperactivity and inattention). For example, with regard to ADHD, genetic analyses suggest that *DSM-III-R* ADHD may be best viewed as an extreme end of a dimension that varies genetically in the population (Levy, Hay, McStephen, Wood, & Waldman, 1997).

### ***Resilience Association: Personality May Avert the Development of Psychopathology in the Face of Stress***

Although some personality traits may put children at risk of psychopathology in adverse environments, other traits may promote resilience in the face of adversity: Some personality traits may be protective factors under conditions that, on average, put children at risk for psychiatric disorders (Luthar, Cicchetti, & Becker, 2000; Masten, 2001). For example, Werner and Smith (1992) studied a group of high-risk children who were exposed to perinatal stress, poverty, and multiple family problems. Children who showed positive, resilient adult outcomes were described in infancy as very active: Males were also described as easygoing, and females were also described as affectionate.

It seems obvious that attention must be given to the possibility that some personality factors protect against psychopathology, whereas others predispose to it. However, to the extent that protective and risk factors operate dimensionally—at opposite ends of a continuum—there is little to be gained, either in theory or in practice, from focusing on the beneficial effects of, for

example, low Neuroticism more than on the harmful effects of high Neuroticism. But there is a great deal of value in testing two hypotheses: (1) that some personality factors provide protection in the presence of risk, even though they have no effect in the absence of such risk and (2) that higher levels of a trait are necessary for protection under adverse conditions than are necessary for competent functioning in low-risk conditions. Theoretically, the processes through which individual differences in children's temperament and personality traits promote resilience should be the same as those six processes described in reference to personality as a vulnerability factor.

Much remains to be learned about the potential protective role of individual differences in children's personality traits. Researchers have called for increasing focus on the processes underlying resilience (Luthar et al., 2000; Masten, 1999), and personality research should be an important part of future work in this area. Behavior genetic research should also be used to address genetic and environmental sources of resilience. A recent study demonstrated that, for example, children's outgoing temperament promoted resilience in the face of socioeconomic adversity (Kim-Cohen, Moffitt, Caspi, & Taylor, 2004): This link between resilience and sociable temperament was largely accounted for by genetic factors but included environmental processes as well.

***Maintenance Association: Personality May Influence the Course and Prognosis of a Disorder***

Most risk-factor research on personality has focused on the role of individual differences in causing (or averting) the onset of disorder. In addition, individual differences in personality may influence the manifestation, course, and prognosis of a disorder once it has started. In some cases, such traits may have played a role in the onset of the disorder; in other cases, these traits may not be etiologically related to the disorder. Studies on depression have examined the potential role of personality in maintaining a depressive episode. For example, in one study of depressed adults, those with lower levels of the BAS after the onset of the depressive episode had worse outcomes than those with more initially positive BAS functioning (Kasch, Rottenberg, Arnow, & Gotlib, 2002). Some personality traits appear to predict response to treatment. For example, research on tobacco dependence shows that persons with high Neuroticism are more likely to relapse following participation in smoking cessation treatments (Kenford et al., 2002). Still other per-

sonality traits may increase the risk of recurrence of psychiatric conditions (Teasdale & Barnard, 1993). Although these types of associations have been studied in adults (Widiger et al., 1999), they have received very little attention in research with children, despite their potential developmental significance.

***Scarring Association: Psychopathology May Alter Personality Functioning***

The experience of significant psychopathology has the potential to alter children's personalities in lasting ways. Such a relationship is often referred to as a "scarring" effect of psychopathology on personality (e.g., Rohde, Lewinsohn, & Seeley, 1990). Personality changes that are secondary to physical disorders are well documented, but, at least in adulthood, there is little solid evidence of lasting changes to personality secondary to psychopathology. For example, the possibility of scar effects has been explored in several studies of adult depression; the evidence thus far indicates that, although depression may have negative long-term effects on other aspects of functioning, it does not appear to result in personality change (Ormel, Oldehinkel, & Vollebergh, 2004; Zuroff, Mongrain, & Santor, 2004). The situation may be very different earlier in life. Because identity and a sense of self are under construction throughout childhood and adolescence, children may be particularly vulnerable to the negative effects of psychopathology that emerges early in the life course. This hypothesis has received practically no research attention and warrants further exploration.

## CONCLUSION

Throughout this chapter, we have summarized definitive findings, identified promising research leads and hypotheses, and underscored existing methodological limitations. Our concluding comments are thus devoted to sketching the requirements for improved research.

Longitudinal research is the lifeblood of developmental psychology, but simply tracking people over time is not good enough. There is room for improvement on three fronts. First, longitudinal research on personality can be improved through better trait measurement. The availability of a taxonomy of measurable individual differences in temperament and personality is an indispensable aid to developmental research. However, few off-the-shelf measures assess the full range of higher- and lower-order

traits described in this chapter: The development of reliable, valid, and comprehensive measures of child and adolescent personality remains an important task. Until these become available, researchers need to consider several issues when selecting methods and instruments for measuring temperament and personality: (a) Ideally, more than one method should be used to provide a more valid assessment of a particular trait; (b) more than one trait should be measured, even in studies focused on single traits in isolation, because this provides critical information about etiological specificity and discriminant validity; (c) researchers need to consider carefully whether a measure truly taps the trait of interest because labels for measures (i.e., scale names on questionnaires) are often misleading; and (d) researchers should consider not just what is included in a particular instrument, but also what is left out, because many measures do not tap the full range of individual differences observed in children. Second, longitudinal research can be improved by relying on theoretically informed data-collection schedules. Rather than dictated by convenience, longitudinal studies should make an effort to organize data collection around well-defined developmental tasks, whether these tasks are defined by evolutionary imperatives, sociological realities, or maturational changes. The organization of data collection across periods of environmental-maturational changes offers an opportunity to test hypotheses about how individuals select and shape their environments (processes of social selection) and how environments influence individuals (processes of social causation). Third, longitudinal research can be improved by integrating epidemiological concepts and methods into studies of personality development to test hypotheses about risk factors and causal processes.

Longitudinal research is not always developmental research and, conversely, many developmental questions require different types of research designs. In particular, little is known about how early-emerging individual differences become elaborated into the consistent ways of behaving, thinking, and feeling that we call personality. Throughout this chapter, we listed some ideas and working hypotheses about these processes. These will need to be examined using traditional observational methods and, increasingly, the tools of neuroscience as well. First, to the extent that the most important sources of influence on the processes of developmental elaboration are to be found in interpersonal settings, the ideal study of individual development ought to be conceived of as a study of social relationships, one in which longitudinal partici-

pants are successively studied alongside their significant others at different points in the life course. These types of studies will include both global ratings of individual differences and minute-to-minute assessments of social interactions to document how behavior patterns are evoked and sustained. Second, just as research in social cognition inspired deeper understanding of personality dynamics in the latter part of the twentieth century, the fusion of differential psychology and neuroscience will lead the way to a fuller understanding of how personality traits are linked to processing emotional stimuli.

Finally, research into personality development will need to embrace genetics. Questions about the extent to which genetic factors influence individual differences in personality are increasingly less interesting, if only because it is by now so well established that genetic factors do have a large influence. But this does not mean that behavioral genetics research has served its purpose and worn out its welcome. To the contrary, discoveries about the human genome open up new research possibilities in which measured genotypes will be used to study the origins of personality differences and the links between personality and psychopathology. To ignore genetics is not only irresponsible but also a missed opportunity.

These concluding observations are intended to stimulate new research into personality development and also to promote discussion about the kind of multidisciplinary (re)training that is increasingly required of new students (and seasoned researchers), spanning psychometric theory, epidemiology, neuroscience, and genetics. It is a daunting and exciting task.

Reactivity to the Environment 410

What Is the Route by Which Children's Experiences  
Lead to Different Outcomes? 412

INTEGRATION 414

REFERENCES 416

Throughout history, parents and communities have been concerned with ways to influence the young. Children are born into many different types of worlds, and caregivers hope to prepare them to cope well in their own particular world. Socialization represents the preparation of the young to manage the tasks of social life and involves the continuous interplay between:

- Biological mechanisms that facilitate receptivity and motivation to acquire competency in the experienced environment
- Social-cultural mechanisms by which the environment serves to shape and strengthen those competencies
- Variations in the child's biological, social, and cognitive outcomes that occur in response to the experienced environment

In this system, biological and social-cultural factors build on each other in a recursive fashion.
