Preface to Handbook of Child Psychology, Sixth Edition

WILLIAM DAMON

Scholarly handbooks play several key roles in their disciplines. First and foremost, they reflect recent changes in the field as well as classic works that have survived those changes. In this sense, all handbooks present their editors' and authors' best judgments about what is most important to know in the field at the time of publication. But many handbooks also influence the fields that they report on. Scholars—especially younger ones—look to them for sources of information and inspiration to guide their own work. While taking stock of the shape of its field, a handbook also shapes the stock of ideas that will define the field's future. It serves both as an indicator and as a generator, a pool of received knowledge and a pool for spawning new insight.

THE HANDBOOK'S LIVING TRADITION

Within the field of human development, the *Handbook of Child Psychology* has served these key roles to a degree that has been exceptional even among the impressive panoply of the world's many distinguished scholarly handbooks. The *Handbook of Child Psychology* has had a widely heralded tradition as a beacon, organizer, and encyclopedia of developmental study for almost 75 years—a period that covers the vast majority of scientific work in this field.

It is impossible to imagine what the field would look like if it had not occurred to Carl Murchison in 1931 to assemble an eclectic assortment of contributions into the first *Handbook of Child Psychology*. Whether or not Murchison realized this potential (an interesting speculation in itself, given his visionary and ambitious nature), he gave birth to a seminal publishing project that

not only has endured over time but has evolved into a thriving tradition across a number of related academic disciplines.

All through its history, the *Handbook* has drawn on, and played a formative role in, the worldwide study of human development. What does the *Handbook's* history tell us about where we, as developmentalists, have been, what we have learned, and where we are going? What does it tell us about what has changed and what has remained the same in the questions that we ask, in the methods that we use, and in the theoretical ideas that we draw on in our quest to understand human development? By asking these questions, we follow the spirit of the science itself, for developmental questions may be asked about any endeavor, including the enterprise of studying human development. To best understand what this field has to tell us about human development, we must ask how the field itself has developed. In a field that examines continuities and changes, we must ask, for the field itself, what are the continuities and what are the changes?

The history of the *Handbook* is by no means the whole story of why the field is where it is today, but it is a fundamental part of the story. It has defined the choices that have determined the field's direction and has influenced the making of those choices. In this regard, the *Handbook's* history reveals much about the judgments and other human factors that shape a science.

THE CAST OF CHARACTERS

Carl Murchison was a scholar/impresario who edited *The Psychological Register*; founded and edited key psychological journals; wrote books on social psychology,

politics, and the criminal mind; and compiled an assortment of handbooks, psychology texts, autobiographies of renowned psychologists, and even a book on psychic beliefs (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure research in the field of experimental psychology than is being spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion, of course, is from another era; it could furnish some good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time Murchison wrote the preface to his *Handbook*, developmental psychology was known only in Europe and in a few forward-looking American labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For his original 1931 *Handbook*, Murchison looked to Europe and to a handful of American centers (or "field stations") for child research (Iowa, Minnesota, the University of California at Berkeley, Columbia, Stanford, Yale, Clark). Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," quoted extensively from interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide American readers with an introduction to his seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on children's social behavior. In this chapter,

which still is fresh today, Bühler described intricate play and communication patterns among toddlers, patterns that developmental psychology would not rediscover until the late 1970s. Bühler also anticipated the critiques of Piaget that would appear during the sociolinguistics heyday of the 1970s:

Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social . . . that children from 3 to 7 years accompany all their manipulations with talk which actually is not so much intercourse as monologue . . . [but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Buhler, 1931, p. 138)

Other Europeans included Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development."

The Americans whom Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies, an enterprise that remains familiar to us today, and Stanford's Louis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character*, a notion that was to become lost to the field during the cognitive-developmental revolution, but that reemerged in the 1990s as the primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the views that Piaget, Levy-Bruhl, and other nascent "structuralists" had put forth concerning "animism" in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow animism.) Mead reported some data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or

inanimate objects” (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology’s ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead also offered a research guide for developmental fieldworkers in strange cultures, complete with methodological and practical advice, such as the following: Translate questions into native linguistic categories; don’t do controlled experiments; don’t do studies that require knowing ages of subjects, which are usually unknowable; and live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison assembled for the 1931 *Handbook of Child Psychology*, his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: “Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology*. This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor” (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already evolving.

Murchison saw fit to provide the following warning in his second edition: “There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience” (Murchison, 1933, p. vii). It is likely that sales of Murchison’s first volume did not approach textbook levels; perhaps he received negative comments regarding its accessibility.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison’s continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children’s drawings, and Gesell wrote a general statement of his maturational theory that went well beyond the twin studies.

But Murchison also made some abrupt changes. He dropped Anna Freud entirely, auguring the marginalization of psychoanalysis within academic psychology. Leonard Carmichael, who was later to play a pivotal role

in the *Handbook* tradition, made an appearance as author of a major chapter (by far the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual-manual functions during the first 2 years of life, and one on physiological “appetites” such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* more of a biological thrust, in keeping with Murchison’s long-standing desire to display the hard science backbone of the emerging field.

Leonard Carmichael was president of Tufts University when he organized Wiley’s first edition of the *Handbook*. The switch from a university press to the long-established commercial firm of John Wiley & Sons was commensurate with Carmichael’s well-known ambition; indeed, Carmichael’s effort was to become influential beyond anything that Murchison might have anticipated. The book (one volume at that time) was called the *Manual of Child Psychology*, in keeping with Carmichael’s intention of producing an “advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature” (Carmichael, 1946, p. viii).

The publication date was 1946, and Carmichael complained that “this book has been a difficult and expensive one to produce, especially under wartime conditions” (Carmichael, 1946, p. viii). Nevertheless, the project was worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to the 1954 second edition, “The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child” (Carmichael, 1954, p. vii).

Carmichael’s second edition had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of the third edition; it was called, improbably, *Carmichael’s Manual of Child Psychology*, even though it had a new editor and an entirely different cast of authors and advisors. Paul Mussen took over as the editor, and once again the project flourished. Now a two-volume set,

the third edition swept across the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The set became an essential source for graduate students and advanced scholars alike. Publishers referred to *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

The fourth edition, published in 1983, was now redesignated by John Wiley & Sons to become once again the *Handbook of Child Psychology*. By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as “the Mussen handbook.”

WHAT CARMICHAEL CHOSE FOR THE NOW EMERGENT FIELD

Leonard Carmichael, who became Wiley's editor for the project in its now commercially funded and expanded versions (the 1946 and 1954 *Manuals*), made the following comments about where he looked for his all-important choices of content:

Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition*. (1946, p. viii)

Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition*, were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (1954, p. viii)

The first quote comes from Carmichael's preface to the 1946 edition, the second from his preface to the 1954 edition. We shall never know why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael's notice. Or perhaps 8 years of further adult development increased Carmichael's generosity of spirit. (It also may be possible that Murchison or his family com-

plained.) In any case, Carmichael acknowledged the roots of his *Manuals*, if not always their original editor. His choice to start with those roots is a revealing part of the *Handbook's* history, and it established a strong intellectual legacy for our present-day descendants of the early pioneers who wrote for the Murchison and Carmichael editions.

Although Leonard Carmichael took the 1946 *Manual* in much the same direction established by Murchison back in 1931 and 1933, he did bring it several steps further in that direction, added a few twists of his own, and dropped a couple of Murchison's bolder selections. Carmichael first appropriated five Murchison chapters on biological or experimental topics, such as physiological growth, scientific methods, and mental testing. He added three new biologically oriented chapters on animal infancy, physical growth, and motor and behavioral maturation (a tour de force by Myrtal McGraw that instantly made Gesell's chapter in the same volume obsolete). Then he commissioned Wayne Dennis to write an adolescence chapter that focused exclusively on physiological changes associated with puberty.

On the subject of social and cultural influences in development, Carmichael retained five of the Murchison chapters: two chapters on environmental forces on the child by Kurt Lewin and by Harold Jones, Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled “Character Development—An Objective Approach”), and Margaret Mead's chapter on “primitive” children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stayed with three other Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them. But Carmichael dropped Piaget and Bühler.

Carmichael's 1954 revision, his second and final edition, was very close in structure and content to the 1946 *Manual*. Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook*. Not surprisingly, the chapters that were closest to Carmichael's own interests got the most significant updating. Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet he still kept the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and

Vernon Jones, and he even went so far as to add one new chapter on social development by Harold and Gladys Anderson and one new chapter on emotional development by Arthur Jersild.

The Murchison and Carmichael volumes make for fascinating reading, even today. The perennial themes of the field were there from the start: the nature-nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow inextricably joined in the dynamic mix of human development.

These things have not changed. Yet, much in the early editions is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were written prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience*, *neuronal networks*, *behavior genetics*, *social cognition*, *dynamic systems*, and *positive youth development* were of course unknown. Even Mead's rendition of the "primitive child" stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's *cultural psychology*.

Most telling, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That, of course, is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

By 1970, the importance of theory for understanding human development had become apparent. Looking back

on Carmichael's last *Manual*, Paul Mussen wrote, "The 1954 edition of this *Manual* had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The Mussen 1970 edition—or *Carmichael's Manual*, as it was still called—had a new look and an almost entirely new set of contents. The two-volume edition carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset . . . that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn) and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in an ethological chapter by Eckhard Hess and a behavior genetics chapter by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next 3 decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He reappeared in the *Manual*, this time authoring a comprehensive (and, some say, definitive) statement of his entire theory, which now bore little resemblance to his 1931/1933 sortings of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek all gave major treatments to one or another aspect of Piaget's

body of work. Other approaches were represented as well. Herbert and Ann Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was soon to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the book's previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshback), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us in the new millennium.

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, a bit unruly but glorious in its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume Mussen *Handbook*, with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented by his 1970 piece, but his influence was on the wane throughout the other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. No return to dust bowl empiricism could be found anywhere in the set. Instead, a variety of classical and innovative ideas were coexisting: Ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none

quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

This brings us to the efforts under the present editorial team: the *Handbook's* fifth and sixth editions (but really the seventh and eighth editions, if the germinal two pre-Wiley Murchison editions are counted). I must leave it to future commentators to provide a critical summation of what we have done. The volume editors have offered introductory and/or concluding renditions of their own volumes. I will add to their efforts here only by stating the overall intent of our design and by commenting on some directions that our field has taken in the years from 1931 to 2006.

We approached our editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: "to provide," as Mussen wrote, "a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development" (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed "specifically for the scholar," as Murchison declared, and that it should have the character of an "advanced text," as Carmichael defined it. We expected, though, that our audiences may be more interdisciplinary than the readerships of previous editions, given the greater tendency of today's scholars to cross back and forth among fields such as psychology, cognitive science, neurobiology, history, linguistics, sociology, anthropology, education, and psychiatry. We also believed that research-oriented practitioners should be included under the rubric of the "scholars" for whom this *Handbook* was intended. To that end, for the first time in 1998 and again in the present edition, we devoted an entire volume to child psychology in practice.

Beyond these very general intentions, we have let chapters in the *Handbook's* fifth and sixth editions take their own shape. We solicited the chapters from authors who were widely acknowledged to be among the leading experts in their areas of the field, although we know that, given an entirely open-ended selection process and

no limits of budget, we would have invited a large number of other leading researchers whom we did not have the space—and thus the privilege—to include. With very few exceptions, every author whom we invited agreed to accept the challenge. Our only real, and great, sadness was to hear of the passing of several authors from the 1998 edition prior to our assembly of the present edition. Where possible, we arranged to have their collaborators revise and update their chapters.

Our directive to authors was simple: Convey your area of the field as you see it. From then on, the authors took center stage—with, of course, much constructive feedback from reviewers and volume editors. No one tried to impose a perspective, a preferred method of inquiry, or domain boundaries on any of the chapters. The authors expressed their views on what researchers in their areas attempt to accomplish, why they do so, how they go about it, what intellectual sources they draw on, what progress they have made, and what conclusions they have reached.

The result, in my opinion, is still more glorious profusion of the English garden genre, but perhaps contained a bit by some broad patterns that have emerged over the past decade. Powerful theoretical models and approaches—not quite unified theories, such as the three grand systems—have begun once again to organize much of the field’s research and practice. There is great variety in these models and approaches, and each is drawing together significant clusters of work. Some have been only recently formulated, and some are combinations or modifications of classic theories that still have staying power.

Among the formidable models and approaches that the reader will find in this *Handbook* are the dynamic system theories, the life span and life course approaches, cognitive science and neuronal models, the behavior genetics approach, person-context interaction theories, action theories, cultural psychology, and a wide assortment of neo-Piagetian and neo-Vygotskian models. Although some of these models and approaches have been in the making for some time, they have now come into their own. Researchers are drawing on them directly, taking their implied assumptions and hypotheses seriously, using them with specificity and control, and exploiting their implications for practice.

Another pattern that emerges is a rediscovery and exploration of core processes in human development that had been underexamined by the generation of researchers just prior to the present one. Scientific interest

has a way of moving in alternating cycles (or spirals, for those who wish to capture the progressive nature of scientific development). In our time, developmental study has cycled away from classic topics such as motivation and learning—not in the sense that they were entirely forgotten, or that good work ceased to be done in such areas, but in the sense that they no longer were the most prominent subjects of theoretical reflection and debate. Some of the relative neglect was intentional, as scholars got caught up in controversies about whether psychological motivation was a “real” phenomenon worthy of study or whether learning could or should be distinguished from development in the first place. All this has changed. As the contents of our current edition attest, developmental science always returns, sooner or later, to concepts that are necessary for explaining the heart of its concerns, progressive change in individuals and social groups over time, and concepts such as learning and motivation are indispensable for this task. Among the exciting features of this *Handbook* edition are the advances it presents in theoretical and empirical work on these classic concepts.

The other concept that has met some resistance in recent years is the notion of development itself. For some social critics, the idea of progress, implicit in the notion of development, has seemed out of step with principles such as equality and cultural diversity. Some genuine benefits have accrued from that critique; for example, the field has worked to better appreciate diverse developmental pathways. But, like many critique positions, it led to excesses. For some, it became questionable to explore issues that lie at the heart of human development. Growth, advancement, positive change, achievement, and standards for improved performance and conduct, all were questioned as legitimate subjects of investigation.

Just as in the cases of learning and motivation, no doubt it was inevitable that the field’s center of gravity sooner or later would return to broad concerns of development. The story of growth from infancy to adulthood is a developmental story of multifaceted learning, acquisitions of skills and knowledge, waxing powers of attention and memory, growing neuronal and other biological capacities, formations and transformations of character and personality, increases and reorganizations in the understanding of self and others, advances in emotional and behavioral regulation, progress in communicating and collaborating with others, and a host of other achievements documented in this edition. Parents, teachers, and

other adults in all parts of the world recognize and value such developmental achievements in children, although they do not always know how to understand them, let alone how to foster them.

The sorts of scientific findings that the *Handbook's* authors explicate in their chapters are needed to provide such understanding. The importance of sound scientific understanding has become especially clear in recent years, when news media broadcast story after story based on simplistic and biased popular speculations about the causes of human development. The careful and responsible discourse found in these chapters contrasts sharply with the typical news story about the role of parents, genes, or schools in children's growth and behavior. There is not much contest as to which source the public looks to for its information and stimulation. But the good news is that scientific truth usually works its way into the public mind over the long run. The way this works would make a good subject for developmental study some day, especially if such a study could find a way to speed up the process. In the meantime, readers of this edition of the *Handbook of Child Psychology* will find the most solid, insightful

and current set of scientific theories and findings available in the field today.

Acknowledgments

A work as significant as the *Handbook of Child Psychology* is always produced by the contributions of numerous people, individuals whose names do not necessarily appear on the covers or spines of the volumes. Most important, we are grateful to the more than 150 colleagues whose scholarship gave life to the Sixth Edition. Their enormous knowledge, expertise, and hard work make this edition of the *Handbook* the most important reference work in developmental science.

In addition to the authors of the chapters of the four volumes of this edition, we were fortunate to have been able to work with two incredibly skilled and dedicated editors within the Institute for Applied Research in Youth Development at Tufts University, Jennifer Davison and Katherine Connery. Their “can-do” spirit and their impressive ability to attend to every detail of every volume were invaluable resources enabling this project to be completed in a timely and high quality manner.

It may be obvious, but we want to stress also that without the talent, commitment to quality, and professionalism of our editors at John Wiley & Sons, this edition of the *Handbook* would not be a reality and would not be the cutting-edge work we believe it to be. The breadth of the contributions of the Wiley staff to the *Handbook* is truly enormous. Although we thank all these colleagues for their wonderful contributions, we wish to make special note of four people in particular: Patricia Rossi, Senior Editor, Psychology, Linda Witzling, Senior Production Editor, Isabel Pratt, Associate Editor, and Peggy Alexander, Vice President and Publisher. Their creativity, professionalism, sense of balance and perspective, and unflagging commitment to the tradition of quality of the *Handbook* were vital ingredients for any success we may have with this edition. We are also deeply grateful to Pam Blackmon and her

colleagues at Publications Development Company for undertaking the enormous task of copy editing and producing the thousands of pages of the Sixth Edition. Their professionalism and commitment to excellence were invaluable resources and provided a foundation upon which the editors’ work was able to move forward productively.

Child development typically happens in families. So too, the work of editors on the *Handbook* moved along productively because of the support and forbearance of spouses, partners, and children. We thank all of our loved ones for being there for us throughout the several years on which we have worked on the Sixth Edition.

Numerous colleagues critiqued the chapters in manuscript form and provided valuable insights and suggestions that enhanced the quality of the final products. We thank all of these scholars for their enormous contributions.

William Damon and Richard M. Lerner thank the John Templeton Foundation for its support of their respective scholarly endeavors. In addition, Richard M. Lerner thanks the National 4-H Council for its support of his work. Nancy Eisenberg thanks the National Institute of Mental Health, the Fetzer Institute, and The Institute for Research on Unlimited Love—Altruism, Compassion, Service (located at the School of Medicine, Case Western Reserve University) for their support. K. Ann Renninger and Irving E. Sigel thank Vanessa Ann Gorman for her editorial support for Volume 4. Support from the Swarthmore College Provost’s Office to K. Ann Renninger for editorial assistance on this project is also gratefully acknowledged.

Finally, in an earlier form, with Barbara Rogoff’s encouragement, sections of the preface were published in *Human Development* (April 1997). We thank Barbara for her editorial help in arranging this publication.

Introduction: Child Psychology Research in Practice

K. ANN RENNINGER and IRVING E. SIGEL

APPLIED DEVELOPMENTAL RESEARCH

We undertook the job of editing this volume of the *Handbook of Child Psychology* with a sincere interest in and concern for supporting research that is use-inspired and will impact practice. The applied developmental researcher is a conduit between basic research and real people and activity. By studying questions about a person or a group in context, rather than focusing on some aspect of a person's cognitive and affective functioning in isolation, the applied developmental researcher is positioned to contribute to the ways in which professional activity, including educational or clinical intervention, is carried out and/or text, software, curriculum, and media are designed. This form of developmental research draws on both theory and basic research to address the potential for change and development (age-related and/or content-related). It also can validate basic methods and developmental theory.

The basic methods of the applied developmental researcher may include rich description (participant observation, in-depth interviews, discourse analysis, micro-analysis) that supports hypothesis generation and, in later phases of the research process, serves to illustrate and explain quantitative findings. Basic methods may also include controlled hypothesis testing and use of control groups, randomized sampling, and existing questionnaires and tests. The choice of methods reflects the requirements of the research question.

Identifying relevant indicators for study and tracking change and development is critical to establishing and meeting curricular, therapeutic, and/or social policy goals, as is care in their measurement. A developmental focus assumes that (a) change is dynamic and requires

time, (b) the process of effecting change may involve what can look like forward and backward movement, and (c) change needs to be studied in terms of the individual or group as well as the context.

Although no form of research is a prescription for practice, research can inform practice if it is undertaken as a collaboration. Research collaborations in educational, clinical, and social policy contexts typically involve at least one party who is trained in and/or reads research and other(s) who may lack an understanding of, a real interest in, or a readiness to think about either the research literature or its process. These are most successful when all participants hold a jointly articulated vision of purpose and a readiness to build on serendipity, to build on new information, and to delve into and work through problems and/or differences of abilities, interests, prior experiences, and beliefs.

USE-INSPIRED BASIC RESEARCH

Although psychologists such as Binet (1901) and Murchison (1933) used research to inform practice, it is only in recent years that basic research and practice have not been considered distinct efforts. In fact, there has been increasing interest in using developmental research to address problems of practice, or what Stokes (1996) calls "use-inspired basic research." This increased interest can be attributed, in part, to Stokes's articulation of the importance of grounding research in practice in order to meet societal needs. Stokes argues that neither basic nor applied research needs to be exclusive or linear. Rather, he suggests that the study of practice is enhanced by the rigor that characterizes basic

research methods and that government would effect change if it supported research that was use-inspired. In *Pasteur's Quadrant* (Stokes, 1997), he describes Louis Pasteur's work on vaccination and pasteurization as emblematic. Pasteur was a scientist and a humanitarian who was as interested in understanding microbiological processes as he was in how he might control the influences of these processes. Pasteur's interest in finding the source of germs inspired his work on a basic research problem. Stokes notes that information from basic research and the field informed Pasteur's work, and that Pasteur's work, in turn, made contributions to basic research as well as to practice.

Child development research that focuses on change and development in contexts of practice is use-inspired research. The first edition of this volume of the *Handbook of Child Psychology, Child Psychology and Practice*, was in press as Stokes's volume was being published. A newsletter (*Quarterly Newsletter of the Laboratory of Comparative Human Cognition*) and three journals (*Applied Developmental Science, Cognition and Instruction, and Journal of Applied Developmental Psychology*) focused on the application of child psychology to practice had preceded this effort, and a number of significant volumes have followed (e.g., Bransford, Brown, & Cocking's, 1999, *How people learn: Brain, mind, experience, and school*; Lerner, Jacobs, & Wertlieb's, 2002, *Handbook of applied developmental science: Promoting positive child, adolescent, and family development through research, policies, and programs*). Each of these publications highlights the importance of research to addressing problems related to education, clinical practice, and social policy. They also reflect a belief that research can provide needed data that make a case for changed and improved practice and evaluate its effectiveness.

Consistent with the model of use-inspired basic research, government and private foundations have begun championing research specific to practice in contexts that are sorely challenged (e.g., schools, out-of-school care, health care). Such initiatives highlight the importance of evaluating change, or impact. It is expected that studies will: include an evaluation component; demonstrate clear impact; document change; and use the information gathered as a basis for developing models that can be used to scale impact.

In this funding climate, the researcher trained in developmental methods with some experience in practical settings (and/or the possibility of partnering with others

who have experience) is positioned to: (a) identify relevant indicators of change, (b) select methods that will provide information about these indicators, and (c) develop partnerships that support and effect change even when the researcher is no longer present. This is a creative endeavor, one that involves building on existing theoretical models, research methods and findings—but not directly. Rather, theory, method, and prior research provide a basis for collaborating on the identification and prioritizing of questions to be investigated and methods to be used in the practice setting, so that change can be both assessed and effected.

Importantly, what counts as theory, method, and prior research is not necessarily all “developmental” in its origin. While developmental approaches that enable attention to change and human development have particular relevance to questions of practice, use-inspired basic research does not draw on a single theoretical or research tradition. Of necessity, developmental research that applies to practice builds on research specific to the context of inquiry, research focused on the general nature of context, and identifiable principles for practice. Depending on their questions, researchers studying human development may draw on other fields of psychology (clinical, cognitive, educational, neuropsychology, social) and/or disciplines as wide-ranging as anthropology, biology, communications, economics, learning sciences, linguistics, mathematics, and political science.

THE CONTENTS OF THE PRESENT HANDBOOK

In planning the contents of this volume, we selected three fields that are exemplars of how research is informing practice in contexts that are challenged and of social significance: education, clinical practice, and social policy. Within each of these areas we sought authors who, because of their involvement with practice over time, could speak to their decision-making as researchers using basic research to address issues of practice.

For this volume, we specifically invited authors working in a wide variety of practice contexts to write a chapter that included a selective review of the literature and a description of their own research program as an exemplar. Summaries of prior research were considered to be informative, but not sufficient since the aim of this volume of the *Handbook* is to support use-inspired basic research. Similarly, while theoretical models can pro-

vide a language with which to think about practice, they typically do not map the particulars of use and how its study might be undertaken.

We encouraged the authors to include case material in order to provide (a) readers with a context for thinking about the study of change and development and (b) a basis for discussing points raised in the empirical literature and the ways in which these do (or do not) inform practice. We also asked authors to consider a number of questions:

- What are the working assumptions in the research questions being asked? What are the competing hypotheses?
- What are the methods or interventions? On what are they based? What types of adjustments or iterations have they required?
- What principles for practice are suggested by the findings; and what are the caveats about their generalizability? Are there considerations of culture, individual and group needs, gender, and so forth that need to be acknowledged? Was the implementation mandated? What are the ethical issues that need to be addressed?
- What types of decisions get made all of the time in practice even when there is no research to inform practice? What kind of formative assessments can be used in these instances?
- What are the questions with which you and/or the field are still wrestling or still need to wrestle? What are the open questions that are suggested by practice that researchers need to address?

The inclusion of case material, a selected review of the literature, and discussions of decision making were intended to enhance the readability and the utility of chapter contents. These features should also distinguish this volume from others.

Importantly, a volume such as this is expected to hold different meanings for each reader. In fact, each reader is expected to find his or her own favorite or most useful chapters, and these can be expected to differ from those of the next reader. Together, these chapters showcase the thinking that informs use-inspired research on change and development. The chapters provide a basis for thinking about both the ways in which theory and methods inform child psychology research in practice. This volume also addresses the way in which research can inform those working together in practice and mediate decision-making that influences children, their families and/or caretakers, and the professionals who work with them.

The children in Linda Sims's class have gathered on the rug first thing in the morning. All of the children in this Head Start class live in poverty. Four of the children are living in homeless shelters and several others have par-

ents who are in substance abuse treatment programs. Two children have Autism and three have speech and language disabilities. Four of the children speak a language other than English at home.

The authors of this chapter express sincere appreciation to Elena Bodrova and Deborah Leong for their frank and generous discussions of the Tools of the Mind curriculum; to the Tools of the Mind teachers in Maryland and New Jersey, who allowed us to visit their classrooms; to reviewers Linda Espinosa and James

Johnson, and to Martha Bronson and Susanne Denham, for their helpful comments on an earlier draft of this chapter; and to supportive staff and colleagues at the National Association for the Education of Young Children and the Educational Testing Service.

4 Early Childhood Development and Education

The teacher begins to lead the children through a series of beginning-the-day activities that, on the surface, might look familiar to anyone who has been around preschools. However, significant and purposeful differences—driven by specific developmental theory and related research—influence the curriculum and teaching strategies in this classroom. For example, because it is Monday the children are planning their “jobs” for the week. Rather than assigning jobs, however, the teacher guides the children to look at the labels and pictorial representations on the wall and match their names to their preferred job, placing their names in the slots beside the job listing. Those who do not get jobs are reminded that next week there will be another chance to have a special job.

Although the jobs choices and other seated activities have taken no more than 15 minutes, the teacher spontaneously decides to lead the children in a familiar physical activity, the Freeze Game, before moving on. Putting on a tape, she gets the children on their feet, moving in time to lively music. While they are still dancing, she holds up a stick figure in a pose. Knowing the game, the children continue dancing as usual but remember the stick figure’s position. When the music stops, they “freeze” in an approximation of the pose they had seen—this time, with their arms raised. The music starts again, and they dance with vigor, once again ignoring the stick figure’s new pose until the music signals them to stop dancing and they freeze in the pose. At one point, Ms. Sims holds up a particularly complex drawing (two figures, each with one foot up and holding hands) and says “Wow! I know this is hard!” The children grin, dance, and then pair up and respond with extra efforts.

Afterward, the children settle onto the rug again for the final activity of the day’s opening meeting: Share the News. Many preschool classrooms have something like a show-and-tell or other time for each child to tell something to the rest of the class. Share the News is organized differently: Each child is paired with another and invited to share the news on a topic suggested by the teacher, this time, “Tell your friend what your favorite snack is.” The children are accustomed to this ritual and take turns talking and listening with minimal prompting from Ms. Sims. Many children are talking at once as they share their news in partner fashion, but Ms. Sims leans over and listens with interest to each pair, sometimes suggesting a question or reminding a pair of the turn-taking procedures.

This vignette, and others from the same program, provides a real-world context for this chapter’s discussion of developmental theory and research in relation to early childhood programs. The *Handbook of Child Psychology* has not previously included a chapter specifically focused on early childhood education, although early childhood issues have formed an important part of chapters on child care, prevention and intervention, and other related topics. The presence of this chapter in Volume 4 attests to the increased recognition that early childhood education is a powerful tool to promote positive development and learning. Clearly, the scope of early childhood education is far too broad and complex to be comprehensively addressed in a chapter of this length. Rather than attempting to review many aspects of the education of young children, the authors have chosen a different approach, one that is consistent with the overall focus of Volume 4 of this *Handbook*.

THE CHAPTER’S FOCUS AND AIMS

Along with other influences and aims, to a notable extent early childhood education programs have grown out of, and aim to promote, child development. Chapters in the first three volumes of this *Handbook* and other chapters in Volume 4 provide extensive summaries and analyses of research in critical domains of early development and learning.

Despite this abundance of data, a continuing challenge is to make effective connections between developmental theory and research on the one hand, and early childhood programmatic and pedagogical decisions, on the other. As this chapter suggests, that relationship is both critically important and more complex than it may appear at first glance. In this chapter, we illustrate and examine these complex relationships by focusing on two foundations of early development and education: the development of cognitive essentials, specifically children’s representational thinking, self-regulation, and planning; and the development of children’s emotional competence, taking as examples the key areas of emotional security and emotion regulation (ER). Although other developmental domains play a central role, these areas have been identified as critical underpinnings of literacy and other academic skills and of longer-term life success. Both of these foundational areas are also supported by extensive developmental research. Yet at times, each has been inad-

equately represented in early childhood education policies and practices. Connecting and strengthening the two foundational areas is a third focus: the implementation of developmentally appropriate, classroom-embedded assessment practices that can document children's progress and guide teachers' decision making. Here again, research has great potential to inform the selection and use of assessment tools, and yet developmental perspectives have been insufficiently emphasized in early childhood assessment practices.

We focus our discussion on research and programs for children ages 3 to 6, where much public policy attention is currently directed and where a wealth of developmental and educational research is available, although we describe earlier developmental manifestations and, where available, trajectories in each of the areas highlighted in the chapter. Although the chapter has a preschool emphasis, many of our conclusions can be applied to curriculum and educational practices for both younger and older children.

Rather than confining the analysis of these research and practice relationships to an abstract level, we link this discussion to a specific case example: the Tools of the Mind curriculum developed by Elena Bodrova and Deborah Leong (Bodrova & Leong, 1996; Leong, 2005). The selection of this curriculum is not intended as an endorsement of one approach over all others. Rather, we have chosen the Tools of the Mind curriculum as a case example for other reasons. First, in line with this chapter's focus, the Tools curriculum is strongly influenced by developmental theory and research, specifically, by Vygotskian theory and a related body of social constructivist research. Second, unlike some other, more widely adopted curricula such as High/Scope (Hohmann & Weikart, 2002; Schweinhart, Barnes, & Weikart, 1993) and the Creative Curriculum (Dodge, Colker, & Heroman, 2002), the Tools of the Mind curriculum is still in the relatively early stages of implementation and evaluation. Third, as the curriculum becomes better known in the early childhood community, it is facing the challenges of going to scale. Finally, the nature of this curriculum is such that teachers need to assimilate and be committed to a relatively complex set of guidelines. As the curriculum becomes more widely implemented, it is likely that not all of these teachers will have participated in the curriculum's development; indeed, some may disagree with aspects of its approach. For these reasons, Tools of the Mind seems to be a fruitful example to illustrate the

important and complicated connections between theory and research on the one hand, and the world of early childhood practice on the other.

Specifically, we hope this chapter will provide a wide audience of readers with:

- A sense of the contexts within which developmental theory and research have exerted, and continue to exert, influence on early childhood education programs.
- An overview of developmental research in several domains that are essential priorities in early childhood education programs.
- A sense of the opportunities and obstacles facing efforts to use developmental research in designing early education programs.
- Consideration of the implications of these complex relationships for developing, implementing, and evaluating early childhood education programs.

CHAPTER OVERVIEW

The chapter begins by placing the preceding classroom vignette in contemporary contexts for and trends in early education in the United States. Next we discuss the functions and limitations of developmental theory and research in informing the content and implementation of early childhood education programs, previewing some of the challenges that will become apparent in later parts of this chapter.

This background is followed by discussion and analysis of several essential foundations for young children's learning and development (children's cognitive competence, with a focus on representational thought, self-regulation, and planning; and children's emotional competence, with a focus on security and emotion regulation), with effective assessment practices serving to connect, document, and support these two domains. Again we emphasize that these topics do not tell the whole story of what needs to be considered in early childhood education, but they were selected for their centrality, and they will provide key points for analysis. Throughout this discussion, we place special emphasis on the role of the teacher and other significant adults in actively promoting early development and learning. We also examine what research has not yet told us, or may not be able to tell us, about how these essential foundations may best contribute to children's competence in early childhood education programs.

6 Early Childhood Development and Education

We then turn to a more extended analysis of our case example, the Tools curriculum. We describe the theoretical foundations, key features, and current status of this educational approach. The primary task is to examine how the developmental examples that this chapter has presented (representational thinking, self-regulation, and planning; security and emotion regulation; and developmentally appropriate early childhood assessment) are or might be embodied in this still-evolving curriculum approach.

The broader practical, systemic, and policy challenges of linking developmental theory and research with early childhood curriculum, teaching practices, and assessment are the focus of the final section of the chapter. In this discussion, we again build on the examples from Tools of the Mind, identifying the challenges involved in taking a demonstration program to scale; issues of variability and quality in the system of U.S. early care and education; issues in delivering professional development; challenges of maintaining integrity and coherence; expectations for evidence and accountability; and the continuing, critical gaps in the field's knowledge base. The chapter concludes with a summary and recommendations for linking research with practice.

CONTEXTS FOR EARLY CHILDHOOD EDUCATION TODAY: THROUGH THE LENS OF ONE CLASSROOM

The Tools of the Mind classroom just introduced, and revisited in vignettes throughout the chapter, operates in a context that mirrors larger trends in early childhood education. This context provides a framework for our later discussion of relevant developmental theories and research.

The local program of which Linda Sims's classroom is a part would not have existed 5 years ago. Not only is the curriculum itself new, but the program is in session for more hours per day than Head Start programs typically operated in the past: The children attend for 6 hours per day rather than 3 or 4 hours. This shift is consistent with national trends in Head Start and with evidence that the "dosage" of interventions must be adequate to produce results (McCall, Larsen, & Ingram, 2003; S. L. Ramey & Ramey, 1992). Down the hall from Linda Sims's Head Start class is another classroom for 4-year-olds, also using the Tools of the Mind model. This classroom is part of the state prekindergarten sys-

tem. Maryland, where this school is located, is one of at least 38 states investing some resources in this form of early intervention (Barnett, Hustedt, Robin, & Schulman, 2004).

As part of Head Start, Linda Sims's classroom serves children living in poverty; her students are among the millions of young children who are statistically at risk for negative educational and developmental outcomes because of poverty and other forms of adversity (Lee & Burkham, 2002). Furthermore, the many cultural, ethnic, and language groups represented by the children in Linda Sims's class are typical of today's increasingly diverse preschool population (U.S. Census Bureau, 2003). Because she also has in her class a number of children with disabilities and individualized education programs (IEPs), Linda Sims must continually adapt her curriculum and teaching practices to multiple developmental and educational needs.

Despite the children's many challenges, Linda Sims's hopes for her class are high, but they are not unrealistic. The goals and desired outcomes of the Tools of the Mind program are consistent with the research base, synthesized in several major reports (Bowman, Donovan, & Burns, 2001; Shonkoff & Phillips, 2000; Snow, Burns, & Griffin, 1998), that documents the rapid development and great learning potential of the early years. Linda Sims's classroom functions within an educational and policy environment that reflects an ever greater concern with school readiness and a growing discussion of the potential return on investments in early education (Lynch, 2004). The stage was set in 1993 by the National Education Goals Panel's definition of "Goal One": that all children, including children living in poverty, would enter school "ready to learn."

Since that time, policymakers at the federal and state levels have continued to view early childhood education as a strategy, urging even greater attention to cognitive and academic skill development, especially in early literacy. The 1994 reauthorization of Head Start required programs to ensure that all children acquire specific skills and knowledge, including knowing 10 letters of the alphabet. Although Head Start has broader goals than alphabet knowledge (Zigler & Styfco, 2003), and school readiness is often defined more broadly than in some of these policy initiatives (Child Trends, 2001; Kagan, Moore, & Bredekamp, 1995; National Association for the Education of Young Children, 1995; Shore, 1998), a policy climate that prioritizes an academic and literacy-driven definition of school readiness forms part

of the context in which Tools of the Mind is being implemented and evaluated.

This context underscores the potentially significant role of developmental theory and research, both for the new Tools of the Mind curriculum and for many other efforts to create better outcomes for young children. The following section examines the functions and past uses of child development knowledge, as well as trends, challenges, and critical perspectives in bringing child development knowledge to bear on early childhood education.

DEVELOPMENTAL THEORY, RESEARCH, AND EARLY CHILDHOOD EDUCATION

Child development theory and research have a long relationship with early childhood education. Ideas about the potential of early childhood education and early intervention, as well as critical decisions about curriculum, teaching practices, and assessment and evaluation approaches, have frequently been grounded in developmental perspectives.

Major Functions

Over the years, developmental theory and research have served several critical functions with respect to early childhood education:

- *Providing developmental rationales for why early childhood education and early intervention may support positive child outcomes.* Examples include rationales stemming from evidence of the importance of early experiences for the development of critical language and literacy skills (Hart & Risley, 1995) and rationales from cognitive developmental theory and research (e.g., the High/Scope Piagetian-influenced curriculum; Schweinhart & Weikart, 1997).
- *Helping to identify specific desired outcomes of early education programs and curricula.* Research on the developmental course of social competence, for example, identifies specific social and emotional outcomes as of particular significance in early childhood (*Handbook*, Vol. 3); studies of literacy development highlight developmental precursors of later reading and writing, such as vocabulary and phonemic awareness (Snow et al., 1998).
- *Helping to specify interventions, curriculum models, experiences, and practices that would be likely to produce positive developmental outcomes.* For example,

Bronfenbrenner's (Bronfenbrenner & Morris, 1998) ecological theory suggests that interventions emphasizing family and community contexts would be likely to produce better outcomes. Social constructivist theory and research (Rogoff, 1998; Tharp & Gallimore, 1988; Wertsch, 1991) suggest that interventions should emphasize peer interactions and scaffolded interactions with more skilled children and adults.

- *Helping to identify what kinds of developmental indicators should be assessed and tracked so as to document children's individual progress in early education programs and to provide evidence of program effectiveness.* What are the connections between earlier and later development, and between earlier and later forms of a behavior? The sequence of early motor development is clearly mapped out, but developmental sequences or trajectories can be difficult to describe in many areas of early development and learning, such as the growth of mathematical understanding. Although more work is needed (Love, 2003), developmental theory and research can help identify the precursors of later competence and can help identify a variety of possible typical and atypical developmental pathways or trajectories.

Developmental theory and research, then, have been sources for goals and practices in early childhood education in general, and early childhood curriculum in particular. A few examples will underscore this point.

Historical Examples

A full history and a critical analysis of the child development-early education connection are beyond the scope of this chapter but are addressed in several other accounts (Chafel & Reifel, 1996; Goffin & Wilson, 2001; Mallory & New, 1994; Stott & Bowman, 1996). However, even a quick overview of this history illustrates the ways that different conceptualizations of children's development have helped shape not only the content but also the specification of outcomes in programs for young children. This history also illustrates the complexity of, and challenges to, the use of developmental theory and research as a basis for early childhood curriculum.

For developmentalists, but also for those in the public policy and advocacy community, interest in U.S. early childhood education has resided in its potential to positively influence the trajectory of children's development

and learning, for example, in Head Start (Zigler & Valentine, 1997). Early optimism about the developmental efficacy of early childhood education was replaced by caution as research appeared to show what were called “fade-out” effects (Cicirelli, 1969), with many short-term gains disappearing in the early years of school.

Yet this perspective on the developmental power of Head Start began, in more recent years, to be replaced with or at least accompanied by another perspective. Longitudinal studies of children enrolled in Head Start and other programs began to show longer-term developmental benefits (Barnett, 1995). Together, these studies provide converging, though still debated, evidence of a set of benefits that go beyond short-term academic outcomes. Indeed, this research suggests that these effects are more likely to be found in other developmental domains and in a different time frame. Over time, children who attended the programs evaluated in these studies were less likely to be retained in grade, less likely to be assigned to special education, more likely to graduate from high school and hold a job, and less likely to engage in a variety of forms of antisocial behavior (Nelson, Westhues, & MacLeod, 2003; C. T. Ramey et al., 2000; Reynolds, 2000; Reynolds, Ou, & Topitzes, 2004; Schweinhart et al., 2005).

Curriculum Models in Early Childhood Education

Research on the outcomes of early childhood education has also examined the relative effectiveness of various curriculum models. As outlined by Goffin and Wilson (2001), theories of child development have served as the principal foundation, though not the only foundation, for curriculum model development, varying according to values about children’s learning and according to beliefs about the processes by which children develop and learn. Interpretations of the results of some past curriculum comparison studies have been mixed. Some have concluded that, although differences in child outcomes tend to reflect the curriculum’s intent, early childhood curriculum models do affect child outcomes, with potential negative consequences associated with highly structured, academic preschool programs (Goffin & Wilson, 2001; Marcon, 1999, 2002; Schweinhart & Weikart, 1997). Yet the National Research Council’s report *Eager to Learn: Educating Our Preschoolers* (Bowman et al., 2001) came to a different conclusion, questioning whether evidence existed to

show that any one curriculum had a clear developmental and educational advantage.

The Questions Reframed: Current Research Initiatives in Early Intervention and Curriculum Comparison Studies

Many writers agree that the debate over questions such as *Is early intervention effective?* or *Does quality in early childhood education matter?* or *Which curriculum is the best?* is over (Guralnick, 1997), or at least has been significantly recast. Now the questions are more complicated, and more interesting: *How does early childhood education in general, or a particular curriculum, make a difference?* *In what domains does early childhood education, or a particular curriculum model, make a difference?* *A difference in what and for whom and under what conditions (conditions both within the child and within the program, curriculum, and teacher characteristics)?* *What are the environmental factors that promote or hinder children’s movement toward important developmental and educational goals?* Recent conceptual frameworks for thinking about early educational interventions reflect this complexity (e.g., C. T. Ramey & Ramey, 1998).

It has not been easy to disentangle what it is about early childhood education programs that produces positive effects, or what types of curriculum and teaching practices, combined with what other family and child supports, may yield the greatest benefits in critical areas of development and learning. These kinds of questions have become the focus of several recent federal initiatives funding large-scale research projects, using carefully designed studies to investigate complex issues around approaches to early childhood curriculum and intervention.

For example, a group of eight research centers, funded in 2003 as part of the Interagency Early Childhood Research Initiative, aims to answer an overarching question: *Which early childhood programs, and combination of program components and interactions with adults and peers, are effective or ineffective in promoting early learning and development, for which children, and under which conditions?* Projects include an evaluation of an enhanced Head Start curriculum that places emphasis on both evidence-based literacy practices and social and emotional competence, and a study comparing different versions of an intervention to decrease behavior problems and thereby promote school readiness, using teacher

professional development, the presence of teachers' aides, and access to mental health professionals. The Head Start Quality Research Center Consortium is supporting the development, testing, and refinement of eight interventions to enhance literacy, social-emotional development, and other domains of school readiness. Finally, another program of research is supported by the U.S. Department of Education's Institute of Education Sciences, with grantees evaluating existing curricula with a focus on the conditions under which curricula may be more or less effective in promoting positive cognitive, academic, and social outcomes.

Complexities and Cautions

These examples from the history of early childhood education, as well as from more recent initiatives, show how extensively a developmental focus has informed the shape, direction, and evaluation of early childhood education programs. However, numerous concerns and cautions have been expressed about the use of child development knowledge in early childhood education.

First, child development knowledge is not the only source of influence on early childhood education. Educators have frequently emphasized that curriculum and program development are shaped by sources other than child development theory and research (Goffin & Wilson, 2001; Stott & Bowman, 1996; Zimiles, 2000). For example, developmental research does not always provide clear guidance about what pedagogical approaches may best produce positive outcomes, and attention to developmental competence has not always been connected to a "knowledge-centered environment" (Bransford, Brown, & Cocking, 2000) needed to promote school success for young children living in poverty (Bowman, 2004). Further, the reconceptualist movement in early childhood education, like other critical perspectives in the broader field of education, has articulated strong challenges to the field's reliance on a child development knowledge base, asserting that generalizations from past developmental research do not hold up across cultures, genders, and other sources of variation, and that the imposition of narrow theoretical perspectives perpetuates imbalances of power and control (Bloch, 1992; Kessler & Swadener, 1992; Mallory & New, 1994). Others have noted that practitioners' insights and "bottom-up" theories of practice are frequently ignored in an emphasis on "top-down" application of formal theory and research (Williams, 1996).

These critical perspectives are important to keep in mind, providing a context in which this chapter's discussion of developmental perspectives should be placed.

Another caution comes from past experiences in which child development research and developmental theory have been misunderstood or misapplied. The 1960s' early optimism about the potential effects of a brief summer dose of Head Start stemmed in part from what Zigler has characterized as the naive environmentalism of that period (Zigler & Styfco, 2004). As developmental knowledge has accumulated, these views have yielded to a more complex and nuanced version of development, but the misuses of the so-called new brain research sounds another cautionary note (Bailey, Bruer, Symons, & Lichtman, 2001). Still another example is the persistent influence of maturationist theory (Gesell & Ilg, 1943) regarding school readiness and school entry age, despite assertions that the theory lacks research support (Graue & DePerna, 2000).

SOME DEVELOPMENTAL ESSENTIALS FOR HIGH-QUALITY EARLY CHILDHOOD EDUCATION

The preceding overview of the history, functions, and limitations of developmental theory and research in relation to early childhood education will serve to frame the discussion that follows. As we will see, research makes a strong case for attention to two significant developmental areas that are the focus of a number of early childhood education curricula, including this chapter's case example, Tools of the Mind: (1) *cognitive competence*, of which *representational thinking*, *self-regulation*, and *planning* are examples, and (2) *emotional competence*, focusing on the examples of *security* and *emotion regulation*. This analysis is followed by a discussion of the need for high-quality early childhood assessment practices to ensure effective teaching and appropriate accountability.

As the next section of this chapter shows, these essentials have a number of points in common. Both cognitive and emotional competence have long been priorities, although, as noted earlier, they are far from the only priorities in early childhood education. Both have been enriched by recent theoretical and research advances in developmental psychology and in some promising applications in early childhood education settings. Yet both

have suffered from periods of neglect. At various times, public policies, competing priorities, and other factors have served to limit the field's ability to implement evidence-based practices in these critically important areas. Although other developmental domains are also significant—such as language, social, and physical development—the breadth and power of both dimensions have great potential to positively influence the direction of early childhood education in ways that benefit not just these specific areas, but other aspects of development and learning as well.

We should also emphasize that, although separated for purposes of review and discussion, cognitive and emotional competence are far from disconnected either at the conceptual or the neurobiological level (Blair, 2002). In the following pages, repeated examples underscore how cognitive and emotional dimensions mutually influence and connect with one another in the early years: how, for example, children's emotional security allows access to cognitive representations, how the emergence of planning skills may be used in the service of emotion regulation, and how adult interactions that support emotional competence also lead to cognitive competence.

If the knowledge base for these essential foundations of early learning is to have a positive influence on curriculum and teaching practices, and therefore on outcomes for the children enrolled in early childhood programs, *assessment* must be another essential and unifying tool. We therefore discuss the multiple challenges of effective early childhood assessments, for example, to inform curriculum implementation and teaching practices and to help evaluate curriculum effectiveness.

An important theme throughout this part of the chapter is the central role of early childhood teachers as potential catalysts for children's cognitive and emotional growth and for gathering, interpreting, and using assessment information about that growth. The field of early childhood education has held, and continues to hold, divergent views about how active teachers should be in direct instruction, coaching, modeling, or otherwise promoting children's development and learning, rather than providing more indirect support and facilitation by setting up the environment and creating conditions for exploration and play. The authors of this chapter are persuaded by research and promising practices that identify teachers' intentional involvement, scaffolding, and collaboration as key supports for early development and

learning (e.g., Bowman et al., 2001; Bransford et al., 2000; Edwards, Gandini, & Forman, 1998; Rogoff, Goodman, Turkianis, & Bartlett, 2001).

FOSTERING COGNITIVE ESSENTIALS IN THE EARLY CHILDHOOD YEARS

As an observer watches, 4-year-old Monique asks the teacher in her Tools of the Mind classroom for paper to draw the house she and her friend Ashid had made with the blocks. "I need paper so we can remember what we did," she says to the teacher. Monique and Ashid take the paper and begin to draw. "Should I draw this?" Monique asks as she points to a part of their block structure. "Yeah, well, I'll do this part," Ashid responds. Together they draw what represents the structure. The next day, they get the paper and huddle together to confer on how to rebuild their block house.

Many experts and policymakers today contend that early childhood programs should stress the literacy and mathematical skills that children need to succeed in school and beyond. Important as these skills are, they could be said to be the tip of the iceberg in early education: critical, but dependent on other vital capacities that should be fostered during the years from 3 to 6. A number of researchers and educators have pointed to fundamental abilities that not only underlie reading, mathematics, and other discipline learning but also make possible children's development of focused attention, problem solving, and metacognition, all key in school success. Of these fundamental cognitive abilities, we focus here on three: representational thought, self-regulation, and planning.

Theory and research in these areas are briefly summarized in the following sections. Also described are a number of educational approaches in which representational abilities, self-regulation, and planning are major themes. These include Montessori (1949/1967), High/Scope (Hohmann & Weikart, 2002), Reggio Emilia (Edwards et al., 1998), the Brookline Early Education Project (M. B. Bronson, Pierson, & Tivnan, 1985), Educating the Young Thinker (Copple, Sigel, & Saunders, 1984), and, most recently, Tools of the Mind (Bodrova & Leong, 2003a, 2003b).

Representational Thought

At approximately the same time in their development, children begin to engage in pretend play, develop receptive and expressive language, and show signs of representing objects and events that are not present. Developmental psychologists thus hypothesize strong relationships among these processes. For Piaget, the common factor among these new achievements of the child was what he called the *semiotic* (or symbolic) function, which he saw as developing through the individual child's interaction with the physical and social world. Vygotsky strongly emphasized the social context as the means through which an object, word, or gesture becomes symbolic for the child. For instance, Vygotsky (1981, pp. 160–161) wrote:

At first the indicatory gesture [pointing] is simply an unsuccessful grasping movement directed at an object and designating a forthcoming action. The child tries to grasp an object that is too far away. The child's hands, reaching toward the object, stop and hover in midair. . . . When the mother comes to the aid of the child and comprehends the movement as an indicator, the situation changes in an essential way. The indicatory gesture becomes a gesture for others.

In other words, the gesture takes on a representational meaning.

Whatever view one takes from these and other perspectives on the dawn of representation, it is clear that a major transition takes place in the 2nd year of life. The ability to form mental images allows children to anticipate and remember objects, people, and events that are not present, that is, to mentally represent (Bruner, 1966, 1983; Piaget, 1926/1955, 1952; Vygotsky, 1962, 1930–1935/1978). It is during this period that children begin to reflect on their actions and perceptions and form symbolic relations among things.

The Burgeoning of Representational Thought

Near the end of the 2nd year, mental representation can be seen in the child's reproducing an event seen earlier, called *deferred imitation* (Piaget, 1962). Also emerging at this time are the more advanced levels of object permanence. Children now systematically search for an object hidden with invisible displacements (Piaget, 1952; Uzgiris & Hunt, 1975). Besides being documented in

systematic research, object permanence can also be seen in children's daily activities. For instance, children late in the 2nd year of life find it necessary to make only occasional visual checks for their mother, far fewer than they did at a younger age (W. C. Bronson, 1973). In all these ways, children manifest the transition to representational thinking at around 18 to 24 months. This advance in thinking is also apparent in children's symbolic or pretend play.

Representation in Pretend Play

The early childhood field has long recognized the many ways pretend play nourishes children's well-being and promotes emotional, social, cognitive, and imaginative development (Bergen, 1988; Johnson, Christie, & Wardle, 2005; Russ, 1994; D. G. Singer & Singer, 1990; Smilansky & Shefatya, 1990). Volumes are written about each of these functions; in this chapter, the major focus is play's cognitive aspects. In considering cognition and play, Vygotsky's work has been a major force.

For Vygotskians, the importance of play lies partly in the fact that children learn to use objects and actions in their symbolic function and thus become more able to think symbolically. Additionally, Vygotsky (1966/1977) saw the dramatic play context, with its system of roles and rules—who does what and what is allowed in the play scenario—as uniquely supportive of self-regulation. Children's eagerness to stay in the play motivates them to attend to and operate within the structure, conforming to what is required by the other players and by the play scenario. Motivation is the first of the four principal ways children's dramatic play influences their development, as identified by Vygotsky's colleague Daniel Elkonin (1977, 1978). In the intensely engrossing play context, children for the first time harness their immediate wants and impulses.

Second, from a Vygotskian perspective, dramatic play facilitates cognitive decentering or perspective taking (Elkonin, 1977, 1978; Vygotsky, 1966/1977). The argument is that taking on a pretend role—being another person for a while—helps the child to move to another perspective and then back to his or her own. In addition, attention to the perspectives of other players is critical for coordinating multiple roles and negotiating play scenarios. Vygotsky and Elkonin also saw cognitive decentering as involved in the assigning of different pretend functions to the same object. Later, children will use

12 Early Childhood Development and Education

this ability in school to recognize another's perspective, coordinating their cognitive perspectives with those of their teachers and learning partners. In time, the ability to coordinate multiple perspectives becomes less outward and more mental, leading to the development of reflective thinking and metacognition (Elkonin, 1977, 1978). The gradual development of this reflectivity and metacognition, including children's notions about their own mental activities and those of others, has also been evident in "theory of mind" research (Bialystok & Senman, 2004; Chandler, 1988; Dunn, 1988).

A third developmental function of play noted in the literature is promoting mental representations, crucial for higher-level thinking. In pretend play, the child begins to separate the meaning of objects from their physical form. At first, children are able only to use replicas of real objects in their pretend play. If this type of play is supported, children then begin to substitute objects that do not closely resemble the object but can perform its function, such as a pencil to serve as a spoon for stirring make-believe soup (Copple, Cocking, & Matthews, 1984; Pulaski, 1973). Finally, experienced players are able to dispense with the object when they choose to do so, often using gestures or speech to bridge the gap, as in "Now I'm carrying a heavy box" (Bornstein, Haynes, Legler, O'Reilly, & Painter, 1997; Corrigan, 1987; Fenson, 1984). Experience in using object substitutes in play appears to help children move from thought that is entirely bound to actions (sensorimotor intelligence) to operational thought, Vygotskian theorists argue. As thought becomes uncoupled from specific actions and objects, children begin to be able to use words and eventually other symbols and signs to represent concepts and abstractions (Piaget, 1962; Vygotsky, 1962).

The final function of play in Elkonin's framework is the development of "deliberateness," or self-regulation, in children's behavior. To stay in the play, the child needs to follow the rules of the play, and play partners monitor each other continually to make sure that everyone is doing so (Bodrova & Leong, 2003a). In early play, this self-regulation is evident in children's physical actions and modification of speech, as in walking heavily to play an elephant, staying still when playing a guard, or talking in a high, babyish voice to portray an infant. Although these are not the only reasons symbolic play occupies a central place in early childhood education, they are the rationales that are most pertinent to our discussion here. For Vygotskians and other constructivists, play is therefore key in preparing children for the learn-

ing demands, social interactions, and behavioral expectations they will experience in and out of school.

Influences on Representational Thinking

The influence of children's experiences on the quantity and representational levels of make-believe play can be seen in the variation found in children of different socioeconomic and family backgrounds (Freyberg, 1973; Fromberg, 1992; Sigel & McBane, 1967; Smilansky, 1968; Smilansky & Shefatya, 1990). Evidence also suggests that training and forms of direct support from adults can increase children's ability to use representation and pretense in their dramatic play (Freyberg, 1973; E. Saltz & Brodie, 1982; Smilansky, 1968). Although differences in mental representation are harder to observe, children who have certain kinds of early education experiences may increase their skills or dispositions with respect to use of mental representations, as the work reported next suggests.

Developing Representational Abilities in Early Childhood Programs

Two programs, one early program and one that is ongoing, are particularly known for their emphasis on children's representations and representational thinking: Irving Sigel's Educating the Young Thinker program (Copple, Sigel, et al., 1984; Sigel, 2000), and the Reggio Emilia approach (Edwards et al., 1998; Malaguzzi, 1998).

In 1975, Irving Sigel, along with colleagues Ruth Saunders and Carol Copple, began the Educating the Young Thinker program in Princeton, New Jersey. It was based on Sigel's work on representational competence and the importance of what he calls "distancing" experiences: those that place on the child the cognitive demand of considering objects, actions, or events that are separate in time and/or space from the immediate present (Copple, Sigel, et al., 1984). Based on the idea that actively engaging in mental construction and representation promotes children's representational abilities and dispositions, teachers in the program frequently engaged preschoolers in anticipating, predicting, recalling, or reconstructing experiences. For example, children planned in considerable detail how to make changes in their playground, prepare for a family night at the preschool, or investigate a science problem. Teachers actively encouraged metacognitive thinking with questions such as, "How can we make sure to remember our plan?"

Children randomly assigned to classrooms using such strategies were found to differ on a number of measures

from children in control classrooms that were comparable in materials, teacher training, parent involvement, and other aspects that might be expected to affect child outcomes (Sigel, 2000). Additional evidence for the effects of such inputs on children's representational competence comes from laboratory studies in which parents were instructed to teach their children a task (e.g., McGillicuddy-DeLisi, Sigel, & Johnson, 1979). In such teaching situations, parents' use of distancing strategies was significantly associated with children's representational competence.

For more than 30 years, educators, together with parents and community members, worked together to develop an acclaimed public system of early care and education in the city of Reggio Emilia, Italy. Numerous early childhood specialists have explored the implications of the Reggio Emilia programs for the theory, practice, and improvement of U.S. early childhood education (e.g., Edwards et al., 1998). Although Reggio programs highly value the role of play in children's development, they are especially well-known for the complex, long-term projects in which children and teachers become engaged over weeks and months. At the start of a project, teachers engage children in bringing to mind what they know and think about the topic or problem of their investigation and about what they want to learn and accomplish in the project. Malaguzzi (1998) sees these predictions and hypotheses at the outset as key in organizing and galvanizing the project work.

For the duration of the project, teachers make observations, tape and make transcriptions of children's discussions, take photographs showing work in progress, and otherwise document the ongoing work. The documentation of the children's thoughts and ideas, which the group comes back to repeatedly, helps them remember significant points and get new ideas. Participating in and making use of the documentation also expands children's understanding of representational modes, including language and visual representation in various media—the “hundred languages of children” of which Reggio Emilians speak (Edwards et al., 1998). In Reggio Emilia, graphic representation is viewed as a communication tool much simpler and clearer than words, and thus as an invaluable way to help children clarify and extend their thinking. Children make extensive use of drawing, as well as models and other concrete forms of representation, as they work together on a project (Malaguzzi, 1998). Because children are trying to communicate with others in these graphic efforts, they often

pause to clarify their ideas before putting them down on paper and making them visible to other people.

Although systematic research, such as comparisons with control and experimental groups, has not been part of the Reggio Emilia tradition or emphasis, some of the program's effects are quite visible. Those who see the products children produce and documentation of the conversations and procedures they engage in along the way are struck by the sophistication and thoughtfulness of the work (Edwards et al., 1998; Katz & Cesarone, 1994; New, 1998).

Several other programs and interventions relating to mental representation are discussed in “Developing Planning Skills in Early Childhood Programs” later in the chapter.

Self-Regulation

Related to but not identical with the domain of emotion regulation discussed later in this chapter, self-regulation is a significant dimension of cognitive competence, with implications for a wide array of developmental and learning outcomes. Self-regulation is by no means a simple or singular construct. It has been defined and studied in various ways, including self-direction, self-regulated learning, self-control, and impulse control (M. B. Bronson, 2000). Although it is beyond the scope of this chapter to detail the distinctions among these various terms and the paradigms used to study them, these differences clearly need to be considered when interpreting implications for developmental expectations and for what supports and educational practices are useful at various ages and in different situations (Blair, 2002; M. B. Bronson, 2000).

Early childhood educators (e.g., Bredekamp, 1987; Hymes, 1955; Montessori, 1949/1967) have long viewed children's development of self-regulation as a primary goal for the preschool years. Research evidence links self-regulation to focusing of attention (Barkley, 1997; Holtz & Lehman, 1995), self-directed thinking and problem solving (Brown & DeLoache, 1978; DeLoache & Brown, 1987), planning, and metacognition (Flavell, 1987; Wellman, Fabricius, & Sophian, 1985). Presumably through this association with behaviors and skills needed in school, self-regulation in school-age children is predictive of academic success (Blair, 2002; Ladd, Birch, & Buhs, 1999; Normandeau & Guay, 1998; Zimmerman, Bonner, & Kovach, 1996; Zimmerman & Schunk, 1989).

14 Early Childhood Development and Education

Over the early childhood years, children become less reactive and more self-regulated and deliberate. With development, they are better able to control their behavior and attention (Barkley, 1997; Holtz & Lehman, 1995; Mischel & Mischel, 1983). They become increasingly capable of self-directed thinking, planning, and problem solving (Berg, Strough, Calderone, Meegan, & Sansone, 1997; Brown & DeLoache, 1978; DeLoache & Brown, 1987; Rogoff, Gauvain, & Gardner, 1987).

In the preschool years, a major force in increasing self-regulation appears to be children's engagement in pretend play. Erik Erikson (1950) describes how children gain control of their emotions and social behavior through their play. In play, they express the world inside them and impose order on the world outside. Thus, in Erikson's view, if children lack sufficient play opportunities or are pushed prematurely out of this stage by external demands, they may not become as self-regulated as other children are.

Elias and Berk (2002) investigated the relationship between play and self-regulation that Erikson, Vygotsky, and others have posited. Observing the complexity of children's dramatic play and recording self-regulation during cleanup and circle time, they found a positive relationship between the time spent in mature dramatic play and the child's self-regulation during cleanup.

The role of language in developing internal control of action and thought has also been emphasized by theorists. Vygotsky (1962, 1930–1935/1978) considered language to be the primary means for developing both understanding and self-regulation, and a substantial body of research supports this idea (Berk, 1992; Fuson, 1979; Luria, 1961). Children repeat the kinds of instruction and guidance that others have given them and begin to give themselves audible directions (e.g., "Put the red ones there"; "That piece doesn't fit"). According to Vygotsky (1962, 1930–1935/1978), in time this private speech becomes internalized as thought.

The ability to store and retrieve mental images, greatly expanded by use of language, enables children to apply past experience in a variety of situations. Moreover, the growing capacity for mental representation allows children to make plans before taking action; their activities take on a more purposeful, goal-directed character (Friedman & Scholnick, 1997; Friedman, Scholnick, & Cocking, 1987; Wellman et al., 1985).

Influences on Self-Regulation

Zimmerman and his colleagues (e.g., Schunk & Zimmerman, 1997; Zimmerman, 1989; Zimmerman, Ban-

dura, & Martinez-Pons, 1992), working from a social-cognitive perspective, conjecture that parents function as implicit and explicit role models in their children's acquisition of self-regulatory skills. With path analysis (Martinez-Pons, 1996) and training-study methods (Zimmerman & Kitsantas, 1999, 2001), they have demonstrated the causal influence of self-regulatory models, such as parents, on children ranging from elementary through high school. The researchers posit that modeling and encouragement of self-regulation are part of the "hidden curriculum" that some children experience and others do not. They offer school-based interventions, such as one at the middle school level (Zimmerman et al., 1996).

Developing Self-Regulation in Early Childhood Programs

Early childhood educators would argue that this focus on self-regulation should take place much earlier than in middle school. Besides the emphasis on promoting children's self-control and self-regulation that runs through much of early childhood education literature (see section on "Fostering Emotional Essentials in the Early Childhood Years"), two early childhood education approaches stand out as particularly concerned with this area.

The Montessori (1949/1967) method values children's becoming independent learners. Developmental milestones such as weaning, walking, and talking are seen as events that enable the child to achieve increased autonomy and self-regulation. A wide range of activities are available to children at all age and maturity levels to reinforce Montessori goals of individualized work, progress, and independence. By encouraging children to make decisions from an early age, Montessori programs seek to develop self-regulated problem solvers who can make choices and manage their time well. Some evidence of these associations comes from research by Kendall (1992), who examined the autonomous behavior among groups of Montessori schools and traditional public schools, finding that Montessori students demonstrated higher levels of self-regulation, independence, and initiative than those from traditional schools.

Similarly, self-regulation is a central goal in the Vygotsky-based Tools approach, the case example examined later in this chapter. The methods used in Tools of the Mind programs to help children become more self-regulated are described there.

Planning

Planning may be defined as the deliberate organization of actions oriented toward a goal (Prevost, Bronson, & Casey, 1995). Both adults and children plan in their daily lives, although young children's planning is far less complex and frequent than it later becomes (e.g., Benson, 1994, 1997; Hudson, Shapiro, & Sosa, 1995). Because planning is a factor in how children approach school tasks, manage their time, and create and modify strategies to reach goals, it is not surprising that planning ability has been found to be associated with school achievement (Naglieri & Das, 1987).

Development of Planning and Related Processes

Early precursors of planning appear in the sensorimotor period when infants and young toddlers begin to vary their actions to get interesting effects (Lewis, 1983; Piaget, 1952). For example, when an infant clutching a rattle in his hand moves his arms and hears the sound, he begins to move his arms more vigorously to create more sound.

Behavior becomes increasingly intentional in the 2nd year of life. Part of what allows embryonic planning to occur at this point is the child's development of mental representation. As Haith (1997) notes, planning seems to depend on the individual's ability both to mentally represent and to have control over action alternatives. Because representation of events is necessary for planning, research on recall and representation of events is relevant here. Research by Bauer and colleagues (Bauer & Hertsgaard, 1993; Bauer & Mandler, 1989, 1990, 1992) demonstrates that preschool children can reproduce a modeled series of actions, thus showing their ability to represent the sequence of events mentally.

Further evidence suggests that young children's knowledge about familiar events is both organized and general (Hudson & Shapiro, 1991; Nelson, 1986; Slackman, Hudson, & Fivush, 1986). Asked about a familiar activity such as going to the grocery store, children give generalized accounts derived from knowledge of what usually happens across many instances. For example, Hudson, Sosa, and Shapiro (1997, p. 77) quote a 3-year-old who was asked to tell what happens when he goes to the store: "I just buy things to eat. We get a cart or box to hold it. When we're done, we just get in the car and go home." What is noteworthy here is that the child gives a general rather than a specific account: He knows that various things may be purchased, that either a cart or a

box may be used to carry the groceries, and that one buys the items before leaving. Having found that young children have considerable event knowledge of this kind, Nelson sees these "generalized event representations" as a significant resource that children bring to the task of planning. Even preschoolers apparently have considerable knowledge about the sequence and steps in familiar events, which they can put to use in planning (Hudson, Shapiro, et al., 1995).

Influences on Planning

Whether it is possible to increase such knowledge and children's access to it by purposeful intervention has not been determined, at least not in controlled studies. Some early childhood approaches (including High/Scope and the Tools of the Mind model) have emphasized planning and reflection experiences and engaged children regularly in both representing past experiences and planning future actions. We look at several of these in the later section on "Developing Planning Skills in Early Childhood Programs."

Language comes into play in children's developing ability to plan. Vygotsky (1966/1977, 1930–1935/1978) viewed the child's private speech, also called egocentric speech or self-speech, as important in the development of thought. Children use private speech to regulate their own behavior in problem-solving situations and as a tool in planning solutions before trying them out (Berk & Winsler, 1995). Moreover, when children employ words to plan and reflect, their language use is decontextualized, that is, focused on nonimmediate events (Dickinson & Smith, 1994), and decontextualized language use is important in reading and other learning tasks in school. In other words, incorporating experiences with planning and reflecting in early childhood settings appears to be a promising way to nurture the kind of language development particularly useful for school learning.

Preschool children vary widely in how planful they are. Casey and her colleagues (Casey, Bronson, Tivnan, Riley, & Spenciner, 1991) found that some 4- and 5-year-olds were very organized and systematic across a variety of tasks, whereas other children of equivalent intelligence showed little evidence of thinking ahead.

Numerous researchers have shown external influences on children's planning processes and their use of planning. Variations in children's experiences with respect to planning or future orientation at home have been documented (e.g., Benson, 1997; Hudson, Sosa, et al., 1997; Rogoff, 1990). Jacqueline Goodnow (1987)

investigated how planning varies in differing social contexts. Studying children's conversations while they planned and executed drawings, Cocking and Copple (1987) observed that children react to their peers' plans and comments, at times by rethinking their own plans. Ellis and Siegler (1997) examined the conditions under which children plan and fail to plan, summarizing the results of numerous studies. The studies included a variety of tasks such as 20 Questions, the Tower of Hanoi (in which the subject faces the problem of transferring rings stacked on a pole in increasing size order to another pole without violating the size order), and other problems that involve multiple moves or choices and may be approached in numerous ways.

Developing Planning Skills in Early Childhood Programs

Children's experiences with planning in education and care settings vary. Generally, the development of planning skills is not an explicit program goal, but some common teacher practices are likely to support a degree of thinking ahead and awareness of temporal sequence. For example, most early childhood teachers usually follow a regular daily schedule of activities and often draw children's attention to the event sequences by saying things like "We will have time for you to finish your building right after we come in from the playground." Beyond such commonplace preschool experiences, one can point to a number of educational approaches in which enhancing children's planning and reflection has been a major objective. Several of these are briefly described here.

The Brookline Early Education Project (BEEP), the first comprehensive school-based early intervention program in the United States, began in 1972. The program involved preschoolers in daily planning in a variety of ways. At the beginning of the day, children discussed with the teacher and decided what they would do during the session. They used planning boards to represent the structure and sequence of their activities. At the end of the day, they gathered with the teacher to review and evaluate their follow-through on their plans: what they actually did and how it turned out. At times, they put together visual examples of what they had done during the day, and sometimes were even able to show the sequence of their activities. Program evaluation indicated that children in the BEEP program outperformed controls on observational measures of mastery skills, social skills, and use of time (M. B. Bronson et al., 1985; Tivnan,

1988). A follow-up study when the BEEP children were young adults suggests long-term differences for program participants as compared to their urban peers. BEEP graduates, especially those living in urban settings, had significantly higher incomes, more years of education, higher rates of employment and college attendance, higher health ratings, and fewer risky health behaviors than those in the comparison group (Palfrey, Bronson, Erickson-Warfield, Hauser-Cram, & Sirin, 2002).

The High/Scope preschool curriculum, initially developed in 1962 by David Weikart and colleagues (Weikart, Rogers, Adcock, & McClelland, 1971), is widely used in the United States and other countries. The curriculum approach is based on constructivist theories of development and learning, particularly that of Piaget (Hohmann & Weikart, 2002). The Piagetian influence is apparent in the curriculum goals, which give priority to the cognitive skills of language, experiencing, and representing, along with classification, number, and other conceptual areas prominent in Piaget's work. A substantial body of research, including longitudinal data more than 35 years after participants attended High/Scope's Perry Preschool Program (Schweinhart & Weikart, 1997; Schweinhart et al., 2005), confirms the positive effects of the program in terms of cognitive, social, and real-world outcomes, such as lower crime rates and unemployment decades after participating in the program.

The plan-do-review sequence is a hallmark of the High/Scope approach (Hohmann & Weikart, 2002). It includes a small-group time of 5 to 10 minutes during which children plan what they want to do during work time: the area they plan to visit, the materials they will use, and the peers they will play with. The children then have a work time of 45 minutes to an hour for carrying out their plans, followed by another small-group time for reviewing and recalling with the teacher and the other children what they have done and learned. Both the planning and review periods become longer and more detailed when children are older and more experienced in the processes of planning and reflecting. Although specific assessment of planning has not been included in evaluations of High/Scope, findings (Epstein, 2003) suggest that High/Scope children score higher than do controls on measures of language, literacy, social skills, and overall development.

Tools of the Mind, described at length later in the chapter, also engages children in a range of planning and reflection experiences, particularly daily planning of

their play and then revisiting and reflecting on their play experiences on the following day.

Summary

This review of the development and educational relevance of three cognitive essentials—representation, self-regulation, and planning—is far from exhaustive. Many other dimensions of cognitive competence are related to those discussed and are also educationally important, such as children’s social-cognitive development, theories of mind, and linguistic abilities. Considerable research, too extensive to be discussed in this chapter, is available in each of these and other areas of developmental and educational significance.

Similarly, the next section of this chapter highlights two specific aspects of emotional competence out of a much broader set of dimensions. First, we make a case for *emotional security*, grounded in positive adult-child relationships, as an essential underpinning of young children’s ability to benefit from educational experiences. Related to but also distinct from the self-regulation just discussed, *emotion regulation* is highlighted as an area that makes substantial contributions to positive development and learning.

FOSTERING EMOTIONAL ESSENTIALS IN THE EARLY CHILDHOOD YEARS

An observer visits a Tools of the Mind classroom in September. During group time, one child, Shana, wanders around the classroom looking at the objects on the shelf. As the children begin their play time, Shana continues to wander, unable to engage in any activity. Going to the sand table where children are playing together, she takes the shovel out of another child’s hand as she looks at the teacher. A pushing match ensues, and the other child raises her fist, threatening to hit Shana. As the teacher approaches, Shana turns her head, struggling to get away, kicking and pushing the furniture over. Picking Shana up, the teacher begins to talk softly to her. When the observer returns in April, she notices a girl and a boy playing with blocks. “Be careful,” the boy says. “I don’t want you to knock this over. But go and get your things and we’ll go on vacation.” The little girl gets up and carefully steps around the structure. For about 40 minutes they play out an elaborate scenario about going on vacation together. The little girl is Shana, the same

child who had shown such disorganized, disruptive, and distressed behavior in September.

Emotional development has been a recurring emphasis in early childhood education, forming part of the field’s core tradition (Bredekamp & Copple, 1997; M. C. Hyson, 2003). In the past few decades, developmental researchers have generated extensive knowledge of young children’s emotions, as reviewed in the chapter by Saarni, Camras, and Campos (Chapter 5, this *Handbook*, Volume 3). Despite this shared attention, research on emotions has not had a significant impact on program developers, practitioners, and policymakers in early childhood education settings. Several factors account for this state of affairs. Until recently, theory and research on emotional development was disseminated primarily through academic journals and conferences in psychology. Although the gap has narrowed with a series of publications that have been disseminated to policymakers and practitioners (e.g., Denham, 1998; Hyson, 2003a; Kauffman Early Education Exchange, 2002; Peth-Pierce, 2000; Raver, 2002), other trends have worked in the opposite direction. In a climate of strong focus on academic content standards and high-stakes skills testing, observers find numerous early childhood programs diminishing rather than heightening their emphasis on emotions.

Reflecting and foreshadowing these trends, the National Research Council’s report *Neurons to Neighborhoods: The Science of Early Childhood Development* (Shonkoff & Phillips, 2000, pp. 387–388) urged the following:

Resources on a par with those focused on literacy and numerical skills should be devoted to translating the knowledge base on young children’s emotional, regulatory, and social development into effective strategies for fostering (1) the development of curiosity, self-direction, and persistence in learning situations; (2) the ability to cooperate, demonstrate caring, and resolve conflict with peers; and (3) the capacity to experience the enhanced motivation associated with feeling competent and loved.

The next section of this chapter begins by defining the domain and components of emotional development, and then describes two specific dimensions of emotional competence.

The Domain and Components of Emotional Development

Rather than being subsumed under the “socioemotional” umbrella, emotional development is now viewed

as a distinct domain, with a rich theoretical and research base deserving of attention in its own right, yet conceptually and empirically linked both to social development and to every other domain of early development and learning.

Emotional development has many components. The construct of *emotional security*, whether indexed by attachment status or in other ways, is generally regarded as an essential developmental foundation. In addition to this dimension, Denham (1998) groups the components of early emotional competence into three areas: *emotion expression* (including using gestures to convey emotional messages, demonstrating empathic involvement, displaying complex emotions appropriately, realizing one may feel one way and outwardly express a different feeling); *emotional understanding* (discerning one's own feelings, discerning others' emotional states, and using emotion vocabulary); and *emotion regulation* (coping with unpleasant feelings or emotion-eliciting situations, coping with strong positive feelings such as excitement, and strategically exaggerating the expression of some feelings to get a desired result).

For the purposes of this chapter, just two components will receive in-depth attention: emotional security and emotion regulation. Closely related to each other and to the previously discussed cognitive constructs of representational thinking, self-regulation, and planning, they appear foundational to young children's successful development and learning in early childhood education programs.

Emotional Security

No single definition of emotional security has dominated the field of child development, and yet the construct has been a consistent emphasis. Erikson (1950, 1959) believed the achievement of "basic trust" to be the first accomplishment of infancy, revisited in different ways at each stage of the life course. Bowlby (1969/1982) and, later, Ainsworth (Ainsworth, Blehar, Waters, & Wall, 1978) posited a universal human need for attachments between children and adults. Building on attachment theory, the "emotional security hypothesis" (Davies & Cummings, 1998; Davies, Harold, Goeke-Morey, & Cummings, 2002) holds that children's adaptive behavior is strongly influenced by the underlying goal of maintaining emotional security within and beyond the family.

Why Is Emotional Security Significant for Children's Development and Learning?

Essentially, "relationships shape the development of self-regulation, social competence, conscience, emotional growth and emotion regulation, learning and cognitive growth, and a variety of other foundational developmental accomplishments" (Shonkoff & Phillips, 2000, p. 265). Consistent, warm, responsive and nurturing relationships with mothers, fathers, family child care providers, preschool teachers, and others are thought to build a sense of emotional security in young children, with specific cultural practices and traditions influencing how that security is experienced and expressed (e.g., Miller & Goodnow, 1995).

Much evidence for the importance of emotionally secure relationships comes from mother-child attachment research (Ainsworth et al., 1978; Cassidy & Shaver, 1999; Thompson, 1999). Secure attachments or, more broadly, emotionally positive relationships have a number of short- and long-term benefits. For example, secure attachment relationships appear to buffer the presence of stress hormones (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996), serving as a protective factor for children at risk. Research syntheses suggest that secure attachments may make children more receptive to adults' socialization efforts and instruction, and that securely attached children are also less likely to have behavior problems (Shonkoff & Phillips, 2000).

Emotional security tends to generalize: Even at a young age, children develop representations or "internal working models" (Main, Kaplan, & Cassidy, 1985) of how future partners in the child's social world may respond. Thus, the child's ability to build secure relationships with others, or to use relationships as a base for future exploration and learning, is powerfully affected by experiences with these early relationships (Thompson, 1999).

The Development of Emotional Security in Infants, Toddlers, and Preschoolers

From the perspective of attachment theory, the development of children's close relationships with important adults follows a predictable course (Ainsworth, 1973; Bowlby, 1969/1982), although with important cultural variations (Shonkoff & Phillips, 2000). In the first 3 or 4 months of life, infants orient themselves to the adults in their environment and begin to signal to them, but do

not yet discriminate particular adults as “attachment figures.” Over the next months, infants begin to show these kinds of preferences, usually for their mother but also for others, depending on who participates in caregiving. After about 8 months of age, most children develop clear signs of attachment relationships, becoming distressed when mother or another preferred person leaves, and following or seeking physical proximity to that adult, especially when the child is distressed or fearful. Over time, and generally by the 3rd or 4th year of life, this relationship is thought to develop into what Bowlby called a “goal corrected partnership,” in which the child is able to tolerate separations and use attachment figures as secure bases for exploration and risk taking. The long-term goal and organizing principle of the attachment relationship is not to maintain physical closeness but for the child to experience “felt security” (Sroufe & Waters, 1977)—an important consideration as we turn to secure relationships in out-of-home settings.

Emotional Security in Early Childhood Education Programs: Characteristics, Influences, and Outcomes

Children of the ages emphasized in this chapter (3 to 6) have typically formed attachments to one or more primary caregivers and are able to hold representations of those figures in mind even in their absence. Building from this body of theory and research, several investigators have recently examined the characteristics of, influences on, and consequences of positive, secure teacher-child relationships in the early years. The premise of much of this research is that adults who are not parents can serve as attachment figures in young children’s lives (Howes, 1999, 2000). These relationships do not entirely replicate the bonds between parents and children, and their developmental course may differ depending on when the relationships are established, but they nevertheless have similar features and functions in early development and learning (Howes, 1999; Howes & Hamilton, 1992). Many children develop a clear desire to stay physically close to their favorite teachers, appear to use them as a base from which to explore the environment, and seek physical proximity when hurt or distressed. Further, these relationships can be classified as secure or insecure using criteria similar to those that have been used in studies of parent-child attachment—again, with attention to cultural differences in how adult-child relationships may be manifested.

Prevalence of Emotionally Supportive Relationships and Environments in Early Childhood Programs. How likely is it that young children will have supportive, emotionally secure relationships with their teachers? According to Howes (1999; Howes & Ritchie, 2002), as many as 70% of young children may fail to develop secure attachments to their teachers, as indexed by, for example, scores on the Attachment Styles Questionnaire (Howes & Ritchie, 2002). Many teachers’ interactions with young children lack the warmth and responsiveness that appear to be essential underpinnings of growth-promoting relationships. For example, in a study of 90 middle-class children and their families, Hyson, Hirsh-Pasek, and Rescorla (1990) found that only about one-third of preschool teachers were observed to spend time talking about feelings. Large-scale child care studies (e.g., Cost, Quality, and Child Outcomes Study Team, 1995; National Institute of Child Health and Human Development Early Child Care Research Network, 2000) have found frequent evidence of emotional insensitivity, detachment, and even harshness among teachers of young children.

Relationships between Teacher-Child Relationships and Outcomes for Children. This lack of consistently secure, emotionally supportive teacher-child relationships is of particular concern in light of recent evidence that positive relationships with teachers have short- and longer-term benefits both in the behavioral or social domains and in cognitive and academic development.

Evidence is accumulating that when young children are able to feel emotionally secure with their teacher, they are more active in exploring the environment and, therefore, have more opportunities to learn (Birch & Ladd, 1997; Howes & Smith, 1995; Pianta, 1999). One of the consistent findings in early education, summarized in the National Research Council’s report *Eager to Learn: Educating Our Preschoolers*, is that an emotionally warm and positive approach in learning situations leads to more constructive behavior in children (Bowman et al., 2001). For example, Howes and colleagues (Howes, 2000; Howes & Smith, 1995) have found that children with more secure attachments to their child care teachers have more competent interactions with adults, play more maturely with other children, and engage in more cognitively complex activities.

Other researchers have investigated the importance of teacher-child relationships for school adjustment and

academic success (Birch & Ladd, 1997; Hamre & Pianta, 2001; Pianta, 1999; Pianta, La Paro, Payne, Cox, & Bradley, 2002; Pianta, Nimetz, & Bennett, 1997). For example, children who have emotionally close relationships with kindergarten teachers are more likely to adjust well to school than those whose relationships are less close. Kindergarten children who were predicted to be retained in grade or referred to special education—but who did not experience those outcomes—were found to have had especially positive relationships with their kindergarten teachers (Pianta, Steinberg, & Rollins, 1995).

Two longitudinal studies support the predictive power of early, positive teacher-child relationships. In a study of children from kindergarten through eighth grade, children who had negative relationships with their kindergarten teachers (either conflicted or overly dependent) were more likely to experience social and academic difficulties in later years (Hamre & Pianta, 2001). Another longitudinal study (Stipek & Greene, 2001) shows that kindergarten and first-grade teachers' ratings of their affectionate and warm versus "conflicted" relationships with individual students in the class predicted those children's feelings about school as well as the children's ratings of their own academic performance.

In addition to their social and academic benefits, children's relationships with teachers can compensate to some extent for troubled family relationships. Several studies (Howes & Smith, 1995; Mitchell-Copeland, Denham, & DeMulder, 1997) indicate that secure attachments to child care teachers can support positive development even if children's attachments to their parents are insecure. For example, Howes and Ritchie (2002) found that children who had insecure attachments to their parents were able to compensate to some extent, both socially and academically, if they had a secure relationship with their teacher.

Emotional Security's Associations with Teacher Characteristics, Curriculum, and Teaching Practices. What conditions promote or diminish the likelihood that teachers will indeed develop these kinds of secure relationships with young children? A number of studies have looked at the effects of teachers' levels of education and training on the provision of emotionally responsive, supportive classroom environments and relationships. In general, higher levels of formal education and specialized training seem to be associated with warmer relationships and interactions with children

(Arnett, 1989; Howes, 1997), although researchers have found it difficult to identify underlying reasons for these associations.

Furthermore, several programs of research have examined relationships between the emphasis of a specific early childhood curriculum or set of teaching practices and the likelihood that the teacher has warm and emotionally positive relationships with children. For example, a study by Hyson et al. (1990) included preschool classroom observations in which the emotional climate of the classroom was rated, along with other features of the curriculum and teaching practices. The results indicated that classrooms with higher levels of adult direction and more didactic approaches to teaching were significantly less likely to be characterized by teacher-child affection and warmth.

In a related set of studies, Stipek and colleagues (Stipek, Daniels, Galluzzo, & Milburn, 1992; Stipek et al., 1998; Stipek, Feiler, Daniels, & Milburn, 1995) examined classrooms that varied in their emphasis on structured, teacher-directed instruction in basic skills, rather than on child choice and autonomy. These studies included systematic observations of teachers' acceptance/warmth and of the classroom's emotional climate. Again, Stipek and colleagues found that highly didactic, basic skills-oriented approaches that emphasized individual success and failure were associated with less teacher warmth and nurturance and less attention to children's individual needs than in the more child-focused classrooms.

Despite these findings, it is impossible to conclude that the only pedagogical approach that supports emotionally secure teacher-child relationships is a strongly child-centered one. A number of recent trends have blurred the distinction between teacher-directed and child-centered early childhood curricula and teaching practices. Influenced by Vygotskian and other social constructivist perspectives, as well as by research on early language, literacy, and mathematical development, by the growing presence of content standards in kindergarten and prekindergarten education, by new position statements from national organizations (Bredenkamp & Copple, 1997; Neuman, Copple, & Bredenkamp, 2000), and by greater knowledge of the wide cultural variations in approaches to early childhood education (Mallory & New, 1994), there are now a greater number of early childhood curricula that cannot neatly be categorized as child-centered versus didactic. These approaches, like the Tools of the Mind

curriculum described in this chapter, place greater emphasis on teachers' active promotion of cognitive and academic competencies (Mayer, 2004) through scaffolding, reflection, and representation, while still embedding these in firsthand experiences linked to young children's interests and within the context of close relationships, rich social interactions, and play.

However, the emotional climate and motivational impact of these curricula have not yet been systematically studied. The previously described federally funded programs of early childhood education research, including curriculum comparisons and effectiveness studies, have potential to answer some of these questions.

Emotion Regulation

In addition to emotional security, a second critical component of early emotional competence is the development of emotion regulation. As suggested earlier in this chapter, emotion regulation is related to but distinct from the more cognitively focused self-regulation, an ability strongly emphasized in the Tools of the Mind curriculum. Kopp (1989, 2002) views ER as "modulating the intensity of emotion responses such as anger, fear, pleasure, sadness, and other emotions. Effective ER means a response is appropriate to context, enhances rather than jeopardizes bio-behavioral well-being, and guides subsequent social and cognitive activities" (2002, p. 11).

Emotion regulation involves a number of crucial skills and dispositions (Denham, 1998; Dunn & Brown, 1991; Saarni, 1999). Children who are acquiring these skills are increasingly able to:

- Keep in touch with their own emotional responses.
- Stop themselves from displaying inappropriate behavior motivated by strong positive or negative feelings.
- Calm, distract, or soothe themselves when strong feelings threaten to overwhelm them.
- Use varied and flexible coping strategies to change the intensity of their emotions.
- Coordinate feelings, thoughts, and actions to reach goals that are important to them.
- Use emotions to help focus and sustain attention.
- Influence others by the use of emotions.
- Follow the standards of their culture about when and how to show emotions.

Why Is Emotion Regulation Significant for Children's Development and Learning?

Like emotional security, emotion regulation has increasingly been viewed as a critical outcome in the preschool years, for all children but especially for those at risk of negative developmental and educational outcomes. Head Start children who begin the year with emotion regulation difficulties are likely to make a poor adjustment to school, including problems adapting to routines, complying with limits, getting along with other children, acquiring academic skills, and developing positive attitudes toward learning (Eisenberg et al., 2001; Shields et al., 2001). Early problems with emotion regulation, especially with the regulation of negative emotions, are consistently found to predict both social-emotional and academic difficulties in later years of school (Raver, 2002). Three- and 4-year-olds who are prone to venting anger and other negative emotions are likely to be lower in social competence when they reach kindergarten (Denham et al., 2003); similarly, children who are unable to maintain "effortful control" are at risk for later difficulties in maintaining good relationships with peers (Kochanska, Murray, & Harlan, 2000). Children with serious regulatory difficulties are on a trajectory that tends to alienate them from other children, from teachers, and from access to learning opportunities. Thus, widespread agreement exists that attention to emotion regulation is an essential priority and goal of early childhood education and early intervention programs.

The Development of Emotion Regulation in Infants, Toddlers, and Preschoolers

At whatever age children enter early childhood education programs, they have begun to develop important emotion regulation abilities. The following brief description is influenced by Kopp's (1989) analysis, focused on the developmental course of children's regulation of distress. It also draws on other reviews, for example, Denham (1998); Fox (1994); Saarni, Camras, Campos, and Witherington (Chapter 5, this *Handbook*, Volume 3); Shonkoff and Phillips (2000); and Thompson (1994).

As Kopp (1989) outlines, the earliest emotion regulation begins in the first days of life, as infants' reflexive reactions help them avoid unpleasant stimuli. Crying babies learn to suck their thumbs and use other strategies to manage their distress, while still relying on adults to

scaffold and support their emotion modulation. In the 2nd year of life and beyond, toddlers' expanding cognitive abilities (e.g., anticipation and planfulness) are used in the service of emotion regulation, and they communicate their needs more clearly. The expansion of language competence provides additional tools to communicate, represent, and regulate emotions. Of course, toddlers and young preschoolers still require a good deal of adult support, as they continue to have difficulty independently managing strong negative or positive emotions.

As children move into the later preschool years, most are increasingly self-reflective about their regulation of their own and others' emotions. Children are able to use a wider repertoire of cognitively oriented coping strategies when faced with distressing situations (Denham, 1998). Preschoolers are increasingly able to distract themselves and use symbolic thought to reframe the meaning of a situation, and they can look at an emotionally arousing situation from multiple perspectives (Saarni, 1999).

Several observations should be made about this description of the early developmental course of emotion regulation. First, it underscores the close relationships between cognitive and emotional development, relationships that recur throughout this chapter. Second, it focuses primarily on the development of regulation of negative emotions, in particular, distress. The regulation of positive emotions is also important, yet has been studied less frequently. In educational settings, children's ability to regulate their excitement or to direct their interest into specific channels is a significant task. Finally, most of the research on which these developmental trajectories are based has not included culturally and linguistically diverse groups of children, and few studies have examined the development of emotion regulation outside of the family.

Emotion Regulation in Early Childhood Programs: Characteristics, Influences, and Outcomes

Much of the research on emotion regulation has focused on the predictors of, or influences on, its development. However, few of these studies have been done in early childhood education programs. As outlined here, research in family contexts suggests some factors that may be relevant for curriculum and teaching practices in early childhood education settings.

Emotion Regulation and Security of Attachment.

A number of studies have found that secure mother-

child attachments predict greater ability to manage distress and regulate negative emotions. Saarni (1999) speculates about the mechanisms that may underlie this relationship: Perhaps securely attached children are able to explore a wider array of feelings with the support and emotion sharing provided by the adult.

Might secure attachments to teachers, or other non-family caregivers, have a similar benefit for children's emotion regulation? There is growing evidence of this link. Preschool children who have secure attachments to their teachers are less likely to have emotion-regulation problems such as unregulated anger displays (DeMulder, Denham, Schmidt, & Mitchell, 2000). And children whose Head Start teachers reported less conflicted, warmer relationships with those children early in the year were seen by their teachers as more emotionally regulated and less angry later in the year (Shields et al., 2001).

Language and Cognitive Skills as Influences on Emotion Regulation. As Vygotsky (1930–1935/1978) and others (Kopp, 1989) have emphasized, children's competence in language supports their ability to regulate their emotions and behavior, as well as to engage in positive relationships with others. Children whose language skills are limited relative to their peers' are also at risk for regulatory difficulties (Greenberg, Kusché, & Speltz, 1991).

Caregivers' Assistance and Modeling to Support Emotion Regulation. Thompson (1994) emphasizes how important caregivers are in helping very young children to modulate their emotional arousal, directly soothing babies and then helping them learn to soothe themselves. Adult modeling is also a significant influence, as studies by Eisenberg and Fabes (1992) and others have shown. In those studies, taking anger expressions seriously and working on anger issues constructively with children led to better, more regulated responses to peer aggression.

Adults also support emotion regulation by talking with young children about emotions (Dunn & Brown, 1991; Kopp, 1989), giving children language and labels for emotional experiences; these labels then begin to be internalized and used by children as they regulate their own emotional expression. In addition, adults respond in different ways to children's negative emotion expressions, and these differences seem to be related to how the children themselves express and regulate emotion.

For example, mothers who said they were likely to punish children's negative emotion expressions had children who were unlikely to seek help from their parents when distressed (Eisenberg & Fabes, 1998).

It is likely that this kind of socialization goes on in early childhood education programs as well, although it has not been studied systematically, widely, and longitudinally. As Shields and colleagues (2001) point out, we still know little about teachers' everyday influences on children's emotional competence, including their emotion regulation.

Provision of Opportunities for Pretend Play. Significant in the development of self-regulation, pretend play may benefit emotion regulation as well. In one of a small number of studies relating pretend play to emotion regulation, Galyer and Evans (2001) found that children whose parents had reported greater prior involvement in pretend play, especially play with adults, showed greater emotion regulation in a distressing experimental situation, and were also rated by their parents as having better emotion regulation skills. If replicated in other studies, this finding may have implications for early childhood programs.

Other Features of Early Childhood Program Quality, Curriculum, and Teaching Practices. It is now understood that many of the challenging behaviors, aggression, and other behavioral difficulties in early childhood and beyond are fundamentally problems with emotion regulation (Raver, 2002). On the positive side, a long-term outcome of several high-quality early intervention programs has been a reduction in antisocial behaviors that are thought to stem from emotion regulation difficulties (Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002; Reynolds, Temple, Robertson, & Mann, 2001; Schweinhart & Weikart, 1997). It is not clear what aspects of these programs contributed to this long-term effect, but McCall and colleagues (2003, p. 269) observe that "the establishment of close, meaningful, warm, caring, stable parent-child, caretaker-child, and child-child relationships is a plausible working hypothesis." Thus, it may be said that high-quality early childhood programs have the potential to serve as a protective factor in supporting emotion regulation, especially for children living in poverty or other adverse conditions.

Looking specifically at curriculum and teaching practices, there is limited evidence that some forms of

highly didactic, adult-dominated curricula in preschool and kindergarten may be associated with child behaviors indicative of stress, or, in other words, of difficulty regulating anxiety or frustration. Higher levels of stress behaviors—nail biting, stuttering, and so on (Burts, Durland, Charlesworth, DeWolf, & Fleege, 1998)—and higher levels of test anxiety (Hirsh-Pasek, Hyson, & Rescorla, 1990) have been observed in classrooms that were more "developmentally inappropriate" or teacher-dominated than in more child-focused classroom environments. But as noted in this chapter's discussion of emotional security and early childhood curricula, an increasing number of curricula combine child choice and playful activities with a high degree of intentional teacher scaffolding and "structure," making the classification of curriculum approaches more complex than in the past.

School-Based Interventions to Support Emotional Competence

The research presented in this part of the chapter makes a compelling case for the importance of children's emotional competence, including their emotional security and emotion regulation abilities. High-quality early childhood education that includes an "emotion-focused" approach to the curriculum provides a foundation for this competence (M. C. Hyson, 2003). Several practitioner-oriented publications (Howes & Ritchie, 2002; M. C. Hyson, 2003) also provide teachers with suggestions about how to create conditions that promote secure and supportive relationships. In addition, as discussed by Denham and Burton (2003), Raver (2002), and Raver and Knitzer (2002), a number of specific interventions have been designed to address various components of emotional competence. These interventions may be targeted either at all children in a class or, in some cases, at those children who are at special risk.

The theme of emotional security is prominent in some interventions. For example, Pianta (1999; Hamre & Pianta, 2001) and others (Greenspan & Weider, 1998) have recommended specific interventions to help teachers build positive relationships with children, especially children who are at risk for developmental and educational difficulties. Other interventions focus more intensely on building children's understanding and regulation of emotions (e.g., Denham & Burton, 1996; Kusche & Greenberg, 2001; Webster-Stratton, Reid, & Hammond, 2001).

Whether these interventions are universal or targeted, whether they are focused on building security or strengthening regulatory competence, reviews of the effectiveness of emotion-related interventions draw some clear conclusions (Raver, 2002; Raver & Knitzer, 2002). To be effective, interventions designed to promote emotional competence must be implemented with a high degree of fidelity. And for children at the highest risk of serious emotional difficulties, dosage and intensity matter a great deal. For those children, a promising approach is to combine a universal intervention (intended for all children in a class) with more focused and intense individual interventions, together with family involvement.

Summary

A persuasive body of research has identified emotional competence as essential to young children's positive development and learning. The dimensions of *emotional security* and *emotion regulation* are related to each other in mutually influencing ways, and they are also connected to the cognitive essentials discussed in the preceding section of this chapter. Although primarily relying on studies within families, the research is beginning to identify teaching practices and features of educational programs that may promote children's emotional development and prevent later difficulties.

To reap the benefits of this research and of research related to representational abilities, self-regulation, and planning, practitioners also require a developmental and evidence-based approach to assessing children's progress and needs in these and other areas. The next section of the chapter addresses this requirement.

IMPLEMENTING EFFECTIVE ASSESSMENT PRACTICES

Two boys are playing in the literacy center in a Tools of the Mind classroom. Four-year-old Josh is decorating the pieces of paper with a rubber stamp after his friend Chris copies the names of other children on each piece. Chris is writing carefully and slowly. Having finished stamping the last piece of paper Chris gave him, Josh has nothing to do. He starts stamping the paper that Chris is writing on, and then he stamps Chris's hand. Upset, Chris looks up as Josh holds the stamp in the air, ready to descend on the arm that was under it. "Was that your plan?" he asks Josh, referring to the play plans the children develop each

morning. Josh stops, with the stamp hovering over the piece of paper. "Well, I'm supposed to stamp. That's my plan." "But I'm not done," Chris protests. Josh responds with "Okay, I'll . . . hmmm" (pondering the options). Encouraged, Chris offers a suggestion: "Why don't you fold them and put them in there?" (he points to the envelopes next to the paper). "Okay!" Josh says. "Then I'll stamp them again." He starts folding the paper and looks at the other side. "Oh look, I didn't stamp here," he says, as he stamps the other side of the paper. They smile at each other and continue working together.

The preceding sections of this chapter have reviewed and discussed what we know about some cognitive and emotional essentials for young children's development and learning: representation, planning, self-regulation, emotional security, and emotion regulation. Although the chapter has emphasized the relevance, as well as the limitations, of this research for early childhood programs and practices, we have not yet addressed a different and important question: How might one assess young children's progress in these and other areas? The way this question is framed and answered is different in the cases of classroom teachers, policymakers, and developmental researchers. This section focuses primarily on classroom-based assessment, but places it in a wider context.

The heightened interest in early learning and the increased calls for accountability and scrutiny of instructional programs have placed assessment and testing of young children at center stage. Classroom teachers, school administrators, parents, and policymakers have legitimate concerns about young children's development and the effectiveness of educational programs. With the Tools of the Mind case example in mind, this section culls from the literature some of the major issues in the implementation of appropriate assessment practices designed to support children's learning in the classroom. The central role of the teacher and the inherent challenges in this type of assessment are discussed.

Defining Assessment

In the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA], American Psychological Association, & National Council on Measurement in Education, 1999, p. 172), assessment is defined as "any systematic method of obtaining information from tests and other

sources, used to draw inferences about characteristics of people, objects, or programs.” This definition consists of three critical components: (1) engaging in systematic (intentional) procedures, (2) collecting information on (evidence of) learning, and (3) making inferences (generalizations) in response to the assessment results.

The intentional ongoing process of identifying, collecting, and evaluating evidence to make informed decisions about young children’s learning is an integral component of any effective instructional intervention, including interventions such as those discussed in this chapter. These three components of assessment frame this discussion.

Intentionality: Purpose Matters

As part of the systematic nature of the assessment process, the major purposes for the assessment of young children, as defined by Shepard, Kagan, and Wurtz (1998) in their report to the National Education Goals Panel, have been widely accepted:

- To support learning.
- For identification of special needs.
- For program evaluation and monitoring trends.
- For high-stakes accountability.

Clarifying the purpose of an assessment process is analogous to crafting a clear research question at the beginning of a study. Defining why the assessment process should take place shapes the content, form, and amount of the evidence that will be needed. The purpose can also have an impact on the format of the results (AERA et al., 1999; Bowman et al., 2001; J. Jones, 2004; Millman & Greene, 1989). For example, assessments intended to provide parents with information on the progress of their 4-year-old’s ability to play with others may look very different from a research report on national trends in the social pretend play of subgroups of children. Both are important, but the tasks, sample size, reporting format, and implications may be quite different. The Tools of the Mind vignettes presented throughout this chapter have provided a glimpse into classrooms in which the primary assessment goal is to support children’s learning. Implicit in these vignettes is that the overarching goal of the teacher’s observations, questions, and conversations with the children is to gather an array of “up close and personal” information on the

learning of a specific child or a group of children and to determine what strategies will advance their learning.

Challenges to the Assessment of Young Children

Researchers have acknowledged that young children present a unique set of assessment challenges (Bowman et al., 2001; Dyer, 1973; Kagan, Scott-Little, & Clifford, 2003; Love, 2003; Shepard, 1994). As described in earlier sections of this chapter and in other parts of the *Handbook*, children’s cognitive and emotional capacities, astonishing in many respects, can constrain the ways those capacities may be assessed validly. The nature of early childhood, with its periods of rapid and episodic growth, can pose significant measurement challenges. Young children’s development may be highly variable, both within and across individuals, posing a potentially negative impact on the reliability of any test and the validity of score interpretation (Messick, 1987, 1989; Powell & Sigel, 1991; Salvia & Ysseldyke, 2004; Shepard et al., 1998). The child’s level of cognitive, linguistic, and physical development will also play a role in how he or she can represent knowledge in ways that educators can interpret. For example, with children from birth to 3 years, teachers and parents are primarily observing and recording children’s linguistic and physical development. From age 3 to 4 years, when linguistic and physical skills have developed to a point where conversation and some drawing is possible, records of language and samples of drawings and constructions may be collected. By age 5, children may be able to respond to developmentally appropriate formal and informal measures (Shepard et al., 1998). Therefore, many of the assessment approaches that work well with older children are ineffective in early childhood education. As Salvia and Ysseldyke state, “Infants and young children are not miniature adults possessed of adult abilities and behavior” (p. 663).

Furthermore, deciding what aspect of young children’s learning should be measured, and by what metric, is a nontrivial matter. The National Research Council’s synthesis of early childhood research (National Research Council and Institute of Medicine, 2000, pp. 82–83) reported:

Measuring growth in psychological domains (e.g., vocabulary, quantitative reasoning, verbal memory, hand-eye coordination, self-regulation) is more problematic. Disagreement is more likely to arise about the definition of the construct to be assessed. This occurs, in part, because there are often no natural units of measurement

(i.e., nothing comparable to the use of inches when measuring height). As a result, units of measurement must be created and defended, and errors of measurement are likely to be quite large.

Regardless of the methodological complexities that are involved in the assessment of young children, to promote children's positive development and learning, early childhood teachers must be engaged in the assessment process in some form in the context of their classrooms.

Classroom-Based Assessment

Early childhood assessment specialists argue that the central purpose of early childhood assessment is to improve instruction for young children (Bowman et al., 2001; Shepard et al., 1998). Specifically, in the context of this chapter, the goal is to better understand children's cognitive and emotional development so as to devise more effective curriculum and teaching strategies. The educational research literature on K–12 classroom-based assessment practices, also termed authentic or formative assessments, can support this goal (Black & Wiliam, 1988; Phye, 1997; Stiggins, 2001, 2002). These assessment practices are linked directly to the instructional program and use teacher observational notes, records of children's language, and work samples as part of a collection of evidence of learning that will guide instruction. Research suggests that assessment procedures that inform teachers' instructional practice can also increase student performance (Black, Harrison, Lee, Marshall, & Wiliam, 2003; Black & Wiliam, 1988). However, using appropriate classroom-based assessment strategies places a greater responsibility on the teacher to take a stance or attitude of inquiry into children's learning and to acquire a considerable understanding of assessment design, use, and interpretation (Calfee & Masuda, 1997; Chittenden, Salinger, & Bussis, 2001; Stiggins, 1999).

Evidence

The second component of the preceding definition of assessment (AERA et al., 1999) is collecting evidence of children's learning. On a daily basis, teachers of young children must provide environments that support and promote the development of each child in their classroom. When asked, many teachers might readily answer such questions as “Is Johnny increasing his ability to fol-

low a plan?” or “Is Maria developing better strategies to cope with her frustration?” Yet, without sufficient, high-quality evidence of young children's learning, teachers may reach qualitatively different and perhaps erroneous conclusions about what children know and are able to do in these and other areas.

The early childhood literature has embraced the use of classroom-based evidence of children's learning. Many early childhood assessment specialists argue that this type of evidence is closer to the child's classroom experiences, more aligned with the child's level of development, has a direct bearing on classroom practices, and can be part of the teaching/learning process (McAfee & Leong, 1997; Meisels, Liaw, Dorfman, & Nelson, 1995; Mindes, 2003; Puckett & Black, 2000).

Rather than a passive recipient of test results, in this approach to early childhood assessment the teacher must become actively involved in setting appropriate developmental and learning goals; creating the opportunities for children to demonstrate what they know; collecting, describing, and analyzing samples of work; evaluating the work against standards; and applying evidence that children are learning (Blythe, Allen, & Powell, 1999; Calfee & Masuda, 1997; Carini, 2000; J. Jones & Courtney, 2003; Martin, 1999).

Observation

The early childhood literature has made a consistent case that teachers' powers of observation, documentation, and deep understanding of child development are critical to achieving high-quality early childhood programs (Dyer, 1973; Genishi, 1992, 1993, 1997; Jablon, Dombro, & Dichtelmiller, 1999). Ongoing careful observation allows teachers to see children's behaviors and work samples and listen to their language. These are the central sources of evidence that will lead to informed inferences about how children are developing and what instructional strategies will be most supportive. Yet, observation alone is not sufficient. The literature describes a rich history of careful description of children's development that includes in-depth case studies, which describe a child's learning styles, interests, and methods of representing knowledge (Avidon, Hebron, & Kahn, 2000; Chittenden et al., 2001; Gruber & Voneche, 1977; Piaget, 1926/1955). The competencies emphasized in this chapter, such as representation, planning, and emotion regulation, appear to be more effectively assessed through this kind of systematic observation than through one-time tests.

It is also clear from the literature that developing the strategies to conduct careful observation and documentation requires some effort and practice (Allen, 1998; Garbarino & Stott, 1989; Genishi, 1997; Helm, Beneke, & Steinheimer, 1998; J. Jones, 2003). Systematic observation is a highly structured process, grounded in classroom practice that reflects the learning goals that have been set for the children. It is the teacher's role to provide the opportunities and classroom settings in which the child can make learning visible—that is, demonstrate what he or she knows and is able to do.

Tests as Evidence

Thus far, the discussion has focused on the use of classroom-based evidence. A more formal form of evidence of children's learning is a test, which is defined in the *Standards for Educational and Psychological Testing* (AERA et al., 1999, p. 183) as “an evaluative device or procedure in which a sample of an examinee's behavior in a specified domain is obtained and subsequently evaluated and scored using a standardized process.” This is a specific form of evidence, gathered at a single session or during multiple time periods, as part of the overall assessment process. When all or a sample of children are asked to perform the same task under the same conditions with a common scoring rubric, a standardized test has been administered. The controversy appears to arise when tests are not linked directly to the teacher's curriculum, may not be aligned with children's developmental levels, and may not be sensitive to the range of cultural and linguistic differences. However, when the purpose of the child assessment is part of an overall evaluation of program effectiveness, a well-constructed test that is administered to an appropriate sample of children can provide important information about a group, rather than about a specific child. As emphasized earlier in this section, a challenge is that very young children may lack the cognitive, linguistic, social-emotional, and physical resources to respond validly to formal tests. These assessment difficulties are multiplied when children are living in difficult circumstances, have disabilities, or speak a language other than the one in which assessments are conducted.

Technically Sound Assessment Evidence

Classroom-based evidence can provide a particularly rich picture of a young child's development and learning. This picture may provide teachers with information that is directly tied to decisions about curriculum and teach-

ing practices. However, this type of assessment has not been the standard by which programs are held accountable to policymakers (Stiggins, 2001). The tension between standardized, norm-referenced assessments and classroom-based assessments may have roots in the fundamentally different perspectives taken by educational researchers and early childhood educators on what constitutes the evidence of young children's learning. Some major theories of child development have emerged from careful observational studies of just a few children (Gruber & Voneche, 1977; Piaget, 1926/1955; Wertsch, 1985), whereas the educational measurement literature has often looked to the large-scale random assignment experimental design as the gold standard. In addition, many measurement experts have expressed limited confidence in the objectivity of teachers' judgments and in their overall understanding of assessment design and use (Plake & Impara, 1997; Stiggins, 1999, 2001).

There appears to be some progress in bridging the essential differences between traditional large-scale assessment procedures and classroom-based assessment. Educational researchers are examining a reconceptualization of the measurement framework that would acknowledge the complex and dynamic nature of classrooms (Brookhart, 2003; Moss, 2003; Smith, 2003). Articulating three aspects of classroom assessment that strain traditional measurement theory—the context-dependence of classroom assessment, its inextricable relationship with instruction, and its simultaneous formative and summative functions—Brookhart states:

Both classical and modern test theory for large-scale assessment consider context a source of irrelevant variance; the aim is to generalize across contexts. In contrast, for classroom assessment, items or tasks are dependent on, and nested within, the instructional environment. For another example, in large-scale assessment, items or tasks are usually assumed to be independent, whereas in classroom assessment they are linked together in students' classroom experiences. For yet another example, large-scale assessment theories usually make assumptions that require large sample sizes. Class sizes are small in comparison, and sometimes classroom assessments are given to even smaller subgroups or to individuals within classes. (p. 5)

Creating this new paradigm will be a challenge to the fields of child development and educational measurement, requiring much greater collaboration. Professionals in both fields can profit from the realization that both types of assessments have value, depending on the

purpose of the assessment. Constructing assessment systems that are based on credible and useful evidence can enhance our understanding of children's learning and development and broaden our perspectives on program effectiveness.

Inferences

The third component in the definition of assessment (AERA et al., 1999) refers to the conclusions, generalizations, and inferences that are made in response to assessment results. The purpose of the assessment and the types of inferences to be made should be clearly articulated and should guide the assessment design process (AERA et al., 1999; Millman & Greene, 1989). However, interpreting assessment results is not always a simple task. The literature suggests that classroom teachers are alarmingly underprepared to design sound classroom assessments and to interpret assessment results appropriately (Plake & Impara, 1997; Stiggins, 1999).

A Documentation Assessment Model

A five-stage model outlines the documentation/assessment process for classroom-based assessment, from identifying learning goals to collecting and evaluating evidence (Figure 1.1). This model places inferences within a cycle in which teachers, including early childhood teachers, identify learning goals, collect evidence, describe and analyze the evidence, interpret results in light of learning goals, and apply this information to future planning.

Identifying

The first stage in designing assessments to support children's learning is the identification of learning goals. Although debates may develop about what constitutes appropriate learning goals, meaningful assessment systems will require some consensus on the major goals for children and the classroom settings in which evidence of learning may be apparent. For example, is the goal to increase children's sense of security and close relationships with their teachers?

Collecting

The evidence of young children's development and learning, their drawings, constructions, and records of their language and behaviors, is apparent in the everyday life of high-quality early childhood classrooms. Teachers

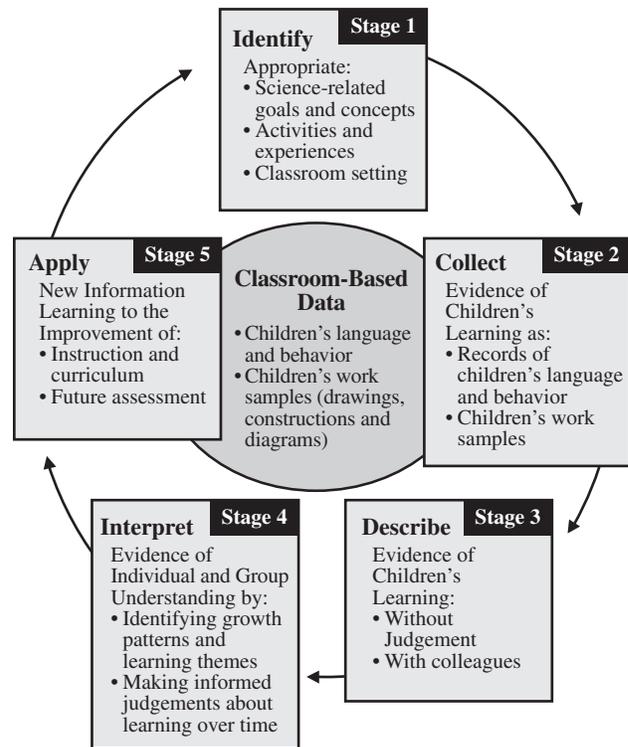

Figure 1.1 A five-stage documentation/assessment cycle.

need to collect this evidence in a purposeful manner, not simply to amass artifacts but to document the learning that occurs. In the case of developing secure relationships, might children's drawings be informative? Would it be useful to collect information from systematic observations of distressed children's behavior with teachers?

Describing

Merely collecting the evidence of learning does not translate it into instructional information. Careful analysis of children's work using strategies such as those outlined in Carini's (1993) descriptive review provide a window into children's thinking, as well as into their emotional responses. The accuracy of a child's response to a specific question provides a background for the teacher's active inquiry into how the child is coming to understand a phenomenon. In the context of this chapter, for example, how might teachers analyze young children's pictorial or written plans for their play activities?

Interpreting/Evaluating

After a careful study and description of children's work, teachers return to their learning goals to evaluate what the classroom-based data reveal about children's prog-

ress toward these goals. Again, what if only a few children are able, at this point in the year, to use teachers as a secure base? Do goals related to emotional security need greater attention?

Applying

This information about how children are learning can inform future instructional planning. What additional teaching strategies can support the child's development? In turn, new questions will inevitably be raised, questions that will require teachers to move once again and continuously through the cycle. This focus on application can inform teachers' decisions as they focus on representation, planning, self-regulation, emotional security, emotion regulation, and other key components of young children's growing competence throughout the year.

Beyond Yet Connected with the Classroom: Guidelines for Researchers

Although the primary focus of this section of the chapter has been classroom-based assessment by teachers of young children, the domains discussed here are also of great interest to developmental and educational researchers. Their studies can also assist in creating more effective learning opportunities. A synthesis of early childhood research (National Research Council and Institute of Medicine, 2000, p. 84) defined the following key components to guide the design of quantitative developmental research:

- A clear definition of the outcome variable or the construct on which the children are believed to be growing.
- A measurement unit or scale that has constant meaning over the age range of interest (e.g., height in inches or the number of words in a child's expressive vocabulary).
- An outcome that can be measured on a common scale across ages, such that the alternative, age-appropriate forms of the assessment can be equated, that is, put onto the same meaningful scale.
- A statistical model for individual change over time. . . .
- A longitudinal study that is optimally designed to ensure a given level of statistical precision for the question at hand. Trade-offs among the length of the study, the frequency of observation, and the sample size are invariably involved.

Whatever their experience with young children, those who intend to conduct research in early childhood programs need to become familiar with the goals and climate

of the program within which children are functioning. Program goals, curriculum and teaching practices, interactions between teachers and children, other assessments being conducted as part of an ongoing system, as well as knowledge of the children's cultures and languages provide an essential context. Understanding this context allows researchers to conduct more effective research and may suggest important variables to include in their analyses.

Establishing mutually respectful and beneficial relationships between the program administrator and staff on the one hand, and the research team on the other, is also essential (Frede & Barnett, 2001). Ethically and practically, benefits should accrue to the early childhood program as a result of being involved in research. To the greatest extent possible, researchers should attempt to incorporate their assessments into the ongoing fabric of the program. When research instruments must be administered through individual, direct assessment procedures, it is important to work with the teacher to minimize disruption and to ensure that the researcher is obtaining the child's best performance. Recommendations about the use of assisted or dynamic assessment procedures (Campione & Brown, 1987; Tzuriel, 2001), such as are emphasized in Tools of the Mind, are worth considering in this regard.

Summary

It is rarely the case that a single assessment question is being asked. Simultaneously, teachers are trying to plan better instruction, administrators are weighing the efficacy of specific curriculum models for various subgroups of children, and policymakers are identifying effective and struggling programs. Thus, the challenge of early childhood assessment is to construct a system of assessment strategies that are methodologically sound, developmentally appropriate, and responsive to the specific questions that are raised by multiple audiences (J. Jones, 2003; Kagan et al., 2003). The dimensions of early development and learning identified in this chapter can indeed be assessed in ways that answer to these multiple constituencies, while keeping young children's characteristics and needs at the forefront of educational decision making.

CASE EXAMPLE: TOOLS OF THE MIND

During play time, Roy walks into the dramatic play or house area dressed up in a man's jacket, accompanied by his friend Vanessa, who is decked out in a too-big

fancy dress, high heels, and a purse. For several minutes they walk silently around the dramatic play area, opening and closing cupboards. Observing this, the teacher thinks this may be immature play; she sees no play scenario and hears no language. She moves in closer to listen. “Look here,” Roy says, as he opens a cupboard. Vanessa leans over, looks in, and nods. Finally, they sit down with a piece of paper and a pencil. Curious, the teacher finally asks, “What are you two doing?” Roy answers, “She’s looking at the place. She’s signing.”

As the teacher thought back, she knew that Roy’s family had been homeless, and his parents had found a new place to live the previous weekend. In the dramatic play area, Roy was playing the role of the apartment manager showing the apartment, and his friend Vanessa was signing a lease.

In this section, we return, in more detail, to our case example: the Tools of the Mind curriculum that has been previewed in earlier sections of this chapter. After providing some background on its history and main features, we examine relationships between this curriculum approach and the cognitive, emotional, and assessment research that has been outlined in the chapter.

Background

Based on Vygotskian theory, the Tools of the Mind approach emphasizes children’s development of self-regulation and the cognitive and metacognitive foundations of literacy. Founders and directors Elena Bodrova and Deborah Leong began their collaboration in 1992 (Bodrova & Leong, 2001), when Bodrova came to the United States from the Russian Federation, so Tools of the Mind is a relatively new program. Since the program’s inception, roughly 4,000 children have participated in the several hundred Tools of the Mind classrooms. As was typical of the children in Linda Sims’s class, profiled in the chapter’s introduction, virtually all the children have been classified as at risk in terms of living in difficult circumstances. Some are homeless, some have substance abuse in their families, and nearly all live in poverty. Some of the children also have developmental disabilities and other special needs. In recent years, over half the participating children have been English-language learners.

As in any well-rounded preschool program, Tools classrooms include many activities, routines, interactions, and environmental features that are designed to

foster children’s learning and development in all areas. In addition, Tools of the Mind has its own distinctive features, some of which we do not examine here. For the purposes of this chapter, we are focusing on a few program features that link most directly to our chapter emphases: the program’s deliberate attention to pretend play and play planning, as well as other activities designed to support self-regulation and emotion regulation. We also look at the program’s approach to developing children’s emotional security. Finally, we make some observations about the Tools approach to assessment. Throughout, a theme is how the developmental research summarized earlier has relevance for, informs, and may create challenges for the curriculum and teaching practices of this specific educational model.

Play and Play Planning

Vygotsky (1930–1935/1978) saw pretend play as the leading activity in young children’s development, that is, the activity that promotes development to the highest degree. It is not surprising that pretend or dramatic play occupies a key place in a Vygotsky-based program such as Tools of the Mind. Dramatic play elements are woven through many of the day’s activities. During the 40- to 50-minute choice time, children can opt to play in the designated dramatic play area or in other centers, such as the block area, where pretend play themes abound. Although teachers in other early childhood programs may give children time and opportunity to engage in pretend play, relatively few work to actively promote mature dramatic play and have explicit strategies to do so. A notable exception is the High/Scope curriculum (Epstein, 2003). A number of other programs around the country (e.g., Davidson, 1996) have built on the play-training research in developing strategies for enhancing the complexity and symbolic levels of children’s play (R. Saltz & Saltz, 1986; Smilansky, 1968; Smilansky & Shefatya, 1990).

Many children are able to sustain rich, interactive dramatic play as soon as they enter a preschool program. However, in some settings, particularly those serving children from difficult circumstances, children may enter with more limited dramatic play experience and skills (Smilansky, 1968; Smilansky & Shefatya, 1990). For this reason, Tools teachers regularly use a variety of strategies consistent with Vygotsky’s work and the research literature to set the stage and actively promote

the high-level play that is viewed as essential for young children's development and learning.

Setting the Stage

To help children initiate and sustain an imaginary situation, the Tools teacher works to ensure that the children have a repertoire of themes—hospital, grocery store, restaurant, and library, to name a few—to inspire their pretend play and have sufficient knowledge of the roles and activities involved in each. The teachers also use field trips, visitors' presentations, videos, and books. Providing such experiences to nourish children's dramatic play and project work is relatively common (Bredenkamp & Copple, 1997; Davidson, 1996; Katz & Chard, 2000). What Tools teachers do reflects their specific, theoretically influenced goals for children's play. For example, when a class visits the fire station, the teachers invite the firefighters to tell the children who they are and what they do and say in their work. On one such trip, one man showed the children how the firefighters relax and live, and another showed how he uses a hose to fight the fire. When the children came back to the classroom, they created their own props for play. They used cardboard tubes for the hoses, and they pretended to cook firefighter stew, which they had learned about on the visit. As the teachers had hoped, the trip inspired the children to engage in firehouse play for many days.

Teachers in Tools of the Mind classrooms also make strategic use of props to stimulate children's interest and help sustain their play in an imaginary situation. Some early childhood programs stock the dramatic play area with lots of realistic props. In contrast, Tools of the Mind uses a mix of realistic and open-ended props, like the cardboard tubes the children used to make hoses after the firehouse visit. In the early weeks of the school year, teachers find that many children in Tools classrooms do not seem to be able to play without the realistic props, and they do not stray far from each item's designated use. Teachers work to reduce children's dependence on realistic props and help them progress to more symbolic object use. Strategies include games in which children come up with different ways to play with ordinary objects: A wooden block can be used as a baby, a ship, or a chair for a doll. With such practice, along with on-the-spot teacher modeling and encouragement, children begin to make use of simple objects to represent things they need in their play.

Again, the play-promoting practices described here are not unique to Tools of the Mind. Early childhood ex-

perts typically call for a mix of open-ended and realistic props (e.g., Bredenkamp & Copple, 1997; Davidson, 1996; Dodge, Colker, & Heroman, 2002), and a variety of education programs and interventions have actively promoted mature dramatic play (Hohmann & Weikart, 2002; Nevile & Bachor, 2002; Smilansky & Shafatya, 1990). Teacher-initiated experiences designed to build children's symbolic abilities outside the play context are less frequently used in other early childhood programs, but they can be found here and there. The most distinctive element of Tools of the Mind with respect to play is the approach to play planning.

Play Planning in Tools of the Mind

Every day, teachers involve children in planning for their center-time activities, asking each child what he or she will do that day. Over the course of the year, the discussion becomes more detailed, going well beyond the "Where will you play today?" question that many teachers ask to give preschoolers a degree of choice. For dramatic play, teachers encourage children to discuss the roles in the play (who they are going to be), the play scenario (what they are going to play, such as grocery shopping or having a picnic), and how the play will unfold.

Early in the year, teachers need to do quite a bit of prompting. Many of the children initially respond by simply naming the center where they intend to play. The eventual goals are more elaborated planning and children's discussing their plans together without teacher prompting. After some months, teachers see children discussing play on their own more often and more fully, both before and during the actual play.

Another key aspect of the program's approach to planning is having children put their plans on paper. When teachers initially tried purely oral planning, the children and the teachers often forgot the plan. The plan on paper is a tangible record of what the child wants to do, and it can be consulted by the child, the teacher, and even other children. Initially, teachers may take dictation and write what the child says about the plan, which is a useful step in literacy learning as well as planning.

In the Vygotskian framework that Tools is based on, planning on paper would be viewed as a "mediator," strengthening play's self-regulation function. In creating, discussing, and revising their plans, children learn to control their behaviors in play, and teachers report that this tendency carries over to situations outside the play context. Further, the creation of play plans allows teachers to influence play without intervening and

disrupting it as it occurs, which those who study children's play see as important (E. Jones & Reynolds, 1992; Rogers & Sawyers, 1988). Instead, the teacher may suggest to children ahead of time how they can try out new roles, add new twists to the play scenario, or devise substitutes for missing props.

Tools teachers engage children in thinking back to and reflecting on their play as well as planning it. This is not the only approach that emphasizes reflection; as part of their curriculum's plan-do-review sequence, High/Scope teachers also make a point of involving children in reflection on what they have done in the centers. A difference is that Tools teachers wait until the following day to elicit children's reconstructions and comments on a play episode. In the early stages of the program, the teachers observed that being asked about changes in plans immediately after play ("Did you do what you said you had planned?") tended to make children feel they shouldn't change their plan or admit to doing so. A day later, the teachers have found, children are able to discuss more freely what happened in a previous play session. Each approach—same-day or next-day reflection—may have its own advantages; this difference has not been investigated to date.

Giving advance thought to their play and reflecting on it later appears to enable children to develop more mature, interactive play (Bodrova & Leong, 2003b). The literature suggests that play of this kind contributes to language skills, problem solving, self-regulation, and appreciation of others' play efforts (E. Saltz & Brodie, 1982; Smilansky & Shefatya, 1990). Over the course of the year, children in Tools classrooms move from engaging in very limited dramatic play to more frequent and substantially more complex, mature levels of play. Some of this progress may be a function of children's development over 8 or 9 months, but research suggests that without interventions, children with low initial levels of play rarely make significant progress (Smilansky & Shefatya, 1990).

Equally striking to observers is each year's marked decrease in peer conflicts from fall to winter to spring. After plans have been used for several months, teachers find that there are far fewer conflicts because potential problems are defused before play begins. Because peer conflicts appear to reflect difficulties in emotion regulation as well as in other capacities such as social perspective taking, these changes, if confirmed, will be theoretically interesting as well as beneficial to

children themselves and to the overall classroom environment.

Other Experiences That Foster Self-Regulation and Emotion Regulation

The play planning process in Tools of the Mind appears to prompt the development of planning and representational skills (writing and drawing about the intended activities). Other aspects of the curriculum support the closely related goals of self-regulation and emotion regulation.

In the Vygotskian tradition, Tools of the Mind sees as an overarching goal the development of self-regulation. As Kopp (1982, 1989, 2002) and others have clarified, self-regulation is focused on children's regulation of their behavior in accordance with societal and cultural norms, including compliance and effortful control (Kochanska et al., 2000). On the other hand, emotion regulation emphasizes children's ability to modulate and direct the experience and expression of feelings, including but not limited to negative emotions, in the service of important goals. Obviously, the two are closely related, both conceptually and in how they are addressed in the Tools curriculum approach.

Children who experience multiple forms of adversity often arrive at preschool with limited capacity for self-regulation and emotion regulation (Raver, 2002). Teachers in Tools of the Mind classrooms confirm that this is the case for many of their children. Accordingly, the curriculum's developers (Bodrova & Leong, 1996) have made regulatory issues an extremely high priority, especially early in the year. Consistent with the program's theoretical perspective, Bodrova and Leong usually frame their discussion in terms of self-regulation rather than emotion regulation, believing that until children have begun to exhibit some degree of physical and self-regulation (and stemming from that, emotion regulation and the integration of emotions and thinking) they will be unable to take advantage of the classroom's learning opportunities. Although informed most directly by Vygotskian theory, this view is generally consistent with research on self- and emotion regulation discussed earlier in this chapter.

A number of specific features of the Tools program are intended to promote self-regulation and emotion regulation. The Freeze Game described in the first vignette of this chapter is an example. The game is designed to help children practice physical self-regulation;

in this case, as children dance, they see a posed stick figure that the teacher holds up, but they keep dancing until the music stops, and they then reproduce the pose they had previously seen. Another example is what the curriculum's developers call Buddy Reading. Sitting in a group, pairs of children select books to "read" together. To help mediate the turn-taking task, each pair of children is given a set of cardboard lips and ears. Whichever child is holding the ears is the listener, and the child holding the lips is the talker. When they exchange props, the roles are reversed.

Many children in Tools classrooms come into preschool with limited language skills or are English-language learners. As in many other early intervention programs, promoting language development is a priority. The curriculum's focus on language, including encouraging children's private speech to guide behavior, may provide at-risk children with resources to help them regulate their emotional responses and behaviors in frustrating or conflict-ridden situations.

Contributions to Secure Relationships

Vygotskian theory is typically viewed as strongly cognitive. Thus, one might expect less emphasis in Tools of the Mind on emotions and on promoting children's emotional development than in programs influenced by, for example, Eriksonian theory. Bodrova and Leong (2003b) point out that Vygotsky did address emotional development, although in a less elaborated way than in the cognitive domain, and several neo-Vygotskians further developed these ideas about emotions. Their formulations have influenced the perspective on emotional development that is evident in Tools of the Mind.

Besides their Vygotskian focus, the developers of the Tools of the Mind curriculum appear to be incorporating other perspectives on the importance of teacher-child relationships (e.g., Hamre & Pianta, 2001). As the curriculum has become more widely implemented, the developers report that many teachers do not easily or intentionally build nurturing relationships with children, especially children whose behavior is challenging. For this reason, the curriculum's developers have worked on two fronts. First, the developers have tried to build teachers' understanding of the importance of and techniques for creating secure relationships. Second, they work to help children become more self-regulated, thereby making it easier for inexperienced teachers to

have positive feelings about the children in their class. The training manual (Leong, 2005) includes suggestions for how teachers may take advantage of everyday opportunities to establish emotional communication and create secure relationships with children, especially at the beginning of the year.

As reviewed earlier in this chapter, some prior research appears to favor child-centered curriculum models in building emotional security and warm teacher-child interactions. Consistent with broader trends and recommendations (e.g., Bowman, Donovan, & Burns, 2001; Bredekamp & Copple, 1997), Tools of the Mind is one of a number of curriculum approaches that do not fit neatly into these categories, emphasizing both a so-called academic emphasis in its focus on literacy and cognitive development, and a strong emphasis on pretend play and social activity. Although the teacher-child relationships in Tools programs have not yet been studied systematically, observations and discussions with teachers and curriculum developers suggest that close relationships may be prevalent. With few exceptions, once the year is well under way, children—including those at risk for relationship difficulties—function calmly and independently in the classroom, checking in with the teacher and appearing to use him or her as a secure base for their exploration and problem-solving activities.

A contribution to the formation of these bonds may be the sequential nature of the year-long curriculum and the changing priorities over the course of the year. As in a number of other early childhood programs, time is deliberately set aside early in the year for a number of foundational priorities, including the development of nurturing teacher-child relationships (Leong, 2005). The daily schedule is also weighted heavily toward peer collaboration and interaction during pretend play and in activities such as shared book reading. Teachers rarely need to put their energy into being in charge of an entire group and need to impose few sanctions on the class. Freed of these constraints, the teacher is better able to spend time getting to know children on a personal level and responding in contingent, nurturing ways. Further, the frequent "scaffolding" interactions, a key component of the Vygotskian curriculum, also create the conditions for relationship building. In an emotional as well as a cognitive sense, the teacher's supportive assistance allows the child to reach desired ends, further cementing the relationship.

Assessment Perspectives on Tools of the Mind

Assessment has an important role in the Tools of the Mind curriculum. Consistent with recommendations for early childhood assessment (National Association for the Education of Young Children & National Association of Early Childhood Specialists in State Departments of Education, 2003; Shepard et al., 1998), in these programs the primary purpose of assessment is to help teachers make the daily classroom decisions that support children's learning. Specifically, in Tools of the Mind classes, the ongoing assessment is intended not just to let the teacher know where the child is functioning, but to give the teacher insight into how to move each child forward to the next level of learning.

In general, there appears to be alignment between the goals of the program and the curriculum-related assessments used by the teachers. For example, teachers use checklists to track children's growth in play planning and in the maturity of their pretend play—significant emphases in the developmental framework of Tools of the Mind. The Tools of the Mind curriculum focuses on explicit development of self-regulation in the context of intentional play (Bodrova & Leong, 1996). Teachers in Tools of the Mind classes must be deliberate in setting up the conditions in which children will interact with one another and must be careful observers of children's interactions. They must constantly observe and listen as children talk, draw, construct, and carry out their activities.

The day-to-day implementation of the curriculum is continually informed by teachers' assessments as they become involved with and observe children's performance. Only through focused observation will the teacher recognize those moments when children need assistance (scaffolding) to move to the next level. Based on those assessments, for example, teachers provide supports in the form of certain external mediators, such as more concrete props for pretend play, gradually withdrawing these supports as children become more cognitively and behaviorally independent. Valuable as this scaffolding may be, some have observed that it may create tension for more traditional approaches to assessment:

Help and coaching that students receive for assessments conducted during and as part of instruction would be seen as contributing to lack of independence of observations or “cheating” and thus a threat to reliability and validity. However, one of the basics in constructivism is that

this is precisely where the learning occurs—in the zone of proximal development (Vygotsky, 1978), that space between what the individual can accomplish independently and what he or she can do with assistance. (Brookhart, 2003, p. 7)

More specifically, the Vygotskian theoretical framework that has shaped the Tools of the Mind curriculum has implications for how assessment is conceptualized and conducted. In Tools of the Mind and other Vygotsky-influenced programs, the assessment approach has been termed “dynamic assessment” (Tzuriel, 2001). Rather than gathering summative information at the end of each unit, from a dynamic assessment perspective teachers are always facilitators of children's learning (Feuerstein, 1979). The teacher's role is to begin by identifying the child's level of independent performance: What can the child do alone? The supports the child needs to learn the target skill or knowledge must also be identified and provided. For example, if the teacher observes that a child needs help in planning for play, several scaffolding strategies are available:

- *Oral language:* The teacher asks the child to put the plan into words.
- *Social interactions:* The teacher anticipates potential trouble spots that might influence the first interactions in the play.
- *Representational drawing/symbolic thinking:* The teacher asks the child to represent the idea on paper.
- *Memory:* The teacher asks the child to repeat the plan after drawing.
- *Literacy:* The teacher models how to put an oral message into print.

The professional development implications of these assessment approaches are substantial. Teachers implementing the Tools curriculum must develop an understanding of human development in general and of the specific ways their children learn and develop. Teachers also need an array of scaffolding procedures and the ability to select the most appropriate strategy for a specific child and a specific point in his or her learning. Clearly, this type of assessment requires a skilled teacher, and therefore teacher professional development is a critical component of the Tools of the Mind approach to early childhood education.

This description of the assessments used in Tools programs reflects the difficulty of implementing com-

prehensive and ongoing assessment. It also underscores the complex relationships between assessment within a specific curriculum and the larger context of assessments that may be (as the next section details) driven by larger federal or state imperatives around assessment and accountability. With its emphasis on self-regulation, the Tools of the Mind curriculum raises interesting questions regarding the use of direct standardized assessment of self-regulation skills in any evaluation of this curriculum. Although some measures currently exist (McCabe, Hernandez, Lara, & Brooks-Gunn, 2000; McCabe, Rebello-Britto, Hernandez, & Brooks-Gunn, 2004), significant work is needed to develop technically sound, culturally and linguistically sensitive direct measures of self-regulation from which generalizations about programs can be made.

THE CHALLENGES OF IMPLEMENTATION

So far, this chapter has illustrated the general relationships between child development research and early childhood education programs, using selected examples. It has described evidence that supports an emphasis on some specific aspects of cognitive and emotional competence in early childhood education and a systematic, developmentally appropriate approach to assessing children's progress in these and other areas. We have just analyzed the components of the Tools of the Mind preschool curriculum in light of these developmental essentials.

However, the process of actually implementing a complex, developmentally based curriculum such as Tools of the Mind is more challenging than this story may have conveyed. This part of the chapter returns to the larger context of early childhood education in the United States, highlighting ways in which difficult societal, policy, and practical issues must be taken into account, not only by this curriculum but also by any effort to implement high-quality early childhood education.

The Challenges of Going to Scale

At present, the Tools of the Mind curriculum has been implemented in a relatively small number of settings, and oversight of implementation and training has remained primarily in the hands of the curriculum's original developers (Bodrova & Leong, 1996). Clearly, the developers would like to see their approach to early

childhood programming used more widely, yet obstacles face any such efforts.

Over the years, early intervention research has raised cautions about the difficulty of taking promising demonstration programs to a larger scale. A point made repeatedly is that the most positive long-term effects of early intervention have been found in programs that were essentially demonstrations, often linked with a major research center, such as the Perry Preschool Project (Schweinhart et al., 1993) and the Abecedarian Project (Campbell et al., 2002). These and other demonstration programs were typically implemented in one setting, with close involvement of the curriculum developers and with highly trained and committed teaching staff and ongoing evaluation. With a few exceptions, such as the Chicago Parent-Child Project (Reynolds, 2000), larger-scale program implementations such as in Head Start—although having clear benefits—have had less dramatic impact. Some specific curriculum models have been scaled up with positive results (the High/Scope curriculum, the Creative Curriculum), but this has taken extensive development and revision of print resources, teacher training materials and training of trainers, assessment tools, and other supports for implementation.

Tools of the Mind is just beginning to face these kinds of challenges. Its training manual is still under development, and training is conducted only by the developers and several other individuals who have worked closely with the developers. Although the curriculum provides many scaffolds for teachers as well as for children, it is not tightly scripted and requires a fairly high level of theoretical and pedagogical insight, as teachers use careful observation and assessment to tailor their interactions to children's individual zones of proximal development. It also assumes a high degree of buy-in or commitment on the part of teachers, which is less likely as any curriculum approach is taken to scale or mandated for adoption (Ryan, 2004).

Ironically, the very features that promise the greatest benefits for children, such as Tools of the Mind's flexible, individualized interactions, make it difficult to quickly and simply communicate the essentials to a wide range of teachers and administrators. In the current climate of limited time and resources, school districts and agencies are often inclined to adopt a curriculum that seems easier to implement on a large scale without a great deal of effort, despite the potential developmental advantages of approaches like Tools of the Mind.

Quality Issues in Early Care and Education

Furthermore, taking any curriculum to scale in the complex and highly variable environment of U.S. early child care and education is far more daunting than in the relatively more homogeneous system of K–12 public education. Ideally, one would want a promising curriculum model to be implemented in a wide range of settings, including Head Start classrooms, state prekindergarten programs, and community-based child care programs that are not part of Head Start or state prekindergarten. However, wide variations exist across these settings in who sets the standards and in what standards apply in areas such as teacher qualifications, adult-child ratios, and group size. For example, child care programs are regulated by state licensing standards, which vary widely from one state to another but that typically emphasize health and safety requirements. State-funded prekindergarten programs operate under the aegis of public schools and typically have higher requirements for teacher qualifications than other child care programs in the same community. Head Start programs operate under a set of performance standards (U.S. Department of Health and Human Services, 1997), higher teacher qualifications than most child care centers, and a well-defined monitoring system, with grantee agencies varying from public schools to community agencies to universities.

Not only does this variation create administrative challenges to implementation, but it also underscores the need for a consistent floor of quality. It is much easier to layer a curriculum such as Tools of the Mind onto a program that already has a relatively high level of quality. The reality is that in this diverse and underfunded collection of early child care and education settings, quality varies widely (Lombardi, 2003) and is generally rated mediocre if not actually harmful to children's development (Cost, Quality, and Child Outcomes Study Team, 1995).

Professional Development Challenges

Related to these concerns, an inconsistent and underfunded system has great difficulty sustaining a well-educated and motivated workforce adequate to implement a developmentally based, cognitively challenging curriculum. Research has consistently identified early childhood teachers' education and training as important to program quality, often predicting the kinds of teacher-child interactions that are associated with better child outcomes (Barnett, 2003; Tout, Zaslou, & Berry, in press). Tools of the Mind is primarily

implemented in classrooms staffed by experienced, committed lead teachers like Linda Sims, who have the bachelor's degrees and early childhood competencies recommended in national reports and professional standards (Bowman et al., 2001; M. Hyson, 2003). As the curriculum is taken to scale, the trainers are likely to be faced with a far less educated and motivated workforce.

Even with highly qualified teachers, an ongoing challenge is to design and deliver effective professional development. The developers of Tools of the Mind have found, and research suggests, that something considerably beyond the usual one-shot workshop is needed (Bransford et al., 2000; National Staff Development Council, 2001). At present, the developers rely on a mix of intensive workshops early in the year, along with regular observation, feedback, and coaching from trainers. Working with teachers who have often spent years implementing quite different approaches can be challenging. Again, as the program attempts to reach a larger audience, the intensive and personalized training approach currently used may come under closer scrutiny, or it may need adaptation and implementation by a much larger group of trainers, running the risk that the curriculum's key emphases may be diluted or distorted.

Selection of important content for professional development is a challenge for the field. With limited time and resources, what is most worth knowing and emphasizing? The Tools training manual clearly emphasizes Vygotskian theory and related research, as well as rationales and techniques for implementing a variety of specific activities and assessment systems in the classroom. Training does not address all aspects of delivering an early education program in comprehensive fashion; to some extent, the Tools programs may be relying on other professional development systems (e.g., Head Start programs have other training in place) to deliver some important content. A concern is that some content may fall through the cracks; for example, a recurring theme in the literature (Raver, 2002; Shonkoff & Phillips, 2000) is the lack of high-quality professional development for teachers who are addressing emotional issues in their classrooms and who are trying to deal with children's challenging behaviors.

The Challenges of Maintaining Integrity and Coherence

Although research has not yet provided evidence for the superiority of any single curriculum model (Bowman

et al., 2001; Goffin & Wilson, 2001), it does seem that a planned, coherent curriculum, implemented with fidelity by qualified teachers, indeed makes a difference for children. A difficult question is how coherent or theoretically consistent a curriculum should optimally be. Tools of the Mind is one of the most theory-driven curricula currently being implemented in early childhood education.

Maintaining this coherence is a challenge, and there may be trade-offs. On a conceptual level, it is not clear that all the answers can be found in Vygotsky and the neo-Vygotskians. For example, the developers make an effort to draw on neo-Vygotskians to inform their approach to emotional development, yet this insistence on Vygotskian underpinnings may result in too little attention to other current work in early emotional development. Similarly, recent work by developmental psychologists on planning, representation, and self-regulation might further strengthen these curriculum emphases.

In addition, as discussed earlier in this chapter, there are many critics of the use of child development theory and research as the primary basis for early childhood curriculum and teaching practices (e.g., Stott & Bowman, 1996; Zimiles, 2000). Early childhood reconceptualists and others note that multiple sources provide knowledge and insight about early childhood education, including the insights of teachers (Ryan, 2004; Williams, 1996).

These suggestions should be tempered with caution. Might a too enthusiastic search for evidence from multiple perspectives and multiple theories, researchers, and practitioners drive the curriculum in the direction of a scattered eclecticism? Maintaining a more “pure” Vygotskian emphasis may run the risk of losing the benefit of key evidence and insights in areas important to the curriculum’s goals; on the other hand, incorporating widely divergent viewpoints and related research evidence runs the risk of diluting the curriculum’s integrity and focus.

Expectations for Evidence and Accountability

The public, policymakers, program developers, and others want clear and credible evidence of the impact of public investments in programs for young children. National reports and government mandates have raised expectations for early childhood teachers. Teachers today are expected to implement more effective and challenging curricula in language, literacy, mathematics, and other content areas and to use more complex assess-

ments of children’s progress (Bowman et al., 2001). Doing this in a developmentally appropriate way is a continuing challenge.

Today, every state has K–12 standards, specifying what children are expected to know and be able to do in various content areas (Align to Achieve, 2004), and a recent survey (Scott-Little, Kagan, & Frelow, 2005) found that more than forty states had or were developing “early learning standards” for children below kindergarten age. As the Tools of the Mind curriculum or other curricula are developed and implemented, they do not exist in a vacuum. These standards and other expectations—which may or may not be theoretically and practically consistent with the curriculum’s emphasis—must be taken into account. In some cases, this integration may be smooth, but in other cases, the expectations of various “masters” may be contradictory and challenging to reconcile.

Tools teacher Linda Sims and other teachers also function within the larger context of evidence expectations: in this case, the expectations of the curriculum’s developers and evaluators (evaluation is ongoing and has not yet been published); the expectations of the state’s early learning standards and assessment system; and, because Linda Sims’s classroom is part of Head Start, regular screening and assessment guided by Head Start’s Program Performance Standards and Child Outcomes Framework. Linda Sims also needs to take into account a newly implemented and controversial Head Start National Reporting System, which was designed to administer standardized tests to every child twice a year on language, literacy, and mathematical knowledge (Administration for Children and Families, 2003; Raver & Zigler, 2004). All of these expectations must be taken into consideration, along with other goals and priorities. The developers of Tools of the Mind comment on these challenges, noting that many of the mandated assessments linked to Head Start, state, or other accountability systems are not well aligned with their curriculum’s developmental assumptions and goals.

The Challenge of Gaps in the Research

Despite the significant body of work discussed in this chapter, a challenge in implementing early childhood curricula such as Tools of the Mind is the continuing lack of developmental and educational research in a number of critical areas. The need for additional

research has been noted throughout the chapter, but examples can be summarized here.

Research priorities include:

- Studies of the development of specific cognitive and emotional competencies in child care and other out-of-home settings.
- Further study of the importance of culture and language in children's cognitive and emotional development and in the early educational approaches that are most effective in promoting the development of linguistically and culturally diverse young children.
- Further specification of what aspects of early childhood curricula, implemented under what conditions and with what resources, lead to more favorable child outcomes.
- Further investigation of what curriculum features, and what teaching practices, are most likely to support the development of warm, secure relationships between teachers and children.
- Closer examination of the characteristics and effects of curriculum approaches that combine intentional, focused teaching with promotion of children's play, social interaction, and exploration.
- Investigation of the conditions that promote teachers' commitment to and involvement in developing and implementing early childhood curriculum and teaching practices.
- Additional studies of the role of pretend play in the development of self- and emotion regulation.
- More precise definition of the critical components of effective classroom-based or formative assessments.
- Design and validation of direct child assessments of social-emotional and vocabulary development that are sensitive to linguistic and cultural differences.
- Studies that lead to a reconceptualization of the constructs of validity and reliability in the context of classroom-based assessment.

To refine and move this research agenda forward, greater communication and collaboration are essential—between researchers with differing specializations (such as cognitive and emotional development) and between researchers, early childhood program and policy specialists, and teachers, who know best what kinds of research questions are most in need of answers.

Certainly, the new directions in curriculum research and in other early intervention research are promising, going beyond winners or losers in the curriculum race to seek more nuanced understandings of complex patterns and effects. As this work goes forward, several additional features will enhance its value. First, as the ecological perspective on development emphasizes, young children participate in many settings beyond the hours they spend in any preschool program. The potential of early childhood education needs to be studied in contexts, including the kind and quality of interactions experienced by children in families and neighborhoods and in informal as well as formal child care. Those experiences may influence and be influenced by the more formal educational program. Second, in-depth studies of the process of developing and implementing new approaches to early childhood education, such as the Tools of the Mind curriculum, will help with the task of bringing developmental knowledge into classrooms and communities, anticipating what some of the barriers and promising pathways may be. Finally, young children will be well served if developmental researchers' own professional development includes attention to skills in identifying program- and policy-relevant research and communicating the results of that research to policy-makers in clear, objective ways.

SUMMARY AND CONCLUSIONS

In this chapter, we have examined the complex relationships between early childhood education programs and child development research, using as a case example the relatively new and still evolving Tools of the Mind curriculum. After an overview of the functions and limitations of developmental theory and research in relation to early childhood education, the chapter focused on two educationally relevant areas: the development of cognitive essentials, specifically children's representational thinking, self-regulation, and planning, and the development of emotional competence, specifically emotional security and emotion regulation. We reviewed principles and research on the assessment of young children's development and learning, emphasizing classroom-based assessment intended to support teachers' ongoing decision making. The practical, systemic, and policy challenges of linking developmental theory and research with early childhood curriculum and teaching practices were the focus of the final section of the chapter, in-

cluding the challenges of taking a demonstration program to scale; issues of variability and quality in the system of U.S. early care and education; issues in delivering professional development; challenges of maintaining integrity and coherence; expectations for evidence and accountability; and gaps in the field's current knowledge base.

Despite these challenges and research gaps, the work discussed in this chapter does have some clear implications for practice. Among other emphases, it guides programs toward the following:

- Greater intentionality on the part of teachers, as they plan and implement curriculum.
- A focus on the big picture in development, giving priority to competencies that have the greatest likelihood of influencing later development and learning in far-reaching and positive ways.
- Attention to the modes of learning found to be especially powerful in early childhood, such as pretend play and other forms of representation.
- Giving high priority to teacher-child relationships.
- A view of assessment as an ongoing process, conducted by knowledgeable and interested teachers, to help them promote the development and learning of every child in their class.
- Creating the kinds of professional development and other resources that can support teachers' ability to implement curriculum and teaching practices and to assess children's progress.

The consequences of not moving in these directions, and others articulated in this chapter, are serious, especially for children most at risk for developmental and academic difficulties. As the research has suggested, lack of planning skills, inadequate development of self- and emotion regulation, lack of enthusiasm and persistence in the face of learning challenges, and an absence of secure and nurturing relationships with teachers will multiply the difficulties young children face as they enter kindergarten and the primary grades.

The challenges described here should be understood in light of the high stakes involved. Growing research that shows the potential to foster positive development through early childhood education is paralleled by the growing number of developmentally vulnerable young children in child care, Head Start, prekindergarten, and other programs. Working together, early childhood edu-

cators and researchers have the potential to identify the most promising curriculum and assessment practices to serve all young children and to devise effective ways to integrate those practices into programs staffed by committed and well-compensated professionals.

Child psychology and education share a long history of mutual interests and reciprocity in their methods of study, theories of development, and practical goals for improving the lives of children. Educational psychologists, for example, have studied learning and motivation, curriculum and instruction, and assessment and intervention in schools for more than 100 years (S. Paris & Cunningham, 1996; Renninger, 1998). The synergy between the fields has improved the knowledge of parents and caregivers as well as the professional development of teachers. Perhaps the area where the synergy is most evident is the field of reading education because developmental research has informed teachers' practices and educational policies directly. At the beginning of the twenty-first century, educators and policymakers show an increasing reliance on scientific research and evidence-based practices to substantiate what works in the classroom for reading instruction and assessment. The national and state policies concerning achievement testing and educational accountability through assessment are based on developmental research, and they have strong consequences for the ways that young children are taught to read.

This chapter examines the developmental issues that surround assessment and instruction of beginning readers. We review the prevailing view of the development and coordination of reading skills and show how assessments of different concepts and skills are important for beginning readers. We suggest that many early reading assessments are confounded by different developmental trajectories of reading skills, and we show how confounded correlations can be misinterpreted to privilege some skills over others in early reading practices. Thus, the chapter connects conceptual, methodological, and practical aspects of children's reading development to show the value of an applied psychological perspective on educational issues. We begin with an example of a typical reading assessment of a first grade student.

CASE EXAMPLE: ROBERT, A FIRST-GRADE STUDENT

Ms. Jones tries to assess the reading skills of every child in her first-grade class at the beginning of the school year, but it often takes 6 to 8 weeks to administer indi-

vidual assessment tasks to each child. Now it is October and she has had many opportunities to test Robert and to observe him during small group instruction. She used the state-sponsored battery of reading assessments and recorded Robert's performance on letter knowledge, concepts of print, phonemic awareness, and oral reading, as well as his daily interactions with texts. He correctly identified 18 uppercase letters of the alphabet, but he had more difficulty with lowercase letters. When given a book, Robert knew how to hold the book and turn pages one at a time and how to track print from left to right. He was able to read some words in a preprimer text, but he did not understand punctuation so he did not know when to pause at the end of a sentence. He guessed at words that he did not know, and his intonation was flat while he read.

Ms. Jones recorded a low score for Robert on the Concepts of Print task because of his problems with punctuation and discriminating words. She noted that he read only 22 words correctly per minute in his oral reading assessment. Because Ms. Jones worried that Robert did not know the correspondence between letters and their sounds, she gave him several assessments of phonological processing skills. Although Robert could supply rhyming words for 6 of the 8 words she gave him, he had more trouble segmenting words into separate sounds (e.g., d-o-g) and blending sounds to form words (e.g., t-a-p), so Ms. Jones recorded low scores for his phonemic awareness.

Based on the assessments and her observations, Ms. Jones noted that Robert was a reluctant reader who guessed at words often. The only comprehension assessment in the state battery was a listening task, but Ms. Jones had observed that Robert seemed to have difficulty retelling stories and answering questions about text. His problems with letter-sound correspondences seemed to hinder his decoding. She identified Robert as a child who needed extra tutoring and placed him in her lowest reading group. She advised the parents to help Robert learn the letters of the alphabet and their sounds. She provided a tutor to drill Robert each day on phonological processing skills such as identifying initial consonants, discriminating long and short vowels sounds, and segmenting and blending sounds in words. She also tried to work one-on-one with Robert several times each week with repeated readings (of the same text they read in small groups) to increase his fluent oral reading.

This kind of report is representative of many first graders, perhaps half the class in schools that serve low-

socioeconomic status (SES) families and students at risk for educational problems (S. Paris & Hoffman, 2004). The positive features of Ms. Jones's report include early testing by the teacher, combining formal assessments and informal observations, and making clear instructional suggestions to help Robert. However, there are some problems with the assessment, mostly in terms of omissions. Because Robert could not read much text, his comprehension and vocabulary skills were not assessed as thoroughly as other skills, and, consequently, the remedial instruction focused on basic skills rather than strategies for understanding words and text. Ms. Jones discussed text genres (e.g., the differences between narrative and informational texts) with her best readers, and she connected writing and reading for them. Robert's motivation and interest in the content of texts were not assessed, so most of his interactions with reading were focused on sounding out words correctly and quickly rather than thinking about the meaning or enjoying the content of the text. Ms. Jones gave priority to Robert's weakest skills, with the understanding that assessment and instruction on comprehension and writing would be deferred until his decoding skills improved. There simply was not enough time in the 90-minute language arts block to teach Robert listening, speaking, and writing skills while he was trying to catch up to the decoding prowess of his classmates. The end result for Robert, as for many struggling readers, is a skill-and-drill approach to reading that is qualitatively different from the curriculum provided to better readers (Allington, 1983).

Many readers will recognize the choice of instructional emphases between Robert's decoding skills and a broader variety of literacy skills as a reflection of a larger polarization between two approaches to reading instruction labeled the "great debate" between basic skills and whole language (Chall, 1967). It has also been referred to as a contrast between top-down and bottom-up processing of text, although Stanovich (1980) showed that both kinds of processes can be mutually compensatory during reading. Adams, Treiman, and Pressley (1998) provided a thoughtful review of this controversy and why it disappeared in the 1990s. They concluded:

Repeatedly and convergently, the heavy majority of the variance in beginning reading success has been traced to just two factors—familiarity with the letters of the alphabet and phonemic awareness—whereas the measurable contributions of even our most intuitively compelling contenders appears weak, evanescent, and remote. (p. 310)

This conclusion has been supported widely in seminal publications, including *The Prevention of Reading Difficulties* (Snow, Burns, & Griffin, 1998) and the National Reading Panel (2000) report.

The consequences of the research evidence for educational practice have been powerful and widespread, facilitated greatly by the federal legislation in the No Child Left Behind Act (2002) that raised the stakes for educational accountability. Assessment of achievement, especially reading, is required annually for grades 3 through 8, and there is increased pressure to demonstrate measures of adequate yearly progress in grades kindergarten through 3. Assessments of progress have focused on early decoding skills and precursors such as letter knowledge because research has shown that they predict later reading proficiency. At the same time that assessment of reading achievement was becoming more frequent and more important at primary grades, instruction was becoming more aligned with the same basic skills on the assessments. Thus, federal policies emphasizing assessment and instruction of basic reading skills have been implemented across the nation. It has been a remarkably swift transformation of early reading practices and policies, built mainly on research evidence about the developmental importance of basic decoding skills for beginning readers. In this chapter, we examine and reinterpret the evidence for these policies, and we suggest an alternative interpretation of the research. To understand the bases for the current practices and policies in reading education, we turn to an examination of the prevailing view of reading development and then to a critical evaluation of the research evidence that supports it.

THE COMPONENT VIEW OF READING DEVELOPMENT

Assessment of reading depends on fundamental theoretical and methodological assumptions about the skills that are measured. Most theories of reading development regard proficient reading as the assembly, coordination, and automatic use of multiple component processes (Adams, 1990; Stanovich, 2000). These processes include a variety of knowledge and skills, some specific to print and some not, that develop into a coordinated activity of skilled reading, usually during childhood. For example, Rathvon (2004) lists 10 components of reading that predict reading acquisition or diagnose reading problems: phonological processing, rapid letter naming, orthographic processing, oral language, print awareness

and concept of word, alphabet knowledge, single-word reading, oral reading in context, reading comprehension, and written language. The National Reading Panel (2000) identified a shorter list of five essential components of early reading: the alphabetic principle, phonemic awareness, oral reading fluency, vocabulary, and comprehension. The same five skills were endorsed in the Reading First part of the No Child Left Behind Act (2002) as fundamental for K–3 reading instruction and assessment. Researchers and educators generally regard the acquisition and integration of these components to be essential for reading development.

It is surprising, however, that differences among component skills have not been taken into account in research that compares skills during acquisition. There are several consequences of the developmental differences in component skills that influence assessment considerably (S. Paris, 2005). Consider some differences among skills. First, the five essential skills are not differentiated by the scope of knowledge that needs to be learned. Alphabet knowledge (in English), for example, is limited to the names and sounds of 26 letters, and it is much smaller in scope than comprehension. Skills that are smaller in scope may be learned earlier or faster than skills with larger scope. Second, the duration of acquisition differs dramatically for various skills. For example, the basic concepts of print are acquired in a few years, but vocabulary develops throughout the life span. The same is true for awareness of written language conventions compared with spelling abilities. The developmental trajectories of acquisition and automatic use can vary widely for various components. Third, some skills are mastered universally to the same level, that is, every literate person knows the same information, such as learning the alphabet, whereas other skills, such as vocabulary, vary widely among individuals in what they know and how much they know. Universally mastered skills have no variance among novices (because of floor effects) and no variance among experts (because of ceiling effects) and considerable variance during learning. In contrast, skills such as comprehension and vocabulary that develop continuously may exhibit more stable patterns of variance for both individuals and age cohorts, and the variance for unconstrained skills will be evident among beginning and proficient readers too.

Fourth, assembly models of skills regard each skill independently and ignore sequential or codependent relations between them. For example, both orthographic and phonological processing are required for word read-

ing, and it is difficult to separate their contributions. Likewise, reading comprehension depends on multiple visual, cognitive, and linguistic skills. Some skills must meet thresholds of performance to enable other skills to operate. For example, when oral reading accuracy is less than 90% of the words in text, comprehension is seriously degraded. Why is this a problem? Because researchers often use multivariate statistics such as regression analyses and hierarchical linear modeling (HLM) to compare the predictive strength of different skills, but these methods fail to consider codependency among skills or different onsets, slopes, or durations of their developing trajectories.

The failure to differentiate reading skills conceptually is evident in the methods used to analyze developmental data. Consider cross-sectional and longitudinal studies of reading achievement (cf. Lonigan, Burgess, & Anthony, 2000; Morris, Bloodgood, Lomax, & Perner, 2003; Scarborough, 1998). It is common practice to assess a variety of reading skills and use the data to calculate correlations among skills, to conduct factor analyses to determine if skills are closely related, and to conduct regression analyses to determine which skills predict an outcome variable. Correlations are also used routinely to calculate concurrent and criterion-referenced validity for reading components. For example, Snow et al. (1998, p. 110), in a chapter entitled "Predictors of Success and Failure in Reading," include a table of correlations between reading components and difficulties at school entry that are summed over many studies. The median Pearson r correlations are .53 for letter identification, .49 for concepts of print, .42 for phonological awareness, and .33 for receptive vocabulary. Thus, these factors are implicated as predictors, correlates, and perhaps causes of reading difficulties at school entry. These conclusions, and the research methods used to establish validity of reading components, are accepted as robust and scientific evidence in federally endorsed reports on reading (e.g., Adams, 1990; Adams et al., 1998; National Reading Panel, 2000; Snow et al., 1998).

Despite a massive amount of evidence about the development of early reading skills, and the importance of letter knowledge and phonemic awareness, we think there is a different interpretation of the scientific evidence that merits consideration. Our reasoning in this chapter is inductive. We begin by focusing on skills that enable reading and note differences in their developmental courses of acquisition. Some skills, like knowledge of

the alphabet, are mastered completely by all skilled readers. The rate of learning may vary, but the asymptote, that is, the final knowledge shared among readers, is the same for everyone. The developmental curve is sigmoidal in shape, like an S curve, with gradual learning initially, followed by rapid learning, and slowing down as an expert level is approached. Most important, letter knowledge has the *same* end point or intercept for all readers, that is, knowing the names and sounds of 26 letters. We suggest that decoding skills, including basic phonemic awareness, have similar trajectories, and furthermore, these trajectories are different from other less-constrained skills, such as vocabulary knowledge, that continue to develop continuously and do not reach identical asymptotes. We attribute the fundamental differences in developmental trajectories to the nature of the skills, the course of learning, and the universality of some skill asymptotes. The implications of these different skill trajectories are profound for research, practice, and policymaking because they have been neglected for 100 years. The arguments may be extended to other skills, such as arithmetic, that are constrained by mastery and similar asymptotic growth curves. Thus, the lessons from assessments of reading skills have implications for psychoeducational assessment of other developing skills.

There are potentially many alternatives to the componential view of reading. Not all theories need to assume that skills are equal on many dimensions, nor that growth is linear. For example, Fischer and Bidell (1998) describe dynamic systems theories that can account for variability and uniformity using newer approaches than stages and traditional learning mechanisms. They suggest that many features of development are not linear, and that logistic growth, like the S curve we advocate for some constrained reading skills, is common. They propose methods of analysis to accompany dynamic and nonlinear models of development. However, their approach does not address universally mastered and constrained skills nor the implications of parametric data analyses of such skills, so we do not attempt in this chapter to integrate their approach with our own interpretation of constrained reading skills.

THE ASSESSMENT OF ALPHABET KNOWLEDGE

As children are exposed to print, they learn to identify letter names and the sounds associated with them. This

is generally referred to as the alphabetic principle, letter knowledge, or graphophonetic knowledge. With practice, fluency (i.e., speed) increases for identifying and producing letters and their sounds. The letter names that are easiest to learn occur early in the alphabet and may occur in the child's name. Letter sounds are easiest to learn when the sound of the letter is in the letter name and when letters usually occur in the initial position of words rather than in the final position (McBride-Chang, 1999). Learning the names of letters precedes and facilitates learning letter-sound correspondence because the latter includes identification of phonemes (Stahl & Murray, 1994). Thus, letter-naming knowledge "does not appear to have a direct causal influence on word reading skills" (Rathvon, 2004, p. 122) but does promote phonemic awareness. This may explain why teaching children the names of letters and improving their letter-naming fluency do not improve reading skills (Fugate, 1997). In contrast, letter-sound knowledge may contribute directly to phonemic awareness, decoding, and word recognition (Treiman, 2000).

Alphabet knowledge is one of the five essential components of early reading identified by Snow et al. (1998) and the National Reading Report (2000), so it is not surprising that it is included in many early reading assessments. For example, it is part of the Texas Primary Reading Inventory (TPRI, 2002), the Virginia Phonological Awareness Literacy Screening (PALS, 2002), the Michigan Literacy Progress Profile (MLPP, 2002), and the Illinois Snapshots of Early Literacy (ISEL, 2003). Rathvon (2004) lists 26 different assessments of alphabet knowledge and letter-naming fluency; it is clearly a popular and frequent part of early reading assessments. Alphabet knowledge can be assessed with a variety of tasks, including letter identification, letter naming, rapid automatic naming, spelling, and phonological awareness. The format of assessment can require recitation, recognition, identification, or production. Rathvon notes that identification or recall methods are the most common, but the format may contribute to differences in sensitivity of the assessments. Whether the letters are presented in uppercase, which is easier to decode, or lowercase or even cursive, may also affect the assessment. Few assessments include all 26 letters of the alphabet, and assessments vary widely on whether they include all single-letter sounds, digraphs, blends, and diphthongs. Usually, the assessments use prototypical sounds such as initial consonants and frequent long and

short vowel patterns. Fluency of alphabet knowledge is measured in only a few assessments, usually by counting the numbers of letter names or sounds produced in 1 minute, because the speed of saying individual letter names and sounds is not correlated with reading ability (Stanovich, Cunningham, & West, 1981). Rathvon says it is surprising that no fluency norms are available for either letter-naming or letter-sound fluency, and the lack of benchmarks may contribute to the less frequent assessment of the fluency of letter-name and letter-sound production.

The reason alphabet knowledge is such a popular assessment is because of the strong correlations with subsequent reading skill. Knowing the names of letters in kindergarten is one of the best predictors of future reading achievement in first grade and beyond (Scanlon & Vellutino, 1996; Share, Jorm, Maclean, & Matthews, 1984; Stevenson & Newman, 1986). Although there is less evidence about the predictive strength of letter-sound knowledge, when it is assessed in kindergarten, it predicts word identification in first grade and reading group status in fourth grade (Badian, McAnulty, Duffy, & Als, 1990; Byrne & Fielding-Barnsley, 1993). Lonigan et al. (2000, p. 597) write, "Knowledge of the alphabet (i.e., knowing the names of letters and the sounds they represent) at entry into school is one of the strongest single predictors of short- and long-term success in learning to read." Thus, alphabet knowledge is relatively easy to assess, and there is considerable evidence that it predicts subsequent reading achievement.

The correlation between early alphabet knowledge and later reading achievement, however, has been oversimplified and misinterpreted. Although researchers do not suggest a causal relation between them, the inference is so seductive that instruction in kindergarten and remedial help for struggling readers often targets letter names and sounds. This was portrayed in the example of Robert, a struggling first-grade reader whose teacher emphasized sounding out words correctly and quickly. When this happens, three risks are likely. One is that children with few literacy experiences before kindergarten, usually children from homes with low SES or families who do not speak English as a native language, are identified for special remediation. Second, these students are given a curriculum that is focused on isolated skill instruction, such as letter identification, rather than on rich and diverse literacy experiences. The third risk is that the lack of rich and diverse literacy ex-

periences has detrimental consequences for disadvantaged students' learning and motivation. Beginning readers who have more difficulty breaking the code than their peers are usually exposed to less text with less emphasis on meaning making, which can increase, not decrease, the disparities between children (Stanovich, 2000). Children would be in less jeopardy of these risks if the assessments of alphabet knowledge were interpreted as indicators of different developmental trajectories rather than specific skill deficits. The causes for the slower learning of the alphabet can include a range of factors, such as less exposure to books, less print in the home environment, or less adult guidance and instruction, and interventions can accommodate these factors in addition to teaching letter names and sounds.

Unstable Correlations

Although many studies have shown that alphabet knowledge at entry to kindergarten is a strong predictor of later reading, the strength of the correlation declines when alphabet knowledge is assessed in late kindergarten or first grade. Longitudinal research also reveals declining correlations as the same children acquire knowledge about letter names and sounds. For example, McBride-Chang (1999) collected data on children's letter knowledge at four time points and correlated the data longitudinally with measures of word identification and phonological awareness. At time 1, letter knowledge had a mean of 12.4 ($SD = 8.8$). By time point 4, the variable lost 60% of its variance and had a mean of 24.5 ($SD = 3.4$), near ceiling on the task. The effects of ceiling performance on the correlations with other variables were consistent and dramatic. Correlations between letter knowledge and the Word Attack test decreased from $r = .54$ at time 1 to $r = .23$ at the final time point. Similarly, correlations between letter knowledge and phoneme elision decreased from $r = .51$ to $r = .18$. The same decreasing pattern was found for correlations between letter knowledge and every other predictor.

A similar pattern of variable correlations is evident in other longitudinal studies. Hecht, Burgess, Torgesen, Wagner, and Rashotte (2000) analyzed the effects of SES on children's early reading skills from kindergarten to fourth grade with a subset of the data used in previous research by Wagner et al. (1997). Among the 20 measures were three tasks used to assess print knowledge. Print Concepts included 13 items derived from

Clay's (1979) Concepts About Print task, Letter Names required children to name all 26 uppercase letters, and Letter Sounds required children to provide sounds for letters shown on cards. These tasks were given to 197 children in the beginning of kindergarten, and the data were correlated with other variables collected in the beginning of first, second, third, and fourth grades.

The canonical correlations of the three print knowledge tasks with the other 17 variables ranged from $r = .24$ to $r = .60$, all significant at levels similar to previous research. The researchers used a measurement model based on factor analyses and created a latent factor for Print Knowledge composed of an aggregate of the three tasks. This factor was highly correlated with other latent factors across years. For example, Print Knowledge was correlated with Reading Comprehension at grades 2, 3, and 4, respectively, with $r_s = .74$, $.60$, and $.53$. These are impressive correlations, but note the decline with age. Next, HLM procedures were used to determine the amount of variance that each factor accounted for in the longitudinal predictions. The authors found that Print Knowledge scores at kindergarten accounted for significant variance in reading comprehension scores at grade 2 (33%), grade 3 (16%), and grade 4 (9%), again a declining pattern. It should be noted that all other variables accounted for significant variance in reading comprehension across years, with a general decline with increasing grade level. However, the variance accounted for ranged only between 2% and 19%.

Reinterpreting Correlations with Alphabet Knowledge

Many researchers have described decreasing correlations between alphabet knowledge and reading achievement with increasing age (e.g., Adams, 1990; Johnston, Anderson, & Holligan, 1996; Muter & Diethelm, 2001; Muter, Hulme, Snowling, & Taylor, 1998). The developmental trajectory of alphabet knowledge may account for the decreasing correlations longitudinally. Consider several points about the shape of the curve that describes letter naming. First, the trajectory of letter naming from knowing a few letters to 100% accurate performance is relatively brief and rapid, perhaps a year or two, and this learning often occurs by 5-6 years of age. Second, the end point of the skill is the same for everyone: knowing the names of the 26 letters in the English alphabet. The universal intercept is a

critical feature of mastery learning that is 100% of alphabet knowledge (or close to it). Third, the shape of the developmental trajectory is not linear but sigmoidal (for individual data) because the period of rapid learning is brief and accelerated compared to longer periods of floor and ceiling performance on the skill. Consequently, correlations between developing knowledge of letter names and other variables will vary depending on the distribution of individual mastery and the location of data on the sigmoidal curve. When floor and ceiling effects are evident in the data, the skew will attenuate correlations, and only when the data fall mostly in the middle of the acquisition curve will the variance be large and approximate a normal distribution. Thus, the degree of correlation with an emerging skill like letter naming depends on the characteristics of the sample, their degree of knowledge, and the timing of the assessment.

Three problems are evident. The first is the special selection of children who do not exhibit floor or ceiling performance on assessments of alphabet knowledge. Researchers understand the need to avoid floor and ceiling effects in the data, so they are careful to assess alphabet knowledge in 5- to 6-year-olds who know some, but not all, letter names. Although common practice, this sampling technique leads to replicable patterns of correlations but only with children who know some of the alphabet. The observed strong correlations are entirely dependent on the relative skill mastery of the sample. The correlations are transitory and special cases, not enduring stable relations, between two variables. When the sample includes a large number of children with either little or great knowledge, the data reveal floor and ceiling effects. These minimize the variance in the measures and attenuate correlations with other variables. Actually, there is zero predictive power for reading comprehension (or any other variable) when there are ceiling effects in the data. Hecht et al. (2000) minimized the problem of ceiling effects by testing children at the beginning of kindergarten. Their data indicate mean scores on Print Concepts of 11.4 (maximum = 18; $SD = 4.1$), Letter Names of 21.2 (maximum = 26; $SD = 7.5$), and Letter Sounds of 10.4 (maximum = 36; $SD = 10.4$). It is clear that the researchers avoided ceiling effects and there was great variability among the children, but this variability does not reflect stable individual differences. Those two features underlie the positive correlations evident in their data. In contrast, McBride-Chang (1999) encoun-

tered ceiling effects in the sample that diminished the correlations longitudinally.

The second interpretive problem is the transitory nature of the purported relation between print knowledge and reading comprehension. The predictive power of letter naming and print knowledge is restricted to a period of approximately a year or less when children know about half of the alphabet, or at least score near the midpoints on the reading assessments. These are transitory and unstable relations, statistically as well as cognitively, and they yield significant relations only during a brief period of growth. Thus, had Ms. Jones tested Robert just 1 year earlier or later than October of first grade, the state assessment of letter knowledge would likely have revealed a floor or ceiling effect that would not predict later reading comprehension.

Walsh, Price, and Gillingham (1988) described the transitory relation problem as one of diminishing returns. They examined the longitudinal relations between letter-naming accuracy and letter-naming speed at kindergarten with reading development at grade 2 on a multilevel reading inventory and the Gates-MacGinitie Reading Test. Accuracy of letter naming improved from a mean of 67% correct at kindergarten to 100% correct at second grade. The correlation with later reading achievement was zero for the kindergarten data and meaningless for the second graders because of the ceiling effect. The researchers found that letter-naming speed was a significant predictor of reading development and comprehension at kindergarten but not grade 2. This interaction with grade suggests that letter naming has transitory importance. They hypothesized that there is a speed threshold for letter naming, and once the threshold is exceeded, there is little benefit of further increases in letter-naming speed. The diminishing returns hypothesis reflects (a) mastery of a skill (b) within a narrow age range and (c) nonlinear growth that reaches asymptotic levels so that (d) there is little variance left to relate to other variables. The diminishing returns and transitory effects hypotheses appear to describe the case for print concepts, letter naming, and letter-sound correspondence variables.

What is the problem with a transitory relation? First, the transitory qualification is rarely attached to interpretations of the relation between alphabet knowledge and subsequent reading achievement, so policymakers (and others) wrongfully infer that letter-sound or alphabet knowledge is correlated with reading achievement at all ages and skill levels. It has led to policies that em-

phasize the importance of letter naming and letter-sound knowledge first and foremost in early reading assessment and instruction. Second, experimental evidence can be marshaled to show that intervention in the early and intermediate phases of skill learning can accelerate learning letter names and sounds, and, sometimes but not always, it increases growth among other skills such as word recognition and comprehension. For example, Foorman, Fletcher, Francis, Schatschneider, and Metha (1998) suggested that explicit teaching of phonics is more effective for helping at-risk children develop phonemic awareness and phonics skills than embedded phonics and whole-language programs. However, no significant differences in comprehension were found among the groups.

The experimental evidence that alphabet knowledge can be enhanced through direct instruction, coupled with the erroneous inferences made from the correlations between enabling skills and reading comprehension, has led to claims that alphabet skills cause/promote/facilitate reading comprehension and achievement across ages and skill levels. This causal claim is seductive but unwarranted. At best, explicit teaching of phonics leads to better alphabet knowledge and word recognition, and that is usually confined to children who have the least developed alphabet skills. Better word recognition may enable reading comprehension for these children, but it is not the sufficient or causal link. The significant transitory relation focuses too much attention and time on assessment of alphabet skills. When the goals of assessment are focused on mastery of enabling skills, instructional goals become narrowed and the public standards of accountability are reduced to a basic and uninformative level. The age or time at which children know the names and sounds of 5, 10, or 20 letters is not as important as instructing them to mastery quickly and efficiently.

The third interpretive problem is that print knowledge variables are correlated with many other features of children and their development, so they may serve only as proxies for other relations. This is the problem of multicollinearity that confounds all multivariate longitudinal studies, but it is often overlooked in the interpretations of canonical correlations in reading research. For example, Hecht et al. (2000) noted that the effects of SES were severely attenuated by 30% to 50% when print knowledge scores were controlled. They concluded that, "most of the SES related variance in growth of reading skills was accounted for by beginning kindergarten lev-

els of print knowledge" (p. 119). These results led the authors to conclude:

A practical consequence of the present results is that measures of reading related abilities should be included in test batteries used to identify beginning kindergarten children, particularly those from lower social class backgrounds, at risk for later reading failure. . . . In addition, the results suggest that preschool and kindergarten interventions involving intensive training in print knowledge, phonological awareness, and/or rate of access skills may help reduce the incidence of later reading failure among children from lower SES families. (p. 122)

We think this is a misinterpretation of proxy variables as causal variables and that the prescription for instruction is unwarranted. In the Hecht et al. (2000) data, the researchers found that composite scores for SES and Print Knowledge were correlated at $r = .41$, and that when they controlled the effects of Print Knowledge on SES, the effects of SES were attenuated. This led them to conclude that kindergarten Print Knowledge mediated reading scores at grades 3 and 4. However, it is more plausible to interpret Print Knowledge scores at kindergarten as measures of other factors (perhaps related to SES) such as parental assistance and involvement in helping their children learn to read. Those kindergarten children who scored high on Print Concepts, Letter Names, and Letter Sounds were most likely to have had more social supports and opportunities for reading, learning, and education than those kindergarten children who scored lower on these tasks. That should be expected by the strong correlation with SES and might be evident if other data were available, such as preschool experiences, parental education levels, parental time spent with children, or quality of children's literacy materials in the home. Therefore, knowing letter names in kindergarten is probably *not* the mediator of reading comprehension at grades 3 and 4. Instead, home environment, SES, and other enduring variables associated with parent-child interactions probably account for better comprehension in later grades, especially if those same factors continued to be influential several years later. Thus, interventions with parents in the home, not teaching letter names in isolation, are the route to fostering successful readers.

Simplistic interpretations of correlations are easy to recognize, but the relations can be obscured in sophisticated statistical analyses. For example, researchers can aggregate data from different tasks to minimize floor and ceiling effects. The Hecht et al. (2000) data have highly

skewed data for Letter Names that are aggregated with less skewed data on Print Concepts and Letter Sounds. When composite scores are created based on factor analyses or HLM or item response theory, the result may be an artificially normalized distribution that is more influenced by scores on one measure than another. For example, composite scores might disguise floor and ceiling effects on some skills or suggest inappropriately that all subskills are important in the composite score. This problem is exacerbated when researchers aggregate data from highly constrained and less constrained variables.

The problem is also evident when data are transformed to normalize the distributions, when the sample size is so large that it includes many subjects with floor and ceiling effects, and when the skewed data are blocked to create categorical data. For example, the Early Childhood Longitudinal Study—Kindergarten Class of 1998–99 confounds early reading measures with these practices, and the aggregated variables obscure developmental differences among the component knowledge and skills (U.S. Department of Education, 2000). These problems are rarely acknowledged in aggregated data, and alternative explanations based on developmental proxies are rarely offered. It is clear that lack of knowledge about letter names and sounds impedes reading temporarily, but learning letter names and sounds is necessary but not sufficient for successful reading. It is more likely that the enduring effects of SES and early literacy experiences are signaled by poor alphabet knowledge in kindergarten, and if they persist, they are obstacles to successful reading.

Learning the letter names and sounds, and practicing them until fluency is achieved, occurs faster for some children than others. Those who acquire the knowledge sooner are likely to be better readers a year or two later, but this relation must be interpreted cautiously. It is paradoxical that (a) the strong correlations between alphabet knowledge and later reading achievement are only evident when alphabet knowledge is measured early in kindergarten, when the differences due to preschool experiences are greatest; (b) directly teaching letter names does not improve reading skill; and (c) all children learn the names of the letters eventually, so letter-naming knowledge is not an enduring individual difference nor a stable predictor of reading achievement.

The developmental trajectory for letter naming provides a clear example of the onset, rate, and intercept of a skill that is relatively small in scope and mastered completely and universally. The trajectory for letter-sound knowledge may be parallel to letter naming, but it

may have a later onset, a longer period and rate of learning, and a less identical intercept because of the greater number and complexity of letter sounds to master. The developmental trajectories are constrained, but not to the same degree. These constraints involve the set size of knowledge, the universal mastery of the set so that intercepts of learning are identical for everyone, and the consequent effects on the distributions of data. Only in samples that exhibit partial mastery does the distribution of data exhibit wide variance and approach normality. Except for these special cases, the data are never normally distributed empirically or conceptually. The same constraints apply to learning to read in languages other than English, but the number of letters or symbols in any language will determine the set to master and influence the rate of learning.

It is worth noting that some researchers have recognized the potential problems with some component reading skills like alphabet knowledge that are mastered quickly and completely (Adams, 1990; Stanovich, 2000), but no one has provided a coherent account of the connections between different developmental trajectories, statistical analyses, and interpretations of the data. Ironically, Adams et al. (1998) identified similar problems for hypotheses about the importance of variables *other than* letter knowledge and phonemic awareness. In their review of Scarborough and Dobrich's (1994) research on parenting variables, they noted that some variables were nonlinear, some may have thresholds of influence, and some are proxies for other accomplishments: "What is at issue here is not merely the precision, but the very appropriateness of the linear statistical models on which the field so strongly relies" (Adams et al., 1998, p. 211). We think the same statement applies to variables derived from assessments of letter knowledge and phonemic awareness.

ASSESSMENTS OF OTHER EARLY READING SKILLS

There are many skills that precede and accompany early reading so the sequence and relations among them are difficult to identify. We describe three types of skills that are frequently assessed, and we show how each might be constrained developmentally.

Concepts about Print

Other assessments of early reading knowledge and skills may exhibit trajectories that are similar to letter naming.

Print knowledge or concepts about print refers to a small set of knowledge that is learned by beginning readers. For example, Clay (1972) presented a little book to 5-year-olds and asked them to indicate the front of the book, the direction of reading, errors in inverted text, and the function of punctuation marks. The 24 items included a variety of concepts about both functions and conventions of print. Rathvon (2004) summarized the seven typical concepts included in assessments of print knowledge as book orientation; meaning conveyed by print versus pictures; print directionality; voice-word matching; boundaries between letters, words, and sentences; order of letters and words; and punctuation marks. Clay (1979) included concepts about print in a battery of early reading assessments called the Observation Survey, and she cautioned against the use of the assessment as a stand-alone instrument to signal reading readiness or progress. Nonetheless, it has been appropriated and abbreviated as a research tool and is an isolated skill assessment in the PALS, TPRI, MLPP, and other assessments. Assessments vary widely in the number of concepts tested from as few as 4 to 5 to as many as 24, and the concepts vary in difficulty. Most 5-year-olds can identify the front of the book and the left-right direction of reading, but punctuation marks may confuse even 7-year-olds. Thus, the relative difficulty of an assessment depends on the number of items and the difficulty of the assessed concepts.

Concepts about print, like letter naming, is a small set of knowledge that is universally mastered by children, and the same kinds of constraints operate empirically and theoretically. Data from around the world reveal that children learning English understand only a few of the basic concepts about print before age 5, but they understand most, except for punctuation marks, by age 6 (cf. Clay, 1979). The period of acquisition is rapid and reaches the same asymptote for all children, so the variance in any group is small before age 5 and after age 7. Thus, it is only during the period of rapid learning that variance is large and approaches a normal distribution, which is, not by coincidence, the age at which concepts about print are usually assessed and described as the most diagnostic. Several problems are revealed by the developmental trajectory and common asymptote.

First, concepts about print is an assessment of specific rules and conventions that are acquired with reading expertise. All skilled readers of a language learn the same concepts. They are not emergent, universal developmental concepts like conservation in the Piagetian sense; they are language-specific rules that depend on didactic experiences more than maturation. Thus, they

can be taught directly. Second, the knowledge set is small and can be learned relatively quickly given a rich literacy environment and contextualized instruction such as shared reading. Third, the calculation of norms for mastery seems inappropriate because it implies that the knowledge is normally distributed when it is not. For example, Clay (1979) presents normalized scores in stanine groups that show how many concepts are mastered by samples of children. The technical manual of the ISEL also provides age norms. Although there is value in providing norm-referenced rates of acquisition, it is important to note that nearly all children master all the concepts about print by 7 to 8 years of age, so the critical difference among children is in their rate of mastery, not their final knowledge. Norms, therefore, reveal only averages for a particular group, and those norms may vary widely by country, community, and SES.

The characteristics of children's concepts about print can shed light on empirical findings. Rathvon's (2004) review indicates that assessments of children's print awareness may be correlated with other measures of early reading, but they have little predictive power when measures of letter naming and phonemic awareness are included in the regressions. This may be due to the multicollinearity of the variables. Letter naming and phonemic awareness usually are taught at about the same age as print awareness skills, and they emerge from the same kinds of shared reading experiences, so the intercorrelations of the three variables remove their unique variance. Lonigan et al. (2000) suggested that print awareness serves as a proxy measure for print exposure and literacy experiences. This means that children who score high on assessments of concepts about print are ahead of their age-mates, but their superior print awareness is temporary and an indicator only of different previous literacy experiences and not of stable individual differences. A second reason for the lack of predictive power could be the lack of relation between simple concepts about print and more complex decoding and comprehension skills. Thus, print knowledge is easy to assess, and it leads to diagnoses of specific weaknesses, but it does not predict future reading achievement and may be unrelated to other cognitive skills required for proficient reading. Given these problems, concepts about print may have value only for guiding instruction in the first year or two of schooling.

A caveat needs to be added about children's concepts of words, however, because the ability to identify an orthographic unit as a word involves more than a simple concept. When children can point their finger to a

spoken word, they understand boundaries between letters and words as well as some resemblance between letters and sounds. They can even use comprehension and rhythm to identify which word goes with what spoken sounds. Thus, the line is blurred between understanding an entity called a word and the ability to match graphemes and phonemes. Some researchers suggest that understanding the concept of a word facilitates phonemic segmentation (Morris, 1992), whereas other researchers suggest that phonemic segmentation facilitates word recognition. They are intercorrelated, so the direction of influence is difficult to specify. Indeed, both components could be influenced by some other factor.

Orthographic Processing

Children's orthographic processing includes their awareness and processing of printed literacy symbols. Understanding of orthography includes knowing upper- and lowercase letters, print and cursive writing, and the meanings of symbols, numerals, and punctuation marks. The skills are intertwined with developing concepts about print and words as well as phonological awareness. Orthographic processing allows readers to construct visual representations of written symbols and is critical for spelling development (Share & Stanovich, 1995). However, there is some controversy over the construct validity of orthographic processing. Vellutino, Scanlon, and Chen (1994) claim that many tasks assess spelling and word identification skills rather than visual representation of print. Cunningham, Perry, and Stanovich (2001) compared six measures of orthographic processing and found variable correlations among them rather than good convergence. Three points seem clear. First, the set of knowledge required for orthographic processing is finite and relatively small. Second, skilled readers all master the same kinds of knowledge, so the developmental trajectory should proceed from floor to ceiling effects like letter naming. Third, assessments of orthographic processing may reflect several different component skills that contribute differently to performance with increasing age.

Orthographic processing is not assessed routinely, perhaps because many of the assessments require individual administration via computers of the stimuli and recording of reaction times. There are also few norms available for interpreting the data, and the tasks are susceptible to guessing. For example, one common assess-

ment method is to ask children to choose the word from two choices that sound alike, such as "nail and nale." Another method, the homophone choice task, asks children to choose one word, such as "Which is a number—ate or eight?" Despite these problems, there is evidence that orthographic processing differences may help identify different types of dyslexia (Castles & Coltheart, 1993).

Orthographic processing emerges later than alphabet knowledge and concurrently with beginning word identification, but the developmental trajectory of orthographic processing is difficult to identify because it depends on the specific method used to assess it. Orthographic processing is confounded with other variables such as spelling, phonological awareness, and print exposure, although orthographic processing appears to contribute some unique variance to reading achievement beyond these skills (Cunningham & Stanovich, 1990). It is clear, however, that orthographic processing becomes more important with age because the correlations between orthographic skills and reading achievement are stronger among older children (Badian, 1995; Juel, Griffith, & Gough, 1986).

Orthographic processing is necessary for identifying words and reading proficiently, but it is difficult to isolate and assess. First, the set of knowledge of letter patterns is large, so the relative difficulty of an assessment depends on the stimuli that are chosen. For example, distinguishing homophones based on "ai" versus long "a" sounds is easier than discriminating irregular "ough" sounds. On the one hand, there are a small number of high-frequency patterns of letters that need to be mastered by beginning readers, and as they are learned, the patterns may promote phonological awareness, spelling, and related skills (and vice versa). Performance on those patterns may be poor among 5-year-olds and very high among 7-year-olds, so the trajectories may be constrained, as in alphabet knowledge. On the other hand, more complex orthographic discriminations may be difficult for older readers, so the level of skill does not reach ceiling, the period of acquisition is protracted, and the rate of learning may be slower. Thus, the trajectories of learning depend on the particular task and stimuli. Second, measures of orthographic processing may be confounded by individual differences in response speed, print exposure, guessing, and phonological awareness that contribute variance in addition to orthographic processing skills (Swanson & Alexander, 1997). Thus, the resulting measures may be normally distributed because of these

confounds rather than in the normal distribution of underlying orthographic skills.

Phonological Processing

Understanding the sounds of oral and written language includes (a) phonological awareness, (b) phonological memory, and (c) phonological naming, usually assessed as the speed of naming sounds. These important processes begin to develop before exposure to print and continue to develop concurrently with alphabet knowledge, orthographic skills, and other components of reading. Stanovich (1991, p. 78) wrote, “The specification of the role of phonological processing in the earliest stages of reading acquisition is one of the more notable scientific success stories of the last decade.” Phonological processes have been hypothesized to facilitate and perhaps even to cause reading development. Children who exhibit reading disabilities and dyslexia often have deficits in phonological processing (Share & Stanovich, 1995).

The conscious perception and manipulation of the sounds of spoken words, including phonemes, rimes, and words, is referred to as phonological awareness. It has been one of the most frequently studied reading skills during the past 25 years, and it is one of the five essential components of early reading identified by the National Reading Panel (2000). Phonological awareness is usually assessed with tasks based on rhyming, segmenting, and blending distinct phonemes, and it is a core feature of the TPRI, PALS, MLPP, and ISEL. In general, children understand rhyming first, followed by segmenting and then blending phonemes. Abundant research has shown that children’s phonological awareness and reading achievement are strongly related (Adams et al., 1998), but there is controversy about the causal role it might play in reading development. In an extensive review of research on phonological awareness, Castles and Coltheart (2004) found no definitive evidence, from either longitudinal studies or training studies, that phonological awareness precedes and causes reading and spelling development. Instead, they suggest that rather than one causing the other, it is possible that “once children acquire reading and spelling skills, they change *the way in which they perform phonological awareness tasks*, using their orthographic skills, either in addition to or instead of their phonological skills, to arrive at a solution” (p. 102). This interpretation suggests that the skills are highly related and that the correlation between

phonological awareness and reading development is mediated by orthographic skills.

The controversy about the causal role of phonological awareness pivots on two types of evidence: predictive validity and training studies. Consider correlations used to establish predictive validity. The landmark longitudinal study by Bradley and Bryant (1983) claimed a causal relation between phonological awareness and subsequent reading achievement. These researchers tested understanding of rhyme and alliteration among 4- and 5-year-olds (who could not read) with oddity tasks as the measure of phonological awareness. For example, children were asked to choose which word did not fit in a group (i.e., was the odd or different word) among “pin, win, sit, fin.” The remarkable finding was that performance on the phonological awareness tasks predicted reading and spelling achievement 3 years later, even after controlling for the effects of memory and IQ. Many influential reports have reported similar strong correlations that imply a causal role of phonological awareness (Adams, 1990; National Reading Panel, 2000; Snow et al., 1998).

Other researchers, though, have not found strong correlations between rhyme awareness and reading achievement (Hulme et al., 2002; Stuart, 1995). Rathvon (2004) suggests that rhyming tasks administered at kindergarten are poor predictors compared to phonemic awareness measures because of ceiling effects. Castles and Coltheart (2004) suggest that rhyming tasks like the oddity tasks may be answered correctly by noticing the different ending sounds, thus confounding phonemic awareness with rhyming awareness. They also note that the reliability of oddity tasks is low, and conclude that “there is not a strong case to be made for rhyme awareness being a significant independent predictor of reading and spelling acquisition” (p. 90).

These findings can be explained by examining the developmental trajectory of rhyme awareness, and the explanation applies to other measures of phonological awareness. First, rhyme awareness refers to a potentially large set of sounds, but in practice, most assessments focus on a small set of prototypical relations that are relatively unknown by 4-year-olds but mastered by 6-year-olds. The tasks used to assess rhyme awareness are not only confounded with emerging phonemic awareness, they reveal skewed distributions in some samples and are only normally distributed as special cases of selected subjects who score in the midrange of the task. Thus, the difficulty of the task and the distribution of

scores depend on the items included in the test. Second, the strength of the correlations used to establish predictive validity will depend on the relative mastery of the sample and will be diminished for children who score near the floor or ceiling on the tasks. For example, Willson and Rupley (1997) found that phonemic awareness strongly predicted comprehension in lower grades, but by third grade, background knowledge and strategy knowledge were more important. Third, reliability may be low because rhyming is learned rapidly, perhaps even in the testing situation, so children's scores should be expected to improve with retesting. Fourth, it is difficult to assess rhyme awareness in isolation because it is developing concurrently with other phonological and orthographic skills, so regression techniques that partial out variance or compare residual variance are confounded by multicollinearity.

All of these problems mean that the specific items on the assessment and the relative degree of phonological awareness among the specific children tested will determine the shape of the distributions, the degree of skew, and the strength of correlations among variables. The issue is not sampling a random and representative set of items and subjects, because all items are not equally difficult and not all children display normally distributed skills. Thus, the actual construct being assessed, rhyming or phonological awareness, is not an independent and normally distributed component of reading. It can be conceptualized better as a set of knowledge that is gradually mastered and used so the degree of mastery can be assessed and the proficiency or accuracy of use can be determined as both approach asymptotes of 100%. Norms can be calculated for both mastery and use, but it is important to recognize that the norms can vary widely depending on print exposure, joint book experiences, and direct instruction, so the norms may assess features of the literate environments more than individual abilities.

Now let us consider the evidence for the causal role of phonological awareness derived from training studies. Bus and van Ijzendoorn (1999) conducted a meta-analysis of phonological awareness studies and found that training significantly improved phonological awareness and reading (as measured by word identification and word attack skills). The overall correlations were $r = .33$ for phonological awareness and $r = .34$ for reading, so phonological training accounted for about 12% of the variance in the outcomes. Both outcome measures closely resembled the training; the average

length of training was 8 months for phonological awareness outcomes and 18 months for outcomes based on reading letters and words. Bus and van Ijzendoorn concluded, "The training studies settle the issue of the causal role of phonological awareness in learning to read: Phonological training reliably enhances phonological and reading skills" (p. 411).

This conclusion may be inflated, though, given that the set of training studies included training on letter-sound relations and more components than phonological awareness. The training was more effective for preschoolers than kindergarten or primary grade children; short-term effects were larger than long-term effects; and children with reading disabilities did not benefit more than regular children. The authors noted that ceiling effects and normal development of phonological awareness may underlie the diminished impact of training on older children. Training phonological awareness seems to benefit those who exhibit the least knowledge, and the benefits are greater if the treatment includes sustained training on multiple components of alphabet knowledge, phonological skills, and orthographic skills. Nonetheless, Bus and van Ijzendoorn (1999, p. 413) caution that phonological awareness accounted for only 12% of the variance and conclude that it is "an important but not sufficient condition for learning to read."

Castles and Coltheart (2004) examined the causal role of phonological awareness with more rigorous criteria. They reviewed studies that (a) trained only phonological awareness, (b) showed facilitation of reading-related processes beyond the target phonological skill, (c) showed positive transfer only to reading-related skills, and (d) showed improvement specifically on phonological awareness for children who had no pre-existing reading or spelling skills that may have been improved by training. Few studies met these stringent criteria. Castles and Coltheart concluded that "no single study has conclusively established that phonemic awareness training assists reading or spelling acquisition" (p. 101). Their review highlights a number of findings that can be explained by analyzing the developing trajectories of the skills. First, many different types of phonological skills have been trained, and they vary widely. Some, such as rhyming and initial consonant sounds, are learned early; other skills, such as phonemic segmentation and blending, are learned later. Training skills that are beginning to emerge leads to more gains than training skills that are nonexistent or already

mostly learned. Said differently, training in the zone of proximal development leads to the largest improvements, so it is the fit of training to the level of learning that determines the effectiveness of the treatment. If training phonological awareness has only temporary benefits and only for children who have little phonological awareness, then the influence on subsequent reading achievement may be modest.

Second, multicollinearity of phonological skills makes it difficult to train one isolated phonological skill without also providing information and experience on related skills. For example, training children to recognize onset-rime patterns, such as “c—at,” also provides information on letter naming, letter-sound correspondence, and orthographic features. Castles and Coltheart (2004) point out that the window of time for independent skills to develop may be small. Furthermore, emerging interdependencies among skills, such as knowing specific letter-sound relations, may predict specific spelling and reading achievements better than general phonological awareness measures. This means that the sequential facilitation of skills may be specific to letters, syllables, and phonemes, so general assessments of different phonological skills may obscure the developing relations. Third, training can provide diffuse benefits to related skills. Even though the training conditions may be described as focused, they can provide practice and feedback on related skills. Some studies did not measure transfer to other reading and nonreading skills, so the specificity of effects cannot be determined, much less the Hawthorne effects due to the training. Fourth, training may be most effective when it links different skills, such as phonological and orthographic skills (Hatcher, Hulme, Ellis, 1994), or when training includes explicit metacognitive instruction about the skills (Cunningham, 1990).

In conclusion, studies of phonological awareness have shown that children acquire a variety of related skills as they learn to read, and it is difficult to isolate, assess, or train any component skill. Indeed, phonological awareness may be mediated by, or develop concurrently with, orthographic skills. This makes it difficult to identify a direct causal relation between phonological awareness and reading development. The two findings that provide the strongest foundation for the importance of phonological awareness are evidence that struggling readers perform poorly on tasks assessing phonological awareness, and that training, even on multiple or confounded phonological skills, improves the target skill. Thus,

phonological skills may provide a necessary but not sufficient condition for subsequent reading achievement.

CONSTRAINTS ON READING SKILLS

For descriptive convenience, the constraints that influence analyses of reading development can be grouped into three categories: conceptual, developmental, and methodological. The type and degree of constraints can vary widely among reading skills. In general, letter knowledge, phonics, and concepts about print are highly constrained; phonemic awareness and oral reading fluency are less constrained; and vocabulary and comprehension are least constrained. The polarized ends of the continuum exemplify the differences between constrained and unconstrained skills most clearly, but even subtle constraints hinder analyses of reading skills.

Conceptual Constraints

Reading skills, like other psychological constructs, are defined and operationalized to establish consistent measurement and interpretation of the constructs. The validity of the construct is evaluated by reference to its definitions and measures. One fundamental constraint of a construct is the *scope*, defined by its domain, number of elements, or set size. For example, learning the names and sounds of the 26 letters in the English alphabet are two clear examples. Skills with narrow scope are learned quickly, so the trajectory of mastery is steep and the duration of acquisition is brief. The same is true of basic concepts about print (Clay, 1979); they are conceptually constrained by the relatively small number of concepts to be acquired.

The second conceptual constraint on early reading skills and concepts is *importance*, as measured by centrality or typicality of exemplars. Most assessments of children’s understanding of early print concepts pertain to a small set of central and important features of text that beginning readers need to understand. Therefore, early assessments use prototypical stimuli that are mastered by all skilled readers and thus can exhibit ceiling effects. Infrequent letter sounds, for example, “x”, and esoteric concepts about print, such as single quotation marks, may be in the conceptual scope of a skill, but they are rarely included in assessments of early reading because they are less important for learning to read than mastery of other skills and concepts. A third type of

conceptual constraint among reading skills is the *range of influence*, both the domain and temporal range. The concomitant skills influenced by learning the alphabet and concepts about print are tied directly to decoding grapheme-phoneme relations. In contrast, vocabulary development influences (and is influenced by) linguistic, cognitive, and communicative proficiency in wide-ranging ways. Not only is the range of influence less among highly constrained skills, but the temporal range of influence is restricted in constrained skills to that period when rapid acquisition is occurring. Thus, constrained skills such as alphabet knowledge are most related to decoding in early childhood, whereas unconstrained skills such as vocabulary are related to a wide range of academic skills throughout life.

Scope, importance, and range of influence are also evident in constructs involving phonological awareness, although each is broader than alphabet knowledge and their acquisition takes longer. Most early reading assessments include tasks of phoneme identification, segmentation, blending, and rhyming, but the phonemes that are used in the tests are usually important and prototypical. They are based on phonemes and words that have a high frequency of occurrence in oral language and text, they are usually familiar, and they have a wide range of application. Thus, words such as “cat” and “sit” are frequent in early assessments of phonological awareness because the onset-rime patterns are central prototypes for young children. Because most assessments of phonological awareness are limited to a small number of rules that are assessed with central exemplars, they can be considered constrained skills (e.g., Adams & Treadway, 2000; TPRI, 2002). Although there are many distinct phonological rules, and the set size is greater than 26, it is the constrained scope, importance, and range of influence of these rules that enable 7- to 8-year-old children to learn the essential features of phonological awareness and to decode nearly all words they encounter in beginning texts.

Phonological processing is more complicated than phonological awareness because constrained and unconstrained skills may operate together. Thus, assessments of phonological processing may confound constrained and unconstrained skills. For example, the Comprehensive Test of Phonological Processing (CTOPP) by Wagner, Torgesen, and Rashotte (1999) is based on the interactions among three correlated skills: phonological awareness, phonological memory, and rapid naming that, according to the authors, become less correlated

with development. The constrained skills view provides a useful framework for understanding the CTOPP because phonological memory and rapid naming are both individual difference variables between children that endure over time, whereas phonological awareness is a constrained skill that varies within and between individuals during a period of mastery only. After mastery is achieved, phonological awareness carries little variance compared to phonological memory and rapid naming, so the correlations among the dependent skills must decrease for statistical reasons alone. What remains are individual differences in basic information-processing functions of memory and rapid naming, not skills specific to reading.

The CTOPP includes 13 subtests, 7 for children ages 5 to 6 years and 10 for people 7 to 24 years old. The older subjects actually receive all of the same subtests as the younger sample except Sound Matching, presumably because it is mastered by age 7 years, plus four more difficult subtests, blending and segmenting nonwords and rapid naming of colors and objects. The subtest scores are used to create three composite scores for Phonological Awareness, Phonological Memory, and Rapid Naming that are used to establish normative ages for performance. The composite scores are also used as correlates to establish concurrent and predictive validity. The CTOPP combines very different skills in the composite measures that confound developmental and methodological constraints; thus, the interpretations of the data may have less to do with phonological awareness than individual differences in processing speed and memory.

Examination of Table C.1 in the CTOPP manual reveals wide variation in the developmental growth rates of the performance on the subtests between ages 5 and 15. For example, Sound Matching is at 100% by 8 years 3 months; Blending Words is at 87% mastery by age 8 to 9 years; Blending Nonwords is at 80% mastery by the same age; and Phoneme Reversal is at 70% mastery by age 9 years. Floor effects are evident for Segmenting Words because all children who segment fewer than nine words receive the same low score. Growth from 0 to 9 on that scale is from ages 5-0 to 7-9 years, and increases in segmenting words only advance from a raw score of 9 to 12 between ages 7-9 and 14-9 years. Clearly, growth on the subtests is not linear or uniform; ceiling and floor effects are evident in individual subtests, so composite scores derived from the subtests reflect proficiency (or lack of it) for different skills at different ages. Consider

Memory for Digits. The scale of raw scores is from 0 to 14 between ages 5-0 and 14-9 years, but the conversions to age equivalents show that 0 to 10 scores are all expected before age 6 years, with growth during the next 9 years limited to increases of four items. Failure to consider nonlinear growth, the constraints on various skills, and different developmental trajectories of the skills undermines the construct validity of the composite scores in the CTOPP.

Details about CTOPP are presented here to provide a specific example of the differences in developmental trajectories and the asymptotes reached in assessment instruments. Similar criticisms can be directed to other early reading assessments, including the Dynamic Indicators of Basic Literacy Skills (DIBELS), the TPRI, and the PALS, because they include assessments of constrained skills such as letter knowledge, concepts about print, and phonemic awareness. It is worth noting that these early skill assessments typically report Pearson correlations to show the relations with other reading tests to establish concurrent and predictive validity. However, the psychometric data are necessarily skewed from novice to expert status, and those variable distributions influence the correlations. That is why reconsideration of the differences among skills is important.

Developmental Constraints

There are four important constraints on the developmental trajectories of reading skills. The first constraint is *unequal learning* because some letters, concepts, and phonemes are learned more quickly and thoroughly than others. They are fixed effects with heterogeneous variance that result in nonlinear learning among elements. For example, the letters x and q are learned later and more slowly than the letters m and s, and phoneme rhyming is generally easier with consonant-vowel-consonant words than more complex patterns. Unequal learning of exemplars of concepts or instances of rules becomes a problem when skills such as alphabet knowledge and phonemic awareness are treated as uniform skills, especially in assessments that presume random sampling of equivalent elements.

A second developmental constraint is *duration of learning*. Some reading skills, such as learning the alphabet, are mastered in a few years, whereas other skills, such as vocabulary, are not. Whether the learning occurs during childhood or during adulthood does not change the fact that the degree of learning is more rapid

and more complete for some skills. These temporal constraints are not evident in unconstrained skills that continue to develop over the life course. Mastered skills must exhibit floor and ceiling effects in the longitudinal course of acquisition because constrained skills develop from nonexistent to fully acquired to automatic. Granted that some reading skills may not be mastered perfectly or completely, they approach an individual growth asymptote as acquisition slows or a ceiling is attained. Reading rate, for example, becomes more stable for each individual by middle school, yet reading rates vary widely between people.

The third developmental constraint is *universal mastery*. Some reading skills and concepts reveal mastery of identical information among people. All skilled readers of English know the 26 letters of the alphabet and the phonemes associated with them. Likewise, all competent readers know the identical (or nearly so) concepts about print and understand phonemic rhyming, segmentation, and blending in the same manner. On assessments of these reading skills, they would have the identical y-intercepts or asymptotes. This is a critical feature of constrained skills because it results in zero (or at least minimal) variance between individuals when the constrained skill is at asymptotic levels. Contrast a universal constraint with less constrained variables such as growth in height or vocabulary. Both may reach asymptote in adulthood, or at least exhibit slower rates of change, but the asymptotes are different across individuals and the differences in the y-intercepts are normally distributed. This is not the case for universally mastered skills that attain the identical intercepts and have no enduring individual differences. Thus, the differences during acquisition of universally mastered skills (in terms of onset, rate, or duration) are minor compared to the similarity over most of the life span. Unconstrained skills continue to develop over time and may reveal enduring differences between individuals over the life span. This is a crucial distinction that has implications for the kinds of statistical analyses and interpretations that are appropriate with each kind of skill.

The analysis of developmental trajectories is more complicated because the sigmoid growth curves of various skills can vary widely in age of onset and duration of growth. Consider the subtests in the CTOPP. The normative data reveal that Sound Matching, Blending Words, and Phoneme Reversal are acquired rapidly by 7 to 8 years of age, whereas Segmenting Nonwords and Elision are mastered more slowly. When they are combined in

composite scores by statistical techniques, the fundamental differences among different growth curves are obscured. The data may have improved normality of dependent variables but at an undisclosed cost of reduced validity. Evidently, designers of the Woodcock-Johnson reading test recognized the problem with a low ceiling on letter naming, so they created composite scores of letter naming and word identification. Creating composite scores to skirt skewed data solves the normality problem but confounds what is being measured.

There are many studies that illustrate how mastery of constrained skills may confound data analyses and interpretation. For example, Morris et al. (2003) report a longitudinal study of the relations among reading skills in children during kindergarten and first grade. They used a LISREL model to test the relations among emerging skills, but they failed to consider the conceptual and methodological constraints in their data. For example, Table 2.3 in their report shows clearly that children's alphabet knowledge and beginning consonant awareness were at ceiling levels at Times 2, 3, and 4 in their study, and measures of children's word recognition and phoneme segmentation were at floor levels for Times 1, 2, and 3. Nevertheless, they used traditional statistical analyses that assume normally distributed measures. From their longitudinal analyses, they concluded that the developmental sequence of acquisition for seven reading skills is as follows: alphabet knowledge, beginning consonant awareness, concept of word in text, spelling with beginning and ending consonants, phoneme segmentation, word recognition, and contextual reading ability.

The last two skills are unconstrained and would be predicted to develop longer and slower than the other five constrained skills. It is possible to predict the order of acquisition based only on the size of successively increasing knowledge sets within each skill and greater constraints in measurement among the early emerging skills. The authors argue that concepts about words (i.e., finger pointing to words as the story is read) are important precursors to phonemic awareness and should be emphasized in instruction. This may be true only in the trivial sense that concepts about words is a smaller set of knowledge that is learned more rapidly than phonemic awareness, and it is a necessary but not sufficient condition for other skills to emerge. Although the empirical identification of patterns of emerging developmental skills is important, the interpretations would be

more accurate and complete if the conceptual distinctions among developing skills were considered.

A fourth developmental constraint on reading skills is *codependency*. Some precursors might be necessary for a skill to be acquired, so it is constrained by its relation to other skills. For example, there are many skills involved in language reception, discrimination, and production that underlie emerging literacy skills. These skills may be necessary prerequisites for literacy development. Specifically, phoneme identification of consonants precedes identification of vowels and may be a necessary precursor to segmentation and blending skills. In general, comprehension of text depends on decoding the words; decoding is a necessary but not sufficient condition for understanding text. Many constrained reading skills are dependent on cognitive and linguistic development and are acquired during childhood about the same time. The parallel and simultaneous development of language and literacy skills leads to multicollinearity of these variables in research studies and makes it especially difficult to separate the relations among the skills during periods of rapid development. The codependency also may invalidate correlational analyses.

Researchers have analyzed reading skills as if they are independent, when many are required as precursors or enabling skills for others (e.g., Fuchs, Fuchs, Hosp, & Jenkins, 2001). Thus, there is a positive correlation during acquisition between codependent skills that is logically necessary during acquisition, but the relation will disappear when both skills are fully mastered and there is minimal variance in either one. This pattern of transitory relations and later lack of relations between skills is a consequence of the developmentally codependent constraints on the skills. The constrained skills view explains the transitory correlation patterns as logical, conceptual, and empirical consequences of children's mastery of constrained skills that are developmental precursors and enablers of other skills.

It is important to note that the codependency may be asymmetrical when one skill enables another. Thus, the lack of skill A may be correlated with the lack of skill B, if B depends on A, but the proficiency of skill A does not imply that skill B is also proficient (if A is a necessary but not sufficient condition for skill B). This asymmetrical relation is evident among novice readers when the lack of oral reading fluency is correlated with the lack of comprehension, but fluency is not necessarily

correlated with comprehension among skilled readers (S. Paris, Carpenter, A. Paris, & Hamilton, 2005). In more general terms, this means that emerging or novice skills may display codependent relations with other reading skills, as well as greater variance than the same subjects with highly proficient skills. Thus, positive correlations are evident only among partially developed skills and not evident at all among mastered skills. One implication of this asymmetrical relation is that positive correlations might be observed only for novice skill users, struggling readers, or readers with skill deficits because the lack of alphabet knowledge and phonemic awareness is correlated with the lack of effective word recognition, fluency, and comprehension. Consequently, models of reading skills built only on struggling readers with poor skills may overemphasize asymmetrical relations between the lack of codependent skills. The positive correlations between poor basic skills and poor reading achievement are exactly what is expected if the basic skills are necessary but not sufficient for proficient reading development. Thus, a general implication for reading theories and practices is that deficit models of unskilled reading may provide an incomplete and inaccurate characterization of the developmental relations among reading skills for older readers who have mastered basic skills.

Methodological Constraints

Some constraints result from methods used to gather data. Mundane examples of measurement constraints include rubrics with narrow ranges and unreliable interrater agreement and assessment tasks that are too easy or difficult so the data are skewed empirically but not necessarily conceptually. Codependency between skills provides a more compelling example of methodological constraints because the use of one skill may depend on a minimum or critical level of another skill. Consider two examples of reading skill “thresholds”: oral reading accuracy and oral reading rate. Both are constrained skills, yet they have been treated as unconstrained variables in traditional research. Accuracy is constrained conceptually because skilled reading is not distributed around a midpoint of 50% accurate word identification. Indeed, 100% accuracy is the goal and preferred skill level, so the measure is constrained conceptually. Accuracy is also constrained as a research variable because educators and researchers consider a level of 95% accu-

rate word identification to be essential for comprehending text (Lipson & Wixson, 2003). This means that accuracy sets a threshold for comprehension and is a highly skewed skill with limited variance when compared to other reading skills.

Reading rate is constrained by speed of speech production and automatic word recognition, but in practice is less constrained than accuracy. Most children read aloud at similar rates as they learn to decode words, and few read fewer than 40 to 50 words correct per minute (wcpm). The midrange of oral reading rate for first graders in the fall is about 53 wcpm, whereas fifth graders at the 50th percentile in the fall read about 105 wcpm (Hasbrouck & Tindal, 1982). At each successive grade level, children read on average about 13 more words per minute. Thus, the range of reading rate is constrained within and between grades by a modest range of growth each year. By middle school, children’s reading rate approaches adult asymptotes, about 150 to 200 wpm. Reading very slowly or very quickly may degrade comprehension, so oral reading rate is constrained by speech rate, expertise, and attempts to understand text while decoding print. Certainly, the complexity of text, the familiarity of vocabulary, the audience, and the purpose for reading also influence rate of reading. The thresholds for reading accuracy and rate increase with age and instruction, but reading accuracy, and rate to a lesser degree, are constrained skills conceptually, developmentally, and empirically.

Correlations between fluency and comprehension for highly accurate oral readers have little variance to begin with (in the data), so modest correlations are the most that can be expected. Floor effects, though, are paradoxical because of the asymmetrical codependency and because accuracy below a threshold of 90% disrupts understanding. Even though there is little variance in very low scores on fluency and comprehension, they will covary by necessity when assessed on the same text because lack of fluency ensures lack of comprehension; that is, there can be no comprehension if the words cannot be read accurately. It makes no sense to assess the relation between fluency and comprehension when oral reading accuracy is at low levels because the relation will always reveal the obvious and spurious positive correlations. It should not be surprising that children who cannot recognize many words in a passage also cannot comprehend it. The nonindependence of the variables at low levels of decoding certainly confounds and inflates

the positive relation, and it may invalidate correlational analyses involving oral reading accuracy.

So, why do some studies find modest positive correlations between oral reading fluency and comprehension (Kuhn & Stahl, 2003)? Sometimes the studies include data from many readers who are reading below 90% accuracy, so the data include cases of readers who cannot decode or comprehend the text. The variance in scores below 90% accuracy is huge and yields positive correlations with comprehension because both scores are so low for poor readers. Even when the majority of subjects have accuracy scores above 90%, the correlations with comprehension are unduly influenced by the few cases with the most variance, outliers in a statistical sense, because there is little variance in fluency scores among the best readers. Readers who have less than 90% accurate oral reading may have a wide variety of reading problems, including inadequate prior knowledge, poor vocabulary, unfamiliarity with standard English, unfamiliarity with the passage genre and test format, and motivational obstacles such as low self-efficacy and self-handicapping strategies (S. Paris & A. Paris, 2001). Thus, oral reading accuracy can be influenced by many different experiences and skills, and the oral reading fluency score may be only a proxy measure for many other influences on reading development.

Some researchers have correlated fluency and comprehension scores on different tasks to avoid the codependency problem between skills. For example, oral reading fluency can be calculated on one text and comprehension can be assessed on standardized reading tests. This seems questionable because the relation between the two cognitive processes is important within texts, not between texts. Assessing the skills on independent texts treats the skills as independent abilities. Correlations between fluency scores on one reading task and comprehension scores on another task generally yield positive correlations. However, the interpretation is debatable. Advocates argue that the two skills are positively related because of the positive correlation, but the analyses of independent texts indicate that the correlation is between subjects and not cognitive processes. Subjects low in one skill tend to be low in the other skill, but fluent readers are not necessarily good comprehenders because of the asymmetry. Proxy effects also operate, though, because highly fluent readers might have better intellectual skills and more previous literacy experiences than low fluent readers. The apparently simple positive correlation is thus confounded by

the codependency between skills, the asymmetrical relation between necessary and sufficient skills, and the multicollinearity of multiple factors that affect fluency and comprehension.

IMPLICATIONS FOR RESEARCH AND POLICIES

The central point of this chapter is that fundamental conceptual and developmental differences among components of reading influence research methods, data analyses, and interpretations of relations among reading skills. The differences among skills were regarded as constraints to identify how the developing trajectories of different skills can exhibit different slopes, intercepts, durations of learning, and ranges of influence. The effects of the constraints are most evident in the data when the distributions are skewed due to floor and ceiling effects. These may be due to subject selection, task difficulty, or learning at initial or expert levels. The skewed data are not aberrations in data that are usually normally distributed, and they should not be corrected by sampling, data transformations, or data aggregations. Instead, the data are skewed as children acquire and refine the skills except for the brief time when most children in the sample exhibit partial mastery.

In any component model of reading, the skills should also be expected to become interdependent and intercorrelated as they become reciprocally beneficial. For example, as children learn to segment and blend phonemes by identifying and combining onset-rime patterns (such as d-og or b-all), they use knowledge about letter names and sounds, orthographic processes, phonemic awareness, vocabulary knowledge, and previous experience with such tasks to break and make words. Multicollinearity of component skills should be expected in developmental data on reading, and this confounds interpretations of correlations among skills, both concurrent and criterion-related correlations. For example, in the landmark evaluation of first-grade reading programs, Bond and Dykstra (1967) examined a variety of data from pupils, schools, and communities to determine how the variables are related to achievement in reading and spelling in first grade. The pupil measures included a variety of constrained (e.g., phoneme discrimination, letter naming) and unconstrained (e.g., intelligence test, word meaning) skills that were analyzed in the same ways with correlations and analyses of variance. As one example of the multicollinearity of the data, the intercor-

relations among 13 pupil measures, calculated for each of 6 types of reading instruction (see Tables 2 through 7 in Bond & Dykstra, 1967) ranged from $r = .16$ to $.84$ with most correlations between $.3$ and $.6$. Similar correlations were found between all pupil measures of reading and learning and the Stanford Paragraph Meaning Test.

The Bond and Dykstra (1967) study was one of the first large-scale efforts to review reading research with the goal of identifying evidence to substantiate methods to teach reading in primary grades. Recent research reviews, such as the National Reading Panel (2000), had similar purposes with the additional goal of establishing national policies for reading assessment and instruction. Although we applaud the intentions of these efforts, we think that the methods and analyses applied to constrained reading skills should be reevaluated because the developmental differences among reading skills are numerous and important. We examine some implications for policies in the next section.

The Five Essential Components of Reading

Reviews of reading research by Adams et al. (1998), Snow et al. (1998), and the National Reading Panel (2000) provided the foundation for federal legislation based on scientific reading research and evidence-based approaches. One notable outcome of the reports was the emphasis on the five essential components of reading in both instruction and assessment. The impact on reading materials and practices in classrooms across America has been dramatic. Although many psychologists and educators were enthusiastic about the larger role of scientific research, others worried that the evidence was selective and debatable. Protests about the educational policies, however, did not challenge the scientific bases of the claims, so they were interpreted as complaints about accountability or preferences for unproven methods. The constrained skills view challenges the research methods, data analyses, and interpretations of the component view of reading on scientific grounds.

One implication of differential reading constraints is that the five essential components differ widely in developmental trajectories and scope. Alphabet knowledge and phonological awareness are undoubtedly important and necessary precursors to skilled reading, but they are learned in a few years, usually between the age of 4 and 8 years, when children are provided direct instruction and practice with the skills. During rapid acquisition, differences in relative learning are correlated with a

wide variety of other developmental accomplishments (concurrent and predictive correlations) because they provide indicators of an educationally supportive environment and greater relative achievement compared to their peers. Alphabet knowledge and phonological awareness usually are mastered to a high level before other reading skills are proficient, so asymptotic performance decreases longitudinal correlations. This yields unstable and transitory correlations with subsequent reading achievement.

Oral reading fluency is a popular instructional goal and assessment target because children who can read quickly, accurately, and with expression have integrated component skills into automatic word identification. Fluent reading builds on many other component skills and is an indicator of automatic skills, but it is constrained in several ways. The developmental trajectory reveals a period of halting and disfluent word reading, usually fewer than 50 wcpm in first grade, with progressive automatic decoding in elementary grades until an asymptote of 150 to 200 wcpm is reached by adolescence. Correlations with oral reading fluency vary along the trajectory, with weaker correlations evident at both early and late phases of learning to read. Transitory effects of fluency can be explained by the longitudinal course of progressive mastery of a constrained skill.

Oral reading fluency is also constrained in the code-dependent relation with comprehension because readers cannot be expected to understand text when they cannot read at least 90% of the words. Past research has analyzed the relation between fluency and comprehension as if they were independent skills (Fuchs & Fuchs, 1999), but the constrained skills view suggests that there is a threshold of oral reading fluency required to enable comprehension. However, the threshold of fluency is necessary but insufficient for comprehension because many readers, especially after grades 3 to 4, can identify words fluently yet fail to comprehend the text (S. Paris et al., 2005). Correlations between oral reading fluency and comprehension are strongest when assessed in beginning readers or when assessed with different texts, and in both conditions, the variance is explained mostly by readers who have poor fluency because disfluent reading leads to comprehension failures more often than fluent reading leads to comprehension success.

The five essential components of reading, in our view, might be reinterpreted as three important foundation skills and two essential components of reading. Although we have not examined vocabulary and comprehension in

detail in this chapter, both components begin to develop before print-related skills and continue to develop throughout the life span. Both have large scopes and ranges of influence, and both enable the construction of meaning during reading. Variations in vocabulary and comprehension between individuals are enduring and stable differences compared to the transient differences between children in constrained skills. Both deserve amplified instruction and assessment at all phases of learning to read because they are fundamental cognitive and language skills that transcend reading and are fundamental to education (A. Paris & S. Paris, 2003).

Reanalyses of Constrained Skill Assessments

Another implication of the constrained skills view is that traditional reading research and assessments need to be reexamined because the claims made from the data may not be valid. We summarize some of the problems mentioned throughout the chapter. One factor is subject selection. If significant relations among components and achievement measures depend on the relative degree of learning of the subjects, then the effects must be interpreted as transitory rather than enduring. This applies to cross-sectional and longitudinal data for skills that exhibit unstable and decreasing correlations with increasing mastery. A second factor is skewed data. Researchers should analyze and report the skew and kurtosis in their data. They should not apply statistical transformation to the data to normalize distributions that conceptually are not normally distributed. Third, raw scores on component skills should not be aggregated because this confounds different developmental trajectories and artificially creates normalized data. Fourth, researchers may need to use nonparametric statistics to analyze constrained skills that have nonlinear and asymptotic trajectories.

The reason for reanalyzing the data is to avoid misinterpretations of relations among component skills. Two misinterpretations persist in claims about reading components. The first is that the purported correlations between reading achievement and constrained components such as alphabet knowledge, concepts about print, and phonemic awareness are stable and enduring relations. They are not, and the claims ignore the transitory, unstable, and declining correlations with progressive mastery of constrained skills. The second problem is the seductive causal inference made from the consistent correlations between constrained skills and subsequent

achievement. Although some researchers are careful to interpret the correlations between constrained components and reading achievement as an indicator, not a cause, of later achievement, the research paradigms often do not include assessments of other environmental variables that may mediate the effects, such as parental assistance and literacy experiences. The proxy effects are likely for constrained skills because early rapid learning of specific print-related knowledge and skills reflects social and environmental conditions instead of stable and enduring individual differences. For example, Scanlon and Vellutino (1996) reported a correlation between letter identification and reading achievement of $r = .56$, but they also found the correlations between number identification and reading achievement to be $r = .59$ (cited in Snow et al., 1998). Thus, early advantages in letter knowledge compared to peers may simply be a marker of generally advantageous environments that result in better learning and achievement on a variety of skills. That is precisely why it is incorrect to interpret predictive correlations as mandates for specific skill instruction.

Reliability and Validity

Traditional assessments of reading skills use correlations to establish reliability and validity, but we have shown that correlations based on nonlinear developmental trajectories, especially those with universal asymptotes, yield unstable patterns that are dependent on the specific sample tested. How can alphabet knowledge be considered a valid assessment if it yields low, strong, and no correlations with reading achievement when it is tested on the same children at three time points between 4 and 7 years of age? The assertion that it is significant and therefore “valid” for the middle time point alone does not meet the criterion of scientific validity because it is transitory. We believe that all assessments of constrained skills yield a similar pattern of unstable correlations with progressive mastery, so all claims about criterion-related validity of constrained skills are suspect. Traditional research has found significant correlations between constrained skills and later achievement, but those depend on the specific sample of children and stimulus items that yield nonskewed data. They are special cases that are not replicable across children of widely different ages and skill levels.

Another confound in the correlations is the complexity of the skill. Letter knowledge, and associated skills

such as rapid letter naming, are discrete compared to answering multiple-choice questions about the meaning of text. Constrained skills are more discrete and less confounded with other skills than unconstrained skills. Discrete skills are easier to assess and quantify than more complex skills such as vocabulary and comprehension. The ease of measurement may yield higher reliability and validity estimates, too. Unconstrained skills, such as comprehension, will have lower test-retest reliability because of the learning that occurs with the first reading of text. Correlations to establish concurrent and predictive validity may also be lower than those for discrete skills because (a) there are more confounded component skills involved in comprehension, (b) the specific text and questions can vary widely in familiarity and difficulty, (c) comprehension depends on motivation and strategic reading, and (d) discrete skills have more congruence and similarity among items than complex skills (Carpenter & Paris, 2005). The last point is illustrated by the greater similarity of segmenting, blending, or rhyming different words than the similarity of reading different texts and answering questions about them. Thus, traditional psychometric criteria for measuring reliability and validity might privilege some skills over others if only the strengths of the correlations are compared.

Effects of Intervention on Different Skills

Constrained skills can be taught more readily than unconstrained skills, partly because the sets of knowledge are smaller and more discrete. For example, teaching a 5-year-old the names of 10 letters can have a dramatic effect on letter knowledge assessments, whereas teaching the same child 10 new vocabulary words is unlikely to influence a general vocabulary assessment. Of course, interventions will be most effective during a developmental window of rapid acquisition when the prerequisite knowledge and skills are available. Because the scopes of knowledge are smaller, the developmental windows more narrow, and the learning trajectories more rapid, constrained skills show larger responses to intervention than unconstrained skills.

The responses to intervention for constrained skills can be dramatic over short time intervals, but the effects often wash out over time because all children acquire the skills eventually. This is true for alphabet knowledge, concepts about print, and most aspects of phonemic awareness. Interventions on constrained skills usually have highly specific effects also with little

transfer to less related skills. In contrast, when interventions are successful on unconstrained skills, such as vocabulary and comprehension, the effects may last longer and generalize more diffusely because the skills are more complex and interrelated with other skills.

IMPLICATIONS FOR EDUCATIONAL PRACTICE

Let's return to the example of Ms. Jones, a first-grade teacher, to examine the implications of her district's assessment policies for her classroom reading instruction and assessment. Her district uses the Stanford Achievement Test, ninth edition (SAT-9) to assess reading in grades 3 to 8. They also use the state-mandated reading proficiency test in grades 4, 7, and 10. Ms. Jones, like other K-3 teachers, uses the state-sponsored battery of early reading assessments of alphabet knowledge, phonemic awareness, concepts about print, and oral reading fluency. She has attended workshops about informal reading inventories and would like to use them but does not have adequate time to assess each child individually for 20 to 30 minutes. Her district reading coordinator recognized the problem and recommended that all K-3 teachers use the DIBELS (Good & Kaminski, 2002). Part of the appeal of the DIBELS is the 1-minute samples of oral reading and other quick assessments of letter knowledge and phonemic awareness. The DIBELS allows easy scoring and data records along with prescriptions for instruction based on the results. The superintendent is impressed with the use of data to identify struggling readers, the data available to track the adequate yearly progress of each classroom and school, and the fact that the DIBELS is widely used across the country. Ms. Jones learns to administer the DIBELS assessments 3 times per year, more frequently for her poorest readers, and to use the data in reports to parents and the district. She is uncomfortable with the amount of time she spends assessing children's reading, and she wishes there were better assessments of comprehension, but she feels empowered to document students' growth and to align her assessment and instructional practices.

This scenario represents the quandaries of a typical primary grade teacher who must increase the frequency and amount of reading assessment while also increasing the amount and intensity of explicit instruction, usually within a 60- to 90-minute block of time each morning.

Inadequate time for both assessment and instruction is the main problem, but many teachers also complain about the lack of materials, resources, and professional aides needed to work with an increasingly diverse group of students. Many first-grade teachers have 25 or more students in a class, which may include children with learning difficulties, Attention-Deficit/Hyperactivity Disorder, and native languages other than English. Children with special needs often participate in special programs during and after school, so Ms. Jones tries to meet with the paraprofessionals, tutors, and parents to coordinate instruction for each child. Although Ms. Jones is an excellent teacher, she is frustrated by the lack of time to work individually with the children who most need her help to learn to read.

Prescriptive Instruction

Educational assessments should be connected to instruction so that diagnoses of difficulties lead to direct interventions. However, when the diagnoses of reading difficulties indicate incomplete mastery of constrained skills, educators run the risk of treating the symptoms rather than the underlying problems. This problem is evident in the case of Ms. Jones and can be illuminated by an analysis of the DIBELS (Good & Kaminski, 2002). The DIBELS was designed as part of a system of accountability as well as prevention by providing measures of early reading that predict reading success or difficulty (Good, Simmons, & Kame'enui, 2001). The value of the instrument is based on claims about the predictive validity of the DIBELS to assess reading development and to identify individual children who are at risk. Good et al. explain: "The premise of assessment examined in this study is that fluency as represented by accuracy and rate pervades all levels of processing involved in reading . . . and that fluency on early foundational skills can be used to predict proficiency on subsequent skills in reading" (p. 264). The DIBELS (in the original version) assesses three of the five "big ideas" in early reading: letter-sound knowledge, phonemic awareness, and fluency. All of these are constrained skills, and the evidence used to substantiate them is flawed. The same criticisms described earlier about letter-sound knowledge, phonemic awareness, and oral reading fluency undermine the validity of the DIBELS.

Reading rate, as measured by oral reading fluency, is constrained by many factors, including (a) the rate of

speech production, (b) automatic decoding and word recognition, (c) developmental factors such as motor control of the vocal apparatus, and (d) social factors such as anxiety. Clearly, these variables also interact with age and situation. Children speak slower than adults, and they also read aloud more slowly because of these factors. Reading rate is constrained as a measure because beginning readers in first grade rarely read at a rate below 20 wcpm and highly skilled readers in fifth grade rarely read faster than 180 wcpm (Hasbrouck & Tindal, 1982). The average reading rate at each grade level from grades 1 to 5 increases about 10 to 20 wcpm within subjects, so there are developmental normative expectations for reading rate that are constrained within and between grade levels. This means that rate increases with age and expertise, that growth in rate within individuals is small, and that reading rate reaches different asymptotes for different individuals.

Most of the variance in young children's reading rate is accounted for by automatic decoding skills, so this may be the main factor accounting for developmental improvement in reading rate. To the extent that this is true, rate is a proxy for automatic word recognition. This explanation seems reasonable, but automaticity is only one of several factors underlying reading rate. These two factors, automatic decoding and reading rate, have been conflated in explanations of individual reading proficiency versus group differences in relative proficiency because rate generally is a correlate of better reading when compared among children.

One problem is confounding individual development over time with individual expertise at one time point. Reading rate increases within individuals over time with increasing skill, so faster reading is an indicator of better reading due to faster word recognition, automatic decoding, and so forth that improve with age. However, this does *not* imply that the same person can understand a text better if it is read quickly. In fact, there is no evidence from within-subjects research that comprehension is better if individuals are forced to read faster. On the contrary, individuals who read slowly and strategically with rereadings and comprehension checks comprehend more than when those same people read quickly. This is intuitively obvious: Readers can employ more strategies for engaging and checking their comprehension when they read slowly and silently than orally and quickly. Reading aloud prevents readers from using many strategies and places a premium on rate. Thus,

reading quickly does not necessarily indicate good comprehension, and reading a text more quickly is not a within-subject measure of greater expertise when assessed at the same time.

The second problem is now evident: Reading rate is a proxy measure for developmental changes in reading because it assesses differences between subjects (or within subjects over time). Children who can read 150 wcpm are different from children who can read only 50 wcpm due to many factors, including age, automaticity, vocabulary, and reading experiences. Studies that have established the predictive validity of oral reading fluency use between-subjects data to show that reading rate correlates with other measures of reading achievement. For example, Good and Jefferson (1998) found Pearson correlations between .52 and .91 in eight different studies when fluency measures were correlated with later measures of reading achievement. These correlations indicate that children who read slowly at first testing later scored more poorly on achievement tests, and, conversely, children who read quickly at a young age scored better later. The error in method is assuming that fluency scores and achievement data are “ability estimates” of children that are independent of the text that is read (because rate and comprehension were assessed in different tasks) and independent of other concurrent experiences. The error in logic is concluding that reading faster leads to better reading that leads to better achievement test scores. Fleisher, Jenkins, and Pany (1979–1980) showed that training poor readers to decode rapidly did not improve their comprehension. The erroneous reasoning is amplified in the Good et al. (2001) prevention model that assumes that teaching children to read more quickly will make them better readers. This is spurious reasoning based on correlational evidence, and it leads to scientifically false claims about prevention of reading difficulties that are wrong and dangerous.

The errors in interpreting the data are twofold. First, researchers have examined the simple correlations between reading rate and later outcomes in isolation and interpreted them without regard for the other factors that underlie reading improvement over time. This makes the correlations about predictive validity only proxy measures or symptomatic correlations because there is no experimental evidence to support the fact that making people read faster improves their comprehension. The researchers have ignored the underlying factors that ex-

plain why reading rate varies between subjects, such as automaticity and experience, in their focus on rate alone. Second, the researchers have made within-subjects claims from between-subjects data that are not justified. Differences in reading proficiency between children may be indicated by fluency measures, but this does not mean that ameliorating the rate differences will improve reading proficiency within individuals. The prevention models advocated by special educators and school psychologists who created the DIBELS are founded on erroneous reasoning about simple correlations and misinterpretations of between-subjects data. Faster reading is an outcome of more skilled reading, but there is no evidence that it is a cause of better reading.

Does this mean that oral reading fluency is an invalid assessment? No, it can help identify children with reading difficulties, but fluency should be regarded in the same way a thermometer is used to identify illness. Children who read slowly and inaccurately may be poor readers and they may have a wide assortment of problems that contribute to their difficulties, but speedier reading is not the prescription or cure. The irony is that slow readers may benefit from instruction that helps automate decoding skills, and if the desired outcome is only speedier reading, then fluency practice and instruction may help (Rasinski & Hoffman, 2003). However, fluent, accurate oral reading does *not* lead automatically to good reading comprehension. Children may be taught to read more quickly, and some may read with better comprehension, but many will become rapid word callers with poor comprehension. This is an inappropriate educational goal. Thus, reading rate, like other constrained skills, may be a necessary but not sufficient condition for reading proficiency.

CONCLUSIONS

Assessment of children’s reading has a long history in American education and remains a foundation for improving teaching and learning. The consequences for teachers and students are enormous, yet there are few analyses of the developmental parameters that underlie the assessments. Our analysis of early reading assessments reveals how developmental trajectories of different skills may contradict the prevailing component skills view of reading development. The nonlinear

growth, universal mastery, and codependency of some reading skills may confound early reading assessments and lead to misinterpretations of data about early reading.

Our analyses suggest that early reading skills such as alphabet knowledge, concepts about print, orthographic processing, phonological awareness, and oral reading fluency are constrained in their development in ways that vocabulary and comprehension are not. Those constraints include conceptual, developmental, and methodological limitations that influence the developmental trajectories of the skills. Thus, some reading skills are acquired quickly, some completely, and some interdependently at different ages. Data analyses that ignore these different trajectories run the risk of overemphasizing transitory patterns of significant correlations and temporary gains due to intervention. These correlations may be misinterpreted as causal relations, and skill instruction becomes the prescribed intervention or remediation. These prescriptive errors neglect the proxy effects of the assessments and the multicollinearity of the data and result in oversimplified links between assessment and instruction. We think that consideration of the different developmental trajectories of early reading skills requires reinterpretation of data from early reading assessments as well as longitudinal studies of reading (S. Paris, 2005).

There are also implications of the constrained skills view for educational practices and policies. Teachers are frustrated with the amount and frequency of reading assessments, especially when they take time away from instruction. Repeated measures of basic skills in K–3 grades can lead to instruction that overemphasizes basic skills at the expense of comprehension, vocabulary, and other literacy skills. Just because letter knowledge, rhyming, and reading rate are easy skills to measure in beginning readers does not mean that they should become the focus of the curriculum. When oversimplified assessments are aligned with oversimplified instruction, the short-term result may be improved scores and basic skills, but the risk is that deep understanding about text, and the skills needed to discuss, analyze, and write about it, may be neglected in the K–3 curriculum. Students may exhibit frustration with boredom and lack of motivation to read. Teachers are frustrated if the assessments do not reveal the richness of their literacy instruction and the accomplishments of their students. Both risks are unnecessary, and they can be avoided with assessments of a wider variety of skills and accomplish-

ments. Vocabulary and comprehension assessments are sorely needed, but other assessments of listening, speaking, viewing, and writing are also important because they measure students' thoughtful responses to a variety of texts and genres. Educational policymakers should not be seduced by simple data and dramatic claims about assessments of basic skills among beginning readers. The developmental issues for assessment and instruction are more complex, but richer reading assessments may lead to better reading instruction.

The issue of linguistic and cultural differences confronts modern societies ubiquitously. The post-World War II years have been characterized by unprecedented and increasingly massive migrations of human individuals and groups from places where they are competent in the local language and cultural rules to places where they are not (Zhou, 2001). These migrations create grave challenges, both for the migrants and for their host societies. Migrants must learn how to function in novel settings, acquiring a new language, a new set of rules for daily life, and often new work and school skills as well. The indigenous inhabitants of the places where the migrants settle must also learn to interact effectively with the newcomers—to serve them in stores, hire them, work with them, and teach them—or else suffer the economic, ethical, social, and interpersonal consequences of avoiding or failing at these interactions.

These challenges of functioning and interacting might seem, on brief reflection, to be hardest for adults. After all, adults typically have already acquired a language and a culture, so they have to suppress old knowledge while acquiring new knowledge. Adults are widely thought to be

incapable of learning a new linguistic/cultural system to a high level, and may well hold such self-defeating beliefs themselves. Indeed, though pessimism about adult capacities to acquire a second language is unfounded (see Marinova-Todd, Marshall, & Snow, 2000), opportunities for immigrants to become fluent second-language speakers are often restricted. For example, the majority of immigrants to the United States from all major sending nations except Jamaica, India, and the Philippines reported speaking “poor English” (U.S. Bureau of the Census, 1993), and political opposition to ongoing immigration in Scandinavia and the Netherlands reflects the failure of immigrant adults in those countries to acquire proficiency in the local language as much as conflicts around religion, social mores, and cultural commitments. In the Netherlands, for example, a policy of *inburgeringsplicht* (responsibility to assimilate) for immigrants tied financial compensation to participation in language courses (see Verhallen, Janssen, Jas, Snoeken, & Top, 1996, for a description). But dissatisfaction with the levels of participation and accomplishment in those courses has led to restrictions on financial support for them

(<http://www.inburgernet.nl/beleid/bel155.html>, retrieved February 1, 2005).

We do not minimize the difficulties adult migrants face in adjusting to their new settings. Nonetheless, we focus in this chapter on the challenges confronting transplanted children and adolescents, as well as the teachers and other caregiving adults in the host cultures who are responsible for promoting their success. Future opportunities and access to educational advantages for their children are the reasons adults most frequently offer for their decision to migrate (C. Suárez-Orozco & Suárez-Orozco, 2001); evaluating the impact on children of their parents' decisions to move to a new setting, and describing the conditions under which the parental aspirations are most likely to be fulfilled, is thus of considerable practical importance.

These challenges of adaptation to a new language and culture for child migrants are reflected in data about their academic achievement. Language minority children are at demonstrably greater risk than native speakers of experiencing academic difficulty, difficulties that have been documented in the United States (Lloyd, Tienda, & Zajacova, 2002), in the Netherlands (Tesser, Merens, van Praag, Iedema, 1999; Verhoeven, 1994), in Great Britain (Runnymede Trust, 1998), and in Japan (DeVos & Wetherall, 1983; Y. Lee, 1991; Shimihara, 1991). The exact source of these academic difficulties—whether control over the target language, difficulties acquiring literacy, the more general challenges of a novel academic system, the consequences of discrimination, or the emotional and motivational challenges of functioning in a foreign culture—is not always easy to determine. Nonetheless, any society that seeks to avoid persistent socioeconomic differences associated with cultural and linguistic background must seek to understand the reasons for the poor academic achievement of immigrant and language minority children and youth.

Furthermore, the functioning of linguistic and cultural minorities in schools, and in the workplace and other institutions of the host culture, sheds light on basic questions about the language development and cultural learning, not just of immigrant or minority group members, but of all human beings. This is one of the many domains in which problems of practice—how best to assist immigrants with the social and educational challenges of adaptation—can yield insights of interest to basic scientists, by generating questions that might not otherwise have arisen, for example:

- How do children learn to function as successful members of their cultural groups?
- What is the role of parents, of peers, and of institutional and academic settings in cultural learning?
- How closely tied to one another are knowledge of language and knowledge of culture?
- Is it possible to be a “native speaker” but not a “native member”?
- Does achieving at high levels in host country schools require assimilation to the host culture?
- What are the limits, if any, on the achievement of full bilingualism, biculturalism, and biliteracy, and to whom do these limits apply?

Answers to these questions would help us understand some general principles of child development, of language acquisition, of literacy development, and of cultural learning, whether for the first time in infancy and early childhood or for the second time at a later age. In addition, answers to these questions would be of great benefit to the educators responsible for the growth and development of groups that increasingly include child immigrants and the children of immigrants, both in the United States and in other parts of the so-called developed world.

We take literacy learning as a focus in this chapter because it represents an important issue in its own right and because literacy is a litmus test—the final common pathway—for many other domains of learning. As we review here, literacy development is multiply determined; successful reading and writing in the later elementary and secondary grades is not possible without high levels of language proficiency, access to large stores of knowledge, and control over the local cultural norms for communication. Thus, through our focus on literacy, we can discuss many aspects of the challenges learners in general, and language minority learners in particular, face. We focus on the group we call L2/C2 learners: children and adolescents faced with the need to acquire a second language (L2) and/or a second culture (C2), either because they have just arrived in a new setting or because their home language (L1) and culture (C1) differ from that of the schools and the larger society. But in forefronting the specific, practice-embedded challenge of understanding and supporting L2/C2 learners, we also consider research on the general case of literacy acquisition and the chal-

lenges it presents even to monolingual children for whom home and school represent no sharp discontinuities of language and culture.

L2/C2 learners are as a group at greater than average risk of poor literacy outcomes and associated achievement problems (August & Hakuta, 1997; National Center for Education Statistics, 2003), but it is important to note that there are robust differences in academic outcomes within the language minority and immigrant population that help may shed light on some of the mechanisms by which children acquire the language, literacy, and cultural skills they need. Ogbu (1992) argued that these differences could be accounted for by factors leading to immigration—that voluntary migrants, moving to a new setting in part to promote their children’s learning, were more tolerant of the stresses associated with migration, had higher aspirations for social mobility, and were more optimistic for their children’s success, with the result that the children were academically more successful. Ogbu’s ideas on this topic have been highly influential, but they do not entirely fit the data; Mexican immigrants, for example, are voluntary immigrants who are strongly motivated to improve their children’s educational opportunities (C. Suárez-Orozco & Suárez-Orozco, 2001), but their children perform more poorly in school than nonimmigrants or other immigrant groups. It has been argued that the high regard for education Asian immigrants bring with them helps explain their children’s generally good school performance, but this explanation ignores differences within the Asian population (S. Lee, 1996) and fails to clarify a mechanism by which those cultural values are transmitted to the children. Furthermore, as Ogbu has pointed out, Asian migrants perform rather poorly in settings where they are discriminated against. So, for example, if culture explains the high achievement of Korean immigrants in the United States, why does it not protect Korean children whose families have immigrated to Japan, where Korean academic achievement is relatively poor?

These disparities across and within immigrant groups suggest the importance of understanding context as well as development. If we hope to answer questions about the determinants of and limitations on academic outcomes for children in general, and for L2/C2 learners in particular, we need to expand our horizons as researchers to integrate information about processes of development with information about local and societal

conditions affecting those developmental processes. In other words, these are not questions to be answered by thinking purely as developmental psychologists or educational researchers; to be addressed satisfactorily, they require insights from demography, sociology, anthropology, socio- as well as psycholinguistics, and economics.

CASE EXAMPLES: LEARNING A SECOND LANGUAGE IN CHILDHOOD

Consider the cases of two families who display some of the complexities of migration and L2 learning.

The Lopez Family

A Spanish-dominant 5-year-old girl named Rosario, whose parents have recently immigrated from Oaxaca to Austin, Texas, starts kindergarten. Her mother, trying to choose the program that will best support Rosario’s learning of English, puts her in an all-English classroom. Because the adults in Rosario’s family speak very little English, they of course continue to speak Spanish at home. Rosario struggles in kindergarten, partly because she doesn’t understand much English, but partly because many of her classmates have had far more experience than she has being read to, playing with puzzles, learning numbers and letters, and writing. In first grade, Rosario is in the lowest reading group, which gives her access to some one-on-one tutoring from a reading specialist; as it happens the reading specialist is bilingual and reverts to Spanish occasionally in explaining particularly difficult puzzles in English spelling and word reading. Five years later, Rosario is doing well in fourth grade, reading fluently and eagerly in English and enjoying school. Her spoken English is now fluent, accent-free, and grammatically mostly correct. She still speaks Spanish at home with her parents, but increasingly uses English with her younger siblings. She has not learned to read in Spanish and now has some difficulty talking in Spanish with her parents about things that she is learning at school; she doesn’t have the Spanish vocabulary to discuss math, science, or social studies. Thus, her Spanish conversations tend to focus on matters relevant to home and family; if she needs help with homework or wants an explanation about something she heard at school, she turns to her teacher rather than to her parents. By the time Rosario is in high school, she much prefers speaking English to speaking Spanish,

often responds to her parents in English when they speak to her in Spanish, and finds herself occasionally unable to understand her parents' conversations, for example, when they turn to such topics as political change in Mexico or medical procedures.

The Jackson Family

Six-year-old Ashley and her 10-year-old sister, Brittany, move with their English-speaking family to Querétaro, Mexico, where their mother has taken a position at El Instituto de Neurobiología. Their mother is eager for her daughters to become bilingual and thus enrolls them in a nearby school where they are the only English speakers. Ashley has completed kindergarten in South Bend and can already read at a late second-grade level in English. Brittany is a fluent reader at an early sixth-grade level and insisted on including several dozen chapter books in the luggage the family took with them. Both Ashley and Brittany find their Spanish-speaking classroom environments intimidating to begin with; Ashley in particular often has tantrums and crying fits when it is time to go to school and seems somewhat depressed during her first months in Querétaro. Only after 4 months in school does Ashley produce any spontaneous Spanish utterances. Meanwhile, though, she is participating fairly successfully in the literacy instruction activities in her first-grade classroom; these consist mostly of filling in worksheets, copying sentences from the board, and reading aloud in chorus. Brittany is more lost at first, because the instruction she encounters involves a lot of teacher talk, which she does not understand. But within a few months, Brittany has learned enough Spanish to make some tentative friendships; she starts to rely on her desk-mate, Maricarmen, to repeat the teacher's instructions slowly or to explain how to do the assignments. Furthermore, Brittany learns to read Spanish after only a few sessions with a tutor and soon is able to understand her textbooks and the written homework instructions with little difficulty. Brittany can even help Ashley with her homework. During Christmas break, their mother insists that the girls spend some time reading books in English, to be sure they not fall behind in English reading skills. As soon as the school year is over, Ashley and Brittany are sent to spend 6 weeks with their grandparents in Maine, a pattern that will continue throughout their elementary school years. Brittany takes Spanish books with her to read on vaca-

tion, but both children are soon happily reading English books borrowed from the local public library. By the end of *primaria*, both Ashley and Brittany are fully bilingual, able to talk about things they have learned in school with their parents in either Spanish or English or a mix of both languages. Their mother notes that their Spanish literacy skills are somewhat stronger than their English literacy skills and decides to enroll them in a private bilingual secondary school to ensure that they will develop the skills needed to be able to gain admittance to and to succeed at a university in the United States.

Summary of Language-Learning Cases

On the face of it, Rosario, Ashley, and Brittany all faced the same challenge: learning a new language primarily from exposure in school. Their outcomes, though, are different in important ways; Rosario ended up with greater oral proficiency in her L2 than her L1 and became literate only in the language of schooling. Ashley and Brittany ended up bilingual and biliterate, though the equilibrium between Spanish and English dominance shifted back and forth as their circumstances changed. Rosario's parents were somewhat surprised that she did not end up a fully proficient speaker of Spanish, but they did not know how to intervene to ensure full Spanish proficiency. Ashley and Brittany's parents anticipated the possibility of decline of English skills and invested heavily to ensure maintenance of English, sending the children off to an English-speaking environment every summer, buying them books in English, and choosing a bilingual secondary school.

These three child cases concretize some of the general conclusions derived from research on L2 language/literacy acquisition that:

- Acquiring an L2 in childhood can be intimidating and difficult, lead to temporary emotional problems, and take several years.
- An L1 is at some risk of loss or decline under the influence of an L2.
- A child's continued development of the L1 is more likely if the parents are bilingual and/or highly educated in the L1.
- Higher-status languages and languages associated with schooling and literacy are in general less subject to attrition than lower-status languages.
- L1 literacy skills can be a support to L2 acquisition.

- Learning to read an L2 is easier if one is already literate in an L1.
- Literacy skills contribute to higher levels of oral proficiency in both an L1 and an L2.
- Older children typically learn an L2 faster than younger children, perhaps because of their better developed literacy skills.
- Transfer of literacy skills can support L2 literacy but may not occur automatically across even closely related languages.

These case studies of individual language learners illuminate one aspect of L2/C2 learning. But understanding the full range of relevant issues requires considering a case involving policy as well.

CASE EXAMPLE: BILINGUAL EDUCATION IN THE UNITED STATES

Forty years after the establishment of the first bilingual education programs in the United States, researchers still cannot answer straightforwardly the seemingly simple question, “Does bilingual education work?” No proper experiments comparing bilingual to English-only education for English-language learners have been carried out. The debate about the effectiveness of bilingual education, reinvigorated by Ron Unz’s placement of a referendum banning bilingual education on the ballot in California, Arizona, Massachusetts, and Colorado, has been minimally informed by research evidence. Supporters of bilingual education, relying on comparisons of groups that were probably not well matched to begin with, offered data that they interpreted as supporting the greater effectiveness of bilingual education (Willig, 1985). But such data were unconvincing in a political context where the opponents could identify graduates of bilingual education with clearly inadequate English and literacy skills. The slogan adopted by those who had lost faith in bilingual education, “English for the Children,” was highly effective. Furthermore, researchers with integrity had to admit that good English-only instruction could also produce adequate literacy outcomes for English-language learners (e.g., Lesaux & Siegel, 2003) and that quality of instruction was more important in determining outcomes than the language in which it was delivered. The referenda greatly reducing access to bilingual education passed in California, Arizona, and

Massachusetts; the referendum failed in Colorado largely because of funding provided by a staunch and wealthy proponent of bilingual schooling. Furthermore, though some states continue to support and celebrate bilingual programs, the impact of No Child Left Behind, with its provision that all children be tested on reading and math starting in third grade and that test scores for English-language learners be reported separately, shifted attention everywhere to literacy performance in English. School districts and states have made decisions to reduce or eliminate bilingual education partly because of these political pressures and partly because its initial promise, that it would eradicate the academic deficits of language minority children, has demonstrably not been achieved. The data suggesting that bilingual education does make modest contributions to academic outcomes are insufficiently convincing to counter the political opposition raised by Unz, the accountability pressures exacerbated by No Child Left Behind, and the increasing loss of public faith in the capacities of local educators to make decisions about children’s schooling.

As a National Research Council review of evaluations of bilingual education suggested long before Unz brought bilingual education to the ballot (Meyer & Fienberg, 1992), arguing for or against particular educational treatments for language minority students on the basis of evaluation studies is unlikely to be informative. For one thing, the variation within programs labeled bilingual is as great as the variation across bilingual and English-only programs. Furthermore, program quality is almost certainly more important than program type in determining outcomes. What we really want to know is under what societal circumstances, for which children, and with what educational resources certain policies are effective. Then we must analyze the mechanisms that underlie their effectiveness as a basis for designing educational treatments that will work for other groups of children, under other societal circumstances, and with access to a somewhat different set of educational resources.

In other words, we do not endorse the traditional transmission model for applied research: Work from theory (bilingual education develops and exploits a learner’s “common underlying proficiency” and enables the learner to exploit transfer; see Cummins, 1991) toward application (design the program) to evaluation (compare it to some other program). Instead, we suggest reversing the arrows in Figure 3.1: Work from practice

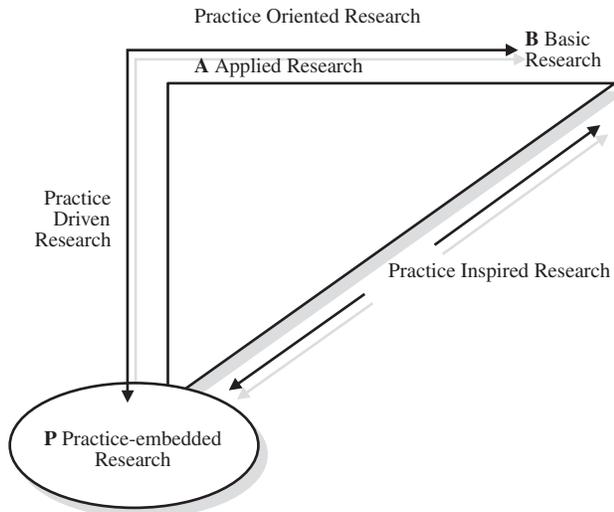

Figure 3.1 The practice-based research triangle. Adapted from Selman and Dray, Chapter 10, this *Handbook*, this volume.

(carefully describe programs that seem to have good outcomes for certain groups of children at risk) toward analysis (figure out what those programs have in common) toward theory (formulate hypotheses about how variations across programs for L2/C2 children in the practices implemented relate to the gains achieved) that can then be tested more rigorously with traditional experimental methods.

This chapter has two closely related goals: to highlight the complexity of the interplay among the various factors influencing educational advancement, in particular achievement in literacy and related academic language skills, for L2/C2 learners, and to argue for the need to substitute practice-embedded and practice-inspired research for traditional transmission-model research in this domain and in other domains similarly characterized by complexity and multidisciplinary. The first goal relates to the argument for a multidisciplinary approach to thinking about L2/C2 learning. The second goal relates closely to the argument made by Selman and Dray (Chapter 10, this *Handbook*, this volume) about models of research in a similarly challenging domain, social development under conditions of risk.

Before turning to the specific case of language minority children, we outline the challenges of literacy development in general and the ways literacy skills form a path toward (or an obstacle to) learning across the entire range of subjects taught in middle and secondary schools. Then we review the literature on L2/C2 children's literacy development in greater depth, seeking

explanations for the overall poorer academic performance of such children. Finally, we provide an overview of the educational treatments available to L2/C2 learners and highlight a few specific programs and interventions that have been implemented for these learners in preschool and elementary school settings.

REVIEW OF EMPIRICAL LITERATURE

In this section we summarize briefly the very large body of work on literacy development from its roots in early childhood through comprehension of complex texts in the middle and secondary grades.

Literacy Development: The General Case

A large and very robust research literature is available to guide us in describing the default course of early literacy development and the factors that are related to success in learning to read during the first few years of school. A somewhat less complete, but nonetheless substantial, research literature has illuminated the processes involved in reading comprehension and the conditions likely to lead to success in reading comprehension. We summarize these bodies of work here, as a backdrop to understanding how the literacy development of the L2/C2 learner might differ from that presupposed in these descriptions.

A 1998 report of the National Research Council, *Preventing Reading Difficulties in Young Children* (Snow, Burns, & Griffin, 1998), summarized the research on the development of literacy skills, organizing it by answering three questions: What is the normal course of literacy development from birth to age 8? What group and individual factors are most associated with risk of difficulties in literacy development? What are the features of skilled reading that all learners need opportunities to acquire? Findings and conclusions from that report are summarized in the next several paragraphs.

How Early Literacy Develops

Answering the developmental question required considering literacy within the larger context of language and cognitive development. In other words, the National Research Council placed the beginnings of literacy development well before school entry. Particularly in the preschool years, before formal literacy instruction starts, children use literacy skills just as they use

other emerging capacities: in play, for purposes of communication, as problems to solve, and in the context of behavioral routines. Playful, communicative, cognitively active engagement with literacy for preschoolers encompasses many sorts of activities, all of which offer opportunities to learn about letters and sounds, to learn about the functions of reading and writing, to acquire cultural rules related to literacy practices, and to develop appropriate affect.

Take as an illustrative example a typical middle-class English-speaking Euro-American child of college-educated parents. She has probably been given books to manipulate and had her attention drawn to pictures in books before her 1st birthday, is read to starting early in her 2nd year as part of a regular naptime or bedtime routine, and by age 2 may well have experienced an accumulated 500+ hours of parent-child book-reading activity (Stahl, van Kleeck, & Bauer, 2003); as a result, by the age of 3 she can recognize dozens of books by their covers, anticipate words or even whole sentences when read to from favorite books, name hundreds of pictures in books, and talk about what will happen next and why in book-based stories. This child probably plays with “refrigerator letters” while her parents are cooking dinner, scribbles with crayons or pens on pads of paper in imitation of adults writing, watches and talks about *Sesame Street* together with her mom or dad, and looks at simple or familiar books on her own; as a result, by age 3 she can write or, using magnetic letters, compose her own name, can recognize and name most upper- and lowercase letters, is starting to notice and “read” print on signs and labels, knows that her parents read the print and not the pictures in her books, and may be starting to produce initial attempts at spelling real words. This child by age 3 has probably heard dozens of different nursery rhymes and songs hundreds of times each, may have completely memorized some Dr. Seuss rhyming books, is starting to be able to respond when asked to name items in a category (fruits, animals, friends), to identify words that rhyme with *cat*, *dog*, or *lick*, or maybe even to select words that match on beginning sounds (*big* and *bad*, but not *moo*).

This child enters kindergarten with a vocabulary of 8,000 to 12,000 words, able to recognize and name all the letters, with sufficient phonological awareness to isolate beginning and ending phonemes in simple words, and extremely eager to learn how to read. Her kindergarten teacher uses a mildly structured phonics approach; all the kindergarteners in this middle-class

suburban school know the letter names already, so she teaches letter sounds, starting with /m/, /n/, /l/, /b/, /p/, and /d/ and four short vowels. She gives the children lots of practice with little word families in which those letter-sound combinations can be practiced, for example:

map, lap, nap
 men, pen, Ben, den
 lip, dip, nip
 mop, lop, bop, pop

and she seeks out some books for read-aloud (e.g., Dr. Seuss’s *Hop on Pop*, Nikola-Lisa’s *Bein’ with You This Way*) in which these words occur, so that the children can be successful in helping her read them in context.

When all the children are pretty good at these distinctions, she teaches a few more letter-sounds, and short u, so that she can expand the lists used in the word sorts (with *cap*, *hen*, *sip*, and *hop*, respectively), can add new lists (*pup*, *cup*, *sup/man*, *can*, *fan*), and can get children looking at variation at the ends of the words as well as at the beginning (*map*, *mad*, *mat*, *man/sip*, *sit*, *sin*, *sis*). Meanwhile, she also spends at least 45 minutes a day reading books to the children and leading or promoting discussions about them, teaching new vocabulary and lots of general knowledge in the process. She also has the children engage in science observation projects, during which they have to record (using a combination of drawing and writing) what they see when studying leaves, buds, and flowers, then larvae, pupae, and insects, then the behavior of ants in the class ant farm.

With this good beginning, going on to learn the various complexities of spelling and longer word reading in first and second grade is pretty easy for our well-prepared reader, and by third grade she is able to read chapter books independently, fluently, with excellent comprehension and great enthusiasm.

Of course, perfectly normal children in highly literate, middle-class households may deviate from this illustrative case in any of a number of ways. Some may have minor learning disabilities that make it harder for them to attend to individual sounds in words, remember which letter represents which sound, or focus sequentially on all the letters in words. Such children need more time to learn these things and more practice with each of them. Others may have been brought up in bilingual or non-English-speaking homes, so their English vocabularies comprise many fewer words at kindergarten entry. Such children will need to learn English

words while learning to read. Others may be physically very active children, or children with short attention spans, so they have had less time being read to and have enjoyed lap-reading less. They may need more explicit instruction in the conventions of literacy because they have had fewer opportunities for incidental learning.

Risk Factors

We sketched here the development of a child who encounters no special difficulties in learning to read. She was not a member of any of the demographic groups that have a higher than average incidence of reading failure: children living in poverty, children with health or nutritional challenges, African Americans, Latinos, L2 speakers, children of parents with low literacy skills, children in homes with few literacy resources. Nor did she have any of the individual factors that are associated with a higher than average risk of reading problems: language delay, hearing loss, a dyslexic or learning-disabled parent, cognitive problems such as mental retardation.

The presence of racial, ethnic, and language minority children in the group at heightened risk of reading difficulties opens up a large set of questions: To what extent are the literacy trajectories of those different risk groups similar? Are Latino children at heightened risk primarily because of limited English skills, or because of poverty and low parental education, or because of a cultural mismatch between their home and their school? Is the risk equivalent for first-generation and later Latinos? For monolingual Spanish-speaking, bilingual, and monolingual English-speaking Latinos? Is the risk for Spanish-speaking Latinos equivalent to that of other immigrant groups of similar social composition who speak other languages, or does identification as a Latino heighten the risks associated with L2 and poverty? Although there are no definitive answers to most of these questions, there are some hints in the data we review in the section on L2/C2 learners.

Skilled Reading

What are the characteristics of skilled reading that constitute the target performance toward which literacy development is aiming? Work using techniques such as eye movement tracking has demonstrated that skilled readers are very dependent on print, looking at and processing most of the letters in almost all of the words on a page. Skilled reading feels as if it goes too fast for such

detailed attention, but good readers manage to process frequently occurring sequences of letters very efficiently because they have seen them and converted them into phonological forms so often. Thus, sequences such as *-ation* and *-itude* can be processed as units. Although readers are not aware of this automatic chunking and rapid processing, it becomes obvious because of the difficulty of reading words in which unfamiliar sequences occur, for example, *Ghazi Ajil al-Yawar, Tblisi*, or *diyethyl-m-toluamide*. This aspect of skilled reading is referred to as automaticity.

Conversion of letter sequences into phonological forms is another feature of skilled reading. It seems as if beginning or poor readers are the ones who have to sound out words, whereas skilled readers can move directly from print to meaning. In fact, though, research findings make it quite clear that skilled readers access word meaning through the phonological, or sound-based, form of the word. Access to phonology is so automatic that it is largely unconscious, but failure to access the phonology of lexical items (a process we all engage in at times, for example, when we remember the names of characters in Russian novels just by their initials or first syllables) is a low-level reading strategy and one that does not work in general.

An implication of the print-dependence and phonological processing of skilled readers is that word recognition is only minimally influenced by context. Thus, for example, knowing that one is reading a report about carburetors does not make it easier to read words like *valve*, *displacement*, or *revolutions*. Knowing that one is reading about carburetors does, of course, help in comprehending the text in which these words occur and in realizing that *valve* refers here to a mechanical device and not a biological structure, and that *revolution* probably has to do with the turning of gears and not the uprising of the oppressed. So contextual information is very important in comprehension, but it has only very minor effects on word reading per se. Thus, good reading instruction focuses on helping children actually read the print in order to read the word, rather than guessing from context at what the word might be.

At the same time, good reading instruction also ensures that children realize that reading the words is not enough. Comprehension is an active process that can be aided by invoking various strategies while reading (e.g., read the title page or chapter headings to see what the text is about, stop and think about why you are reading it, formulate some questions you think the text might

answer, stop every once in a while to summarize what you have read, be alert for words or sentences you don't understand and stop to try to figure them out). Children who have not discovered these strategies on their own can be taught them, and teachers can demonstrate how to use them by modeling comprehension work while reading aloud.

Learning to Comprehend

Comprehension is, of course, the goal of reading instruction. *Preventing Reading Difficulties in Young Children* (Snow et al., 1998) emphasized that children need opportunities to develop language skill and stores of knowledge because those capacities are crucial to success at comprehension. But because that report dealt with children only up to age 8, it did not address in detail many of the challenges of reading comprehension, which emerge for many children only in the middle school years, when the texts they are expected to read become more challenging.

The RAND Reading Study Group (RRSG) was asked in 1999 by the assistant secretary of education to formulate a research agenda for work on reading. In its report *Reading for Understanding* (2002; see also Sweet & Snow, 2003, for a more practice-focused presentation of some of the same themes), the RRSG proposed that reading comprehension should be the focus of future federal funding in the area of literacy. In the process of developing the research agenda, the RRSG summarized the topics related to reading comprehension on which research had been carried out and drew some conclusions from that literature that are relevant to understanding the challenges of achieving good comprehension outcomes for all children, and for language minority children in particular.

The RAND report analyzed variability in reading comprehension success as the product of an interaction among the reader, the text, and the reading activity being engaged in, all embedded in a sociocultural context (see Figure 3.2 for a representation of this heuristic). Reader factors that contribute to success at comprehension include skills with low-level reading processes (word recognition, fluency) and high-level reading processes (comprehension strategies), domains of knowledge (linguistic knowledge, including syntax, discourse, and vocabulary, as well as relevant content knowledge), and motivation and domains of interest. Text features include topic, linguistic complexity, and discourse organization. The category activity includes

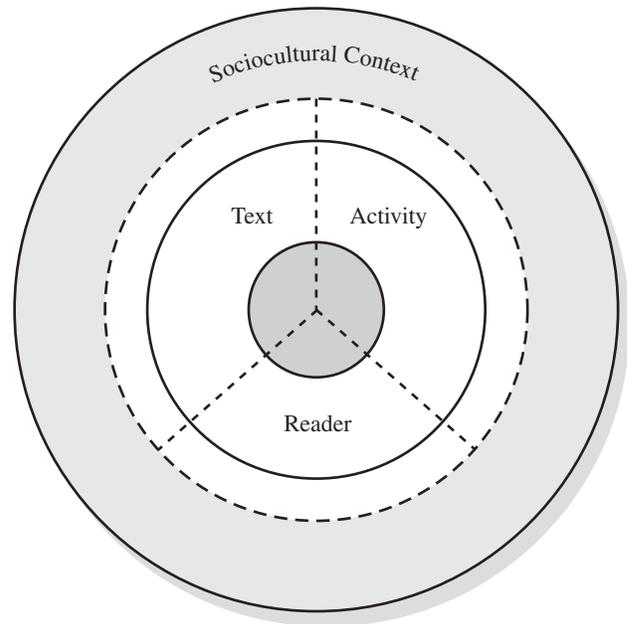

Figure 3.2 A heuristic for thinking about reading comprehension.

formulating a purpose for reading, the attentional and constructive processes involved in reading, and the impact on the reader (e.g., increment to knowledge, engagement) resulting from reading.

The most important portions of Figure 3.2 fall along the dotted lines: the interface between text features and reader capabilities, between reader capabilities and activity, and between activity and text features. Any of us can be rendered a poor comprehender by a text that is very badly written or that deals with a topic about which we lack background knowledge. Some activities—for example, reading quickly for the gist, or reading to understand and challenge the writer's argument, or reading to appreciate the writer's style—will be easier for some kinds of readers than others, and easier with some kinds of texts than others. Thus, the instructional challenge is to provide young readers with texts sufficiently accessible and motivating to keep them reading, but also sufficiently challenging to stimulate growth in their comprehension skills, vocabulary, and world knowledge.

The particular challenges of reading comprehension for the L2 reader can come in any of these domains. First, L2 readers are likely to be less advanced than monolingual or L1 readers in several of the domains that predict reading comprehension; vocabulary knowledge, knowledge of syntactic structures, and knowledge of discourse structures are all language-specific. Second,

the organization of texts and world knowledge presupposed by texts are language- and culture-specific, and thus also likely to be more challenging to L2 than to L1 readers. Third, to the extent that the reading tasks being posed are specific to a particular culture and school context, they might be unfamiliar or even puzzling to the learner. For example, if a student has first learned to read in a school setting where reading for memorization is expected, then being expected to question the text or compare two texts that give different perspectives on an issue requires new learning. If a student's reading experience has been confined to narratives, then reading fact-laden science texts might be a challenge. And if a student's experiences have been limited to reading texts considered reliable and credible, for example, school-assigned history or science books, then reading the wide variety of texts of varying degrees of reliability on the Internet poses new and unfamiliar problems.

LITERACY DEVELOPMENT AMONG CHILD SECOND LANGUAGE/SECOND CULTURE LEARNERS

In this section, we turn to the evidence about the literacy development of L2/C2 learners. We briefly summarize first the evidence that such children are at heightened risk of poor academic outcomes and relate those academic risks to the other risks (health, poverty, family relations, emotional stability) they face. We then turn to a review of the literacy development of these learners, how their knowledge of an L1 (and, for some, L1 literacy) does and does not relate to their L2 literacy development, school achievement, and school adjustment. A major question we address in this section is how individual differences among L2 learners relate to outcomes. Then we consider the influence of social and instructional settings to address questions about the conditions under which language minority children do and do not thrive.

Academic Outcomes of Second Language/Second Culture Learners: A Group at Risk

Analyses of the *National Assessment of Educational Progress: Reading Assessments (NAEP)* reading data (e.g., National Center for Education Statistics [NCES], 2003) make clear that L2/C2 learners in general perform

more poorly than monolingual English speakers. The *NAEP* data do not allow an easy analysis of the degree to which low proficiency in English contributes to deficits in performance, as compared to the contributions of cultural differences, as the data are disaggregated by ethnicity and not language proficiency status. However, analyses of state accountability data disaggregated by both language proficiency status and ethnicity make clear that both these factors independently are associated with poorer performance, and that when they combine, the likelihood of performing at expected levels decreases further. The *NAEP* findings can be summarized as showing that English-language learners, language minority children, and/or Latinos have on average achieved much lower levels of reading skill than English-only, monolingual, Anglo age-mates. What accounts for these effects?

The greater educational risks of this group of L2/C2 learners cannot, of course, be completely disentangled from their greater risks in other areas: poverty, poor health, experiences of family separation, emotional challenges, and so on (see papers in M. Suárez-Orozco and Pérez, 2002, for an overview). Furthermore, there is considerable evidence that some immigrant groups engage in family practices that are less likely to produce 5-year-olds ready for the expectations of U.S. kindergartens. Analysis of the data from the NCES (1995) birth cohort study suggests that Latino mothers are less likely to read books to their children, to make literacy materials available, and to purchase children's books than are Anglo mothers of the same educational level. Furthermore, studies that have examined the relationship between home literacy practices (either in L1 or L2) and L2 literacy and academic achievement of language minority students have found positive effects of certain home literacy factors for immigrant and English-language learning children, and negative effects of their absence. For example, Pucci and Ulanoff (1998) reported that proficient readers were more likely to have a greater number of books in the home. On the other hand, Leseman and de Jong (1998) found that reading comprehension and word decoding skills of Turkish and Surinamese language minority children in the Netherlands at age 7 were strongly determined by age 4 vocabulary on which using Dutch (L2) as the home language had significant effects. Moreover, they reported that home literacy practice, which was found to determine school literacy achievement, was strongly determined by socioeconomic status (SES) and race.

To some extent, these effects of home literacy practices on literacy outcomes may be mediated by their contribution to children's acquisition of the L1. Walters and Gunderson (1985) showed that Chinese immigrant children who heard stories read aloud in Chinese (L1) made significant gains in English reading and experienced no negative effects on their English reading achievement. However, as there was no control group, whether exposure to Chinese storybooks had direct effects on English reading skills or whether the gain in the reading achievement was caused by other factors is unknown. At any rate, it is important to note that such L1 exposure was not detrimental to children's school achievement. Similarly, Nguyen, Shin, and Krashen (2001) reported that Vietnamese students' competence in Vietnamese had no relationship with English literacy and that competence in spoken Vietnamese and high levels of the use of Vietnamese at home were not detrimental to the development of spoken English. That is, L1 use at home had neither positive nor negative effects on English language and literacy development for this population. Likewise, Rosenthal, Baker, and Ginsburg (1983) showed that Spanish-speaking language minority children's low academic achievement was explained more by SES and race than home language. They also found that Spanish language background for Hispanic children was strongly related to deficits in reading achievement at school, but that the language effect was much stronger for preexisting achievement levels than for learning over the school year. In other words, children who used Spanish at home may have started out scoring lower on measures of English literacy, but progressed as fast as English-only speakers, thus indicating no long-term negative effect of L1 use in the home on academic achievement in L2. In fact, though, such children need to progress faster than their English-only classmates if they are to perform at expected levels in later grades.

Though the impact of home language on L2 reading is somewhat equivocal, several studies have found that the percentage of English spoken at home is highly correlated with language minority students' English reading skills (Abedi, Lord, & Plummer, 1997; Beech & Keys, 1997; Connor, 1983; Kennedy & Park, 1994; Umbel, Pearson, Fernandez, & Oller, 1992). Beech and Keys found that Asian children who preferred speaking their L1 at home were significantly behind in English vocabulary development, controlling for nonverbal intelligence, although the impact on reading development was weak. The unexpected weak effects of vocabulary on reading

development that Beech and Keys found may be explained by the monolingual control group's low SES status; low SES children, like language minority children, are considered to be at risk for poor literacy development, especially for vocabulary knowledge. Abedi et al. reported that students who always spoke their L1 at home failed to complete as many test items as students who spoke only English at home. Umbel et al. also showed that Hispanic children who spoke both English and Spanish in the home scored higher on English vocabulary tests than those who spoke only Spanish in the home. These findings contradict Rosenthal et al.'s (1983) finding about the absence of long-term detrimental effects of L1 use at home on later school achievement. This further implies that a longitudinal approach is needed to examine the true relationship between home language use and L2 literacy development. It is only natural that 7- and 8-year-old children who are exposed to and use mainly L1 before starting school need to take some time to catch up and learn the new language. Thus, we should be more concerned about these children's L2 literacy skills after they have had plenty of exposure to L2 language and literacy than about their seemingly low performance in the early grades. Beech and Keys, Umbel et al., and Abedi et al.'s studies did not control for L2 learners' length of residence or length of schooling in the L2, and thus we should not jump to the conclusion that L1 use at the home is detrimental to later academic performance.

Interestingly, Kennedy and Park (1994) found that the role of home language had differential effects on the two ethnic groups of language minority children they studied: For Mexican American students, SES was the strong predictor of academic achievement, whereas home language was not. On the other hand, home language was a strong predictor for Asian American students' reading achievement on a standardized test: Asian American students who spoke English in the home performed significantly better than those who spoke L1 in the home. Such differences may be explained by the relevant language status of the two groups' L1 in the dominant society, the potential role of structural similarities and differences between L1 and L2, length of residency, and so on. Likewise, Fernandez and Nielsen (1986) found, somewhat paradoxically, that the L1 (Spanish) proficiency of Hispanic bilingual students was associated with greater academic achievement, whereas frequency of Spanish use had a negative effect on academic achievement. Their finding may reflect the fact

that the similarities in the linguistic and cultural properties of L1/C1 and L2/C2 facilitate positive influence on Spanish-speaking language minority children's L2 performance. Hence, those with high L1 proficiency may have developed an understanding about L2 linguistic properties in relation to their L1 and transferred their L1 knowledge to other relevant L2 academic settings, whereas merely speaking L1 frequently may reflect their reluctance to or inability to function well in L2.

This finding is somewhat related to what Rosowsky (2001) found with Muslim Mirpuri-Punjabi speakers in the U.K., although in that case, the children transferred their C1 literacy practice to L2 literacy skills. Although the Mirpuri-Punjabi-speaking children were not able to apply their L1 knowledge to L2 tasks, as their L1 does not share linguistic structural similarities with L2, they did as well as the English-monolingual children on English decoding tasks, possibly due to their C1, which emphasizes on accurate reading of the Qur'an. The same children, however, were lagging behind their monolingual counterparts on reading comprehension abilities, which require more C2 knowledge than decoding.

Because the literature shows considerable disagreement regarding the positive and negative effects of home language use on L2 literacy development, a firm conclusion cannot be drawn about the impact of continuity and discontinuity between home and school, which further implies that more in-depth and long-term investigation regarding the role of L1 use at home in different language minority groups' literacy and academic achievement is needed. However, these studies are quite convergent in showing that the amount and quality of home support for literacy development in either L1 or L2 relate strongly to L2 literacy achievement (Leseman & de Jong, 1998; Pucci & Ulanoff, 1998; Walters & Gunderson, 1985) and that L1 use at home does not impede L2 literacy development if it is accompanied by L2 use at home as well (Abedi et al., 1997; Beech & Keys, 1997). Thus, it is important for school literacy instruction to both provide support for and complement language minority students' home literacy experiences.

Possible Transfer Effects from First to Second Language: Evidence of Classroom Challenges Associated with Language Differences

The positive and negative effects of home language use on language minority students' literacy and school

achievement imply the potential existence of both positive and negative transfer effects from L1 on their L2 literacy development. Because such transfer effects may vary for different literacy domains, it is important to examine them for each of the component skills known to contribute to literacy achievement. For the review of literature relevant to each literacy domain, only those empirical studies that involve language minority learners learning the target language in a second language setting, as opposed to foreign-language setting, were considered.

Phonological Awareness

Research with monolingual beginning readers indicates that higher levels of phonological awareness are associated with beginning reading and spelling achievement (Adams, 1990; Bradley & Bryant, 1983). But the question remains whether the same relationship holds for bilingual children who may already have some degree of phonological awareness in their L1 but not in L2. In general, bilingual children seem to be better at phonological awareness tasks than English-monolingual children (Oller, Cobo-Lewis, & Eilers, 1998). Moreover, for bilingual children whose L1 and L2 share similar orthographic and phonological characteristics, there is not only transfer of phonological awareness between the two languages, but their L1 metalinguistic and phonological awareness account for significant variance in L2 literacy skills such as spelling, word recognition, pseudoword reading, and reading comprehension (Cisero & Royer, 1995; Comeau, Cormier, Grandmaison, & Lacroix, 1999; Durgunolu, Nagy, & Hancin-Bhatt, 1993; Gottardo, Yan, Siegel, & Wade-Woolley, 2001; Oller et al., 1998; Smith & Martin, 1997). Durgunolu et al., for example, tested Spanish-speaking first graders in a transitional bilingual education program in the United States on phonological awareness tasks and word identification skills in both Spanish and English. They showed not only that phonological awareness in Spanish was closely related to Spanish word recognition, but also that children who performed well on Spanish phonological awareness tests were more likely to be able to do well on English phonological awareness tests and, most important, on English word and pseudoword reading tests. That is, their L1 phonological awareness was a significant predictor of their performance on early literacy tasks both within and across languages. Similarly, Comeau et al. studied English-speaking grade 1, 3, and 5 children in French immersion classes and found cross-

language transfer in phonological awareness and word decoding skills.

However, such transfer of phonological awareness, which is predictive of early literacy skills in L2, may be constrained to the cases where L1 and L2 share similar phonological and orthographic properties. In fact, unlike Oller et al. (1998), who showed that Spanish-English bilingual children are better at phonological awareness tasks than English-monolingual children, Jackson, Holm, and Dodd (1988) found no difference between English-monolingual and Cantonese-English bilingual children's phonological awareness skills and found better performance of English-monolingual children on reading and spelling tasks as well as manipulation of phonemic information tasks. They also detected bilingual children's patterns of phonological awareness to be language-specific, related to the phonemic and syllabic structure of their L1. Their findings further indicate that bilingualism itself may not be a sufficient condition to heighten phonological awareness. These conflicting findings may be related to the differences in the orthographic characteristics of the two languages (alphabetic versus morpho-syllabic). In a similar study, Liow and Poon (1998) investigated phonological awareness of three different multilingual Chinese groups and showed that phonological awareness in L2 (English) was related to L1 orthographic depth and that tonal phonological awareness of the Chinese L1 children may not be optimal for English literacy development. However, neither study tested the bilingual children in their L1, so no conclusion can be drawn regarding the possibility of negative or zero transfer of bilingual children's L1 phonological awareness. Gottardo et al. (2001), on the other hand, did measure Chinese ESL learners' L1 phonological awareness using a rhyme detection test, and in accordance with research conducted with L2 children with alphabetic L1 backgrounds, showed that children's L1 phonological awareness was related not only to their L2 phonological awareness, but also to their L2 reading skills. This is a very important finding, for it "points to an underlying process that is not specific to the child's L1 phonology but that is related to the child's ability to reflect on all phonology to which he or she has a minimum level of exposure" (p. 539). Phonological awareness requires one to reflect on and manipulate the features of oral language. Gottardo et al.'s finding implies that children's ability to reflect on and manipulate structural features of a particular language can be applied to an L2, whether it is typologically different from L1 or not.

Regardless of the language minority children's L1 backgrounds, the positive relationship between phonological awareness and other literacy skills within L2 is still apparent, as in the case of monolingual children. And for children whose L1 and L2 share similar phonological and orthographic properties, developing or building on the children's L1 phonological awareness is likely to help their L2 literacy development. Questions still remain, however, about how to help language minority children whose L1 is very different from their L2. Spanish-speaking children's acquisition of phonological awareness skills in English and Spanish was found to be in the same order across languages (Cisero & Royer, 1995), but what would it look like if the child's L1 and L2 are typologically very different? More research needs to be done with different populations of language minority children to further shed light on the development of bilingual children's phonological awareness and other language skills and classroom practices.

Word Reading and Spelling

As would be anticipated from the findings relating phonological awareness to word reading, word reading is not normally an insuperable challenge to the language minority child. Lesaux and Siegel (2003), for example, have documented that L2 learners in English-only programs can achieve native-like levels of L2 word reading by the end of grade 2, if provided with systematic instruction and appropriate interventions if they are falling behind.

Most studies of language minority students' spelling development have looked at Spanish-speaking English-language learners in the United States and identified the challenges associated with language differences between L1 and L2. For example, studies of lower-grade Spanish-speaking language minority students have shown that L1 rules for spelling dominated when they were working on new words or pseudowords in L2 and that the L1 spelling system was applied to the L2 spelling task (Ferroli & Shanahan, 1993; Nathenson-Mejía, 1989). For instance, second- and third-grade Spanish-speaking children in Ferroli and Shanahan's study produced spelling errors caused by merged voiced versus voiceless sounds in the spelling system, as Spanish does not attend to differences in voicing as systematically as English does. Thus, some spelled *drink*, as *trink*, a Spanish-influenced spelling that differs from the correct spelling in a predictable way. Likewise, studies of language minority students' spelling in higher

grades also found that the influence of L1 was a predominant source of spelling errors in English (Cronnell, 1985) and that these children produced significantly more predicted L1-related errors than English-only children (Fashola, Drum, Mayer, & Kang, 1996). Moreover, L2 proficiency level was found to play an important role in spelling performance, as the less successful students produced significantly more L1-influenced errors than the more successful ones (Zutell & Allen, 1988).

Although there is not an abundance of studies with non-Spanish-speaking L1 language minority children, Wang and Geva's study (2003) with Chinese-speaking language minority students revealed similar L1 transfer effects in L2 spelling. Moreover, they were able to identify both effects of the L1 orthographic system and learning effects. The Chinese ESL students in Wang and Geva's study performed at a level similar to that of their English-monolingual counterparts in spelling real words. However, they performed significantly more poorly than English-monolingual children in pseudoword spelling. Also, the difference between real word and pseudoword spelling performance was much greater for Chinese ESL children than English-monolingual children. These results were explained by Chinese ESL children's reliance on the nonphonological route in spelling, the strategy employed and practiced for their L1 writing activities. Thus, when spelling unfamiliar words, they encountered difficulty in phoneme-grapheme mapping, which does not occur in their L1 because Chinese has a morphosyllabic orthography and is thus processed with the whole-word approach in spelling. For the same reason, the Chinese ESL children performed better than English-monolingual children in spelling visually presented orthographically legitimate/illegitimate and pronounceable/unpronounceable letter strings. That is, for the particular task that requires visual processing of letter strings, there was a positive L1-specific transfer for Chinese ESL children, who are used to processing letter strings visually as whole words.

In helping language minority children with L1 backgrounds both similar to and different from their L2, teachers need to be aware of the likely error patterns due to the L1 influence and the varying degrees of familiarity with both L1 and L2 phonological and spelling systems. To understand the differential effects of L1 spelling strategies of L2 students from diverse L1 backgrounds, however, studies need to be conducted that control for L1-specific spelling strategies, thus possibly comparing multiple ESL groups with similar L2 profi-

ciency level but whose L1s are orthographically different from and similar to English.

Vocabulary

Although it is known that vocabulary knowledge is related to reading comprehension ability for L1 children (Freebody & Anderson, 1983; Stanovich, 1986), there have been relatively few studies looking at language minority students' L2 vocabulary development in relation to their L1 background and literacy skills. Vocabulary is a crucial domain of literacy skills for L2 learners as well as L1 students, due to the reciprocal effects of vocabulary and reading comprehension and academic achievement in general: Vocabulary knowledge helps reading comprehension, and good reading comprehension leads to a natural process of new vocabulary acquisition.

The findings from the few studies on L2 learners' vocabulary knowledge in relation to their reading comprehension ability conform with studies with L1 learners. Nagy, García, Durgunoglu, and Hancin-Bhatt (1993), for example, not only found a positive relationship between L2 vocabulary knowledge and L2 reading comprehension scores, but also showed evidence of transfer of Spanish-English bilingual upper-grade students' L1 vocabulary knowledge to L2 reading. Moreover, they showed that such transfer is dependent on students' ability to recognize L1-L2 cognates in reading L2 passages. This particular finding holds important implications for literacy and reading instruction for language minority students whose L1 shares similar morphosyntactic features with their L2. In fact, Carlo et al. (2004) showed the positive effects of cognate instructions on Spanish-speaking English learners' English reading comprehension outcomes. However, such vocabulary instruction should take into consideration the L2 learners' level of L2 proficiency, as a certain level of L2 proficiency is required for guessing meanings of unfamiliar words in L2 reading contexts (Hancin-Bhatt & Nagy, 1994; Nagy, McClure, & Mir, 1997). Specifically, it was shown that Spanish-speaking English learners' ability to recognize cognates increased with age as their knowledge of the relationships between English and Spanish derivational suffixes became more concrete. Thus, cognate instruction should take into account the English-language learners' level of understanding of L1-L2 structural relationships.

As in the case of other literacy domains, however, we must be careful about the L1 backgrounds of the language minority children in assuming the positive trans-

fer effects of L1 vocabulary knowledge on L2 literacy skills. Verhoeven (1994), for example, found no predictive power of L1 vocabulary knowledge for L2 vocabulary development in Turkish-speaking Dutch learners in the Netherlands. Thus, more studies on the relationship between L1 vocabulary and the development of L2 literacy skills need to be carried out for language minority children whose L1 is morphosyntactically different from their L2. This, in turn, will yield useful guidelines regarding vocabulary instruction for L2 learners from diverse language backgrounds. The vocabulary (cognate) instruction for Spanish-speaking English learners was successful in Carlo et al.'s study (2004), partly because it relied on the interdependence of L1-L2. But what kind of instruction would benefit L2 learners from Vietnam, for example? What kinds of knowledge do the teachers need to know about L1-L2 relationships for those children to foster vocabulary improvement in L2? Studies addressing such questions will contribute to helping those children's academic achievement as well as reading comprehension.

Reading Comprehension

Research in the reading comprehension of language minority children has yielded evidence that L1 oral language and/or literacy skills can be both an asset and a hindrance in L2 reading comprehension, depending on age, L1 proficiency level, and L1 background.

Researchers have focused on Spanish-speaking English learners in studying the relationship between L1 literacy skills and L2 reading comprehension. Most of the studies are in agreement that those language minority children's L1 reading skills transfer to L2 reading comprehension (Calero-Breckheimer & Goetz, 1993; Langer, Bartolome, Vasquez, & Lucas, 1990; Reese, Garnier, Gallimore, & Goldenberg, 2000; Royer & Carlo, 1991). Calero-Breckheimer and Goetz, for instance, showed that third- and fourth-grade Hispanic students successfully transferred reading strategies between two languages, which contributed positively to reading comprehension in English. Likewise, Royer and Carlo found that the best predictor of English reading performance at the end of sixth grade was Spanish (L1) reading performance the previous year. In addition, Jiménez, García, and Pearson (1996) showed that successful Latina/o readers relied on various strategies, including transferring information and accessing cognate vocabulary across languages, whereas less successful readers were less effective in resolving comprehension difficulties in either language.

However, more careful investigation of the Spanish-speaking language minority children's background variables, including socioeconomic background, immigration status, and home language use, provided a more complex picture of such transfer. Buriel and Cardoza (1988) showed that Spanish oral proficiency and literacy skills predicted reading and other academic achievement variables only of the third-generation language minority children, but not the first- and second-generation children. Overall, the trend was for an increasing relationship of Spanish literacy to school achievement, including reading, across three generations. More specifically, third-generation students with greater literacy skills in L1 scored higher on the L2 reading test. Across three generations, however, L1 oral proficiency showed minimal relationship with L2 language and literacy skills, which further implies that L1 development does not hinder academic achievement in L2. The differential effect of L1 literacy skills on L2 reading across generations, however, does bring up an important issue: If a positive L1-L2 transfer of reading skills occurred only for the third-generation language minority students, those who probably had the most exposure to L2 language and literacy and spent the longest amount of time in the L2 setting, is a certain level of L2 proficiency or L2 input a prerequisite for such a positive transfer? Larger-scale studies with L2 learners from different language and cultural backgrounds within an ethnic group need to be conducted to get a more complete picture.

In addition, we need to pursue questions about L1 to L2 transfer for children from a wider array of L1 backgrounds, as most existing studies are limited to Hispanic students in the United States whose L1 rules and properties may contribute in unique ways to English reading comprehension. Connor (1983) looked at second- to 12th-grade students from 21 different L1 backgrounds and found that the percentage of English spoken at home and family SES had positive effects on reading skills in English, which, in a way, contradicts Nguyen et al.'s (2001) finding that there was no correlation between English reading performance on standardized tests and Vietnamese-speaking English learners' self-reported use of L1 at home. Nguyen et al. did not look at the relationship between the children's English use at home and English literacy outcomes to either support or argue against Connor's findings, although they did certainly show that L1 use at home is not a hindrance to L2 literacy development. On the other hand, Lasisi, Falodun, and Onyehalu (1988)

reported that seventh-grade Nigerian students performed better when reading culturally familiar passages than unfamiliar passages, which implies that the presence of cultural values in texts has an important impact on language minority students' performance in English reading. However, more studies are needed to generate a portrait of challenges and benefits associated with language minority students' language background in relation to their ability to read in English.

Furthermore, one should take into account the order of literacy instruction (submersion versus immersion) and the language minority students' proficiency level in both L1 and L2 before implementing any literacy instruction. Verhoeven (1994) suggested that the transfer of L1-L2 word decoding and reading comprehension abilities could be bidirectional, depending on the order of instruction. The reading comprehension abilities of Turkish-Dutch bilingual children in the Netherlands who were in the transitional bilingual education classes were predicted from their L1 reading comprehension abilities acquired earlier; likewise, Turkish-Dutch bilingual children who underwent an L2 submersion approach showed evidence of transfer in the opposite direction. The findings from Verhoeven's study have important policy and pedagogical implications for promoting L2 learners' academic achievement.

In general, the existing literature highlights the beneficial effect of L1 literacy skills for L2 reading comprehension and the importance of knowing which strategies and knowledge to transfer from L1 to L2 reading. This, in return, points out the importance of acknowledging and promoting language minority students' L1 literacy skills and instructing them on how to effectively use their assets for L2 reading comprehension.

Writing

There has not been much attention paid to the writing (composition) development of young language minority students, although many researchers have studied it in adult language minority populations. Lanauze and Snow's (1989) study is one of the few that looked at fourth- and fifth-grade Spanish-speaking language minority students' writing skills. They showed that children who were rated good in both L1 and English and children rated poor in English but good in L1 (Spanish) scored better in English and Spanish writing than the children rated poor in both languages. The children who were rated poor in English but good in Spanish produced English writing that was equivalent to that of the chil-

dren rated good in both languages in the complexity, sophistication, and semantic content of their English writing. In short, "One determinant of how early in the acquisition of the second language relevant L1 skills become available is their degree of mastery in the first language" (p. 338). Similarly, Nathenson-Mejía (1989), based on a single case study of a Spanish-speaking third-grader, suggested that the relationship between oral and written language is transactional, with benefits for language minority students. These results suggest the potentially facilitative impact of L1 literacy development on L2 literacy and academic skills. Writing is clearly an area in L2 literacy research that needs more attention and research, especially as it is a skill necessary for high academic achievement and success in upper grades and for higher education.

Possible Transfer Effects from First Culture to Second Language/Second Culture: Evidence of School/Classroom Challenges Associated with Cultural Differences

Relatively less attention has been paid to the effect of L2/C2 learners' cultural background on their literacy development in English and school achievement. The existing literature on cultural influences on literacy development falls into roughly three categories: (1) the relationship between C1/cultural familiarity with the C2 and literacy development, (2) discourse differences between home and school and their effect on L2 literacy development, and (3) the relationship between other cultural factors (e.g., SES, educational aspiration) and literacy development and school achievement.

Knowledge of the Second Culture

Research on the effect of cultural differences between home and school on L2/C2 learners' school achievement and literacy development has generated two very different findings. One set of studies found no relationship between C1 and school achievement, whereas the other set found that familiarity with C2 related to better school outcomes.

García-Vázquez (1995) found no significant relationship between measures of acculturation and reading comprehension skills of Spanish-speaking language minority students, which implies that acculturation to the dominant culture is not mandatory for high literacy achievement in English. Similarly, Abu-Rabia (1995) showed that cultural familiarity with reading material

made no difference in reading comprehension outcomes among Arab students whose English proficiency was stronger than their Arabic.

A larger set of studies, though, has shown that cultural familiarity and unfamiliarity with the dominant culture does influence language minority children's performance on reading comprehension (Abu-Rabia, 1998; Droop & Verhoeven, 1998; Hannon & McNally, 1986, Jiménez, 1997; Kenner, 1999; Rosowsky, 2001). Abu-Rabia reported that Arab students performed better on comprehension of Arabic cultural content regardless of the language of the text. Droop and Verhoeven identified a facilitating effect of cultural familiarity on reading comprehension and reading efficiency for Turkish and Moroccan language minority children in the Netherlands, whereas Rosowsky showed that language minority students' comprehension was far behind due to their lack of cultural familiarity with the meaning of texts, although they were able to decode text better than monolingual English-speaking children.

From the existing studies, it seems that, although acculturation does not always have an impact on literacy performance of L2/C2 learners, especially those with a high proficiency in L2, lack of knowledge of the dominant language and culture often has detrimental effects on school performance and literacy skills. Thus, it may be necessary for school literacy instruction to support the continuity of C1 to school and explicit instruction in meaning-making strategies for culturally unfamiliar topics.

Discourse Patterns

Studies that focus on discourse patterns indicate that language minority students benefit from school interaction patterns that are similar to those in their home (Au & Mason, 1981; Ballenger, 2000; Hudicourt-Barnes, 2003; Huerta-Macias & Quintero, 1992; Wilkinson, Milosky, & Genishi, 1986). Au and Mason showed that native Hawaiian children's academic engagement, including reading activities, was facilitated when the classroom instructional interaction was compatible with that of their home. Similarly, Huerta-Macias and Quintero reported beneficial effects of code switching at school for biliteracy development of the language minority students who were used to code switching at home. Wilkinson et al. also found a positive relationship between reading achievement and displaying school-appropriate interaction patterns for Hispanic children. In short, studies are in agreement that ac-

knowledgment of and sensitivity to language minority children's C1 support their literacy development in L2.

Additional Cultural Variables

Although many researchers have examined the influence of parents, family, home culture, and community on L2 literacy and school achievement, no study has documented their exact relationships or effects. The majority of such studies failed to report significant relationships (Buriel & Cardoza, 1988; Duran & Weffer, 1992; Goldenberg, Reese, & Gallimore, 1992). Duran and Weffer, for example, found that parents' educational values were not directly related to ninth-grade reading and 12th-grade school achievement of Mexican American high school students, although they did influence student behavior at school positively; such family educational values affected students' willingness to take math/science enrichment classes, which was significantly related to increase in related academic achievement. Likewise, Goldenberg et al. showed that home literacy practice was not as strongly related to Hispanic language minority children's reading achievement as school use of literacy materials and that parent expectations changed as a result of their child's school performance but not vice versa. Monzó and Rueda (2001) indicated a positive relationship between family literacy practices and resources and children's reading motivation, but their sample size was too small ($N = 5$) to make a general claim.

Kennedy and Park (1994) reported that the significant relationship between use of English at home and reading achievement at school for Hispanic children disappeared when SES was controlled, which suggests that the SES effect on English reading achievement was stronger than the effect of L2 use for this particular language minority group. However, the same was not true for Asian students; the relationship between their home language use and achievement remained significant even with SES controlled. However, little is known about the effect of SES on literacy and school achievement of language minority students in particular, although significant influences may be assumed from other sets of research with English-speaking children (Cook, 1991; Stubbs, 1980).

Summary

Our review of the literature on L2/C2 learners' performance on the key components of literacy demonstrates

the complexity of L1/C1 and L2/C2 relationships and how they vary as a function of the L1's cultural as well as linguistic characteristics, students' and parents' commitment to L1 as well as L2 language and literacy development, the social status of L1, length of residence, and immigration and socioeconomic status. In addition, the L1-L2 relationship is not always the same across different subcomponents of literacy skills, depending on the L2 learners' L1 and L2 proficiency level, degree of similarities and differences between the two languages, and home language use as well as home literacy practice. However, the literature generally agrees on the following:

- L1 and C1 knowledge and skills are not the main source of L2 learners' poor performance on L2 literacy tasks or academic failure. In most cases, they have positive effects on L2 literacy development, even when L2 is typologically different from L1.
- L1 maintenance and use does not impede L2 language and literacy development.
- L2 learners, in many cases, apply their L1 and C1 knowledge and skills to L2/C2 tasks, although sometimes they need instruction on how to transfer L1 knowledge effectively.
- L2 learners benefit from L1- and/or C1-sensitive instructions in L2 literacy development and academic achievement.
- Full acculturation may not be necessary for academic success, but knowledge of C2 does make a difference in reading comprehension and academic achievement.

In general, this survey of recent literature on transfer of L1/C1 literacy-related skills to L2 literacy development has shown both positive and negative relationships between L1 language/literacy skills and L2 literacy achievement. Except for the case of spelling, most studies show that L1 oral and literacy skills are positively correlated with equivalent skills in L2, but of course such positive correlations, though they are consistent with a transfer explanation, hardly constitute strong evidence in support of it. Perhaps learners with better skills in L1 are just smarter and thus faster in acquiring skills in L2.

Most important, we have only hints about the conditions under which transfer is most likely to occur and most likely to be positive and productive. We know, furthermore, that there are many opportunities for transfer

that are missed; for example, Spanish-speaking learners of English are unaware of the value of cognates until taught to use them (Nagy et al., 1993), and even then, students with limited literacy skills in Spanish are unable to recognize many potential cognates that give clues to word meaning. Jiménez (1997) reported on a small number of native Spanish speakers who were poor readers in English and who professed that reading in English and in Spanish were quite different, whereas his small group of better English readers said they used many of the same strategies in both languages, having evidently discovered the value of transfer on their own. Much more research needs to be done on how and when transfer functions, how it is related to differences between the L1 and the L2 and orthographic system, as well as how age, instruction, the sociolinguistics of the language community, and other factors affect the likelihood and the utility of transfer. With this enhanced knowledge base, we could offer stronger arguments about the value of encouraging language minority students' continued development of L1 language and literacy knowledge as an influence on their successful development of L2 literacy skills.

PROGRAMS DESIGNED FOR SECOND LANGUAGE/SECOND CULTURE LEARNERS

Given the long history in the United States and in northern Europe of immigration and of academic underperformance among immigrant students, it is surprising and unfortunate that we still lack incontrovertible evidence about key aspects of programs that best support the development of such children. There is, however, sufficient basis for arguing that certain instructional features contribute crucially to program effectiveness. In this section, we briefly review available evidence about the qualities of effective programs for preschoolers and elementary students, note those domains for which more evidence is needed, and provide sketches of some programs that exemplify both the features shown to be effective and the difficulties of implementing those features widely and consistently.

Preschool-Age Children

Programs designed for preschool-age L2/C2 learners should incorporate opportunities for the children to develop warm relationships with the adult caregivers/educators, rich opportunities for language interaction,

varied opportunities for engagement in literacy activities, and opportunities to acquire knowledge, concepts, and theories about the physical and social world through observation, conversation, discussion, and engagement with books. These features are, of course, precisely those that characterize good preschool education for any child; considerable evidence suggests that they are of particular importance in ensuring good outcomes for children at risk of poor academic outcomes, including children who have limited control over the language and culture of the schools they will attend.

We lack direct evidence concerning language use in preschool programs serving L2/C2 learners. Some would argue that the key characteristics of good programs—warm relationships with adults, access to concepts, theories, and new knowledge, and engagement in rich language and literacy activities—are unlikely to be present in an environment where the only language children know is not used. Others would respond that young children can quickly learn enough of the L2 encountered in the preschool to establish warm relationships with responsive adults, and that the task of acquiring rich language skills in the school language is best started earlier rather than later.

A Few Illustrative Cases

U.S. Head Start programs serve a large and increasing population of English-language learners. Head Start programs are held accountable for standards set centrally but have local control over the specifics of program design. There is some disagreement within Head Start about program responsibilities for teaching children English. Some Head Start administrators and personnel interpret the responsibility to prepare children for school as dictating that they be taught English; others argue that the greater responsibility is to provide children with the social and academic skills that would ease English acquisition once they get to English-medium classrooms.

The historical shift toward all-English programs for immigrant children in elementary schools has had its influence on Head Start program design, increasing the pressure to provide English skills to preschoolers and diminishing the value associated with support for the L1 language and literacy skills. Nonetheless, one of the standards with which Head Start programs must comply is availability of adults who speak the children's native language; for English-language learners, that adult sometimes is the classroom teacher, more often is an aide, and not infrequently is someone working in the office or the kitchen rather than a part of the educational staff.

In 1996, members of the Language Diversity Project team of the New England Head Start Quality Research Center¹ started working with a large Head Start program near Boston, in a town we refer to as Witham. Witham's Head Start served a population that was approximately 40% Spanish-speaking, and that ratio was reflected in each of the classrooms in the program. Most of the classrooms had a Spanish-speaking aide or assistant teacher and an English-speaking head teacher. Because the Witham public schools had a thriving bilingual education program, it seemed to us that promoting the Head Start children's Spanish skills, and their literacy skills through Spanish-language activities, might well be an approach worth considering. Thus, we proposed to the Witham Head Start director that Spanish-medium classrooms be established to serve Spanish-speaking and bilingual children. We offered to provide professional development and other forms of support to the teachers in such classrooms and to collect data on child performance that could be used by the program.

Though initially enthusiastic about this proposal, after reflection the Witham director pointed to a number of difficulties. First, there was only one fluent Spanish speaker on his staff qualified to serve as a head teacher. Second, he felt that parents would object if 4-year-olds were not receiving opportunities to learn English in the program. Third, and most frustrating, he noted logistical difficulties because classroom assignment was determined to a large extent by bus routes; the children who were bussed together would probably be a mix of Spanish and English speakers rather than language-homogeneous.

Despite these difficulties, it did turn out to be possible to create and study a single classroom in which two Spanish-speaking teachers developed and implemented a curriculum designed for a group of 3-year-olds. The coteachers in this classroom were Ana, formerly an English-medium Head Start teacher and a native bilingual with stronger literacy skills in English than in Spanish, and Luisa, a Spanish-dominant bilingual who previously had worked as a Head Start teacher in Puerto Rico and an assistant teacher in Witham Head Start classrooms. Regular professional development with Ana and Luisa was carried out by Aceves (2003), who also systematically

¹The Language Diversity project researchers working in Witham included Consuelo Aceves, Lilia Bartolome, Catherine Snow, and Patton Tabors; David Dickinson was the director of the New England Head Start Quality Research Center.

studied the language use and progress of the children in their class.

There are four kinds of data that cast light on the success of the language intervention in this classroom: teacher interviews conducted by Aceves and Bartolomé, observations of classroom practice conducted by Aceves, child language performance data collected by Aceves, and observations of child social and task-mastery skills collected by Bronson and Fetter (1998). In interviews, both Ana and Luisa reported that the complexity and sophistication of their curriculum was much greater in the Spanish-medium classroom than it had been in other years when they taught mixed-language groups all in English. In the observations, the sophistication of their language use, the levels of participation of their students, and the complexity of the topics they introduced into their curriculum were striking. Their classroom was characterized by curricular units (e.g., deep sea life) that one might encounter in a 4-year-old preschool classroom or even a kindergarten, and it was very different from the routine-oriented classroom, with simplified language and little formal curriculum, described by Tabors (1997) as the pedagogical response to a group composed mostly of L2/C2 learners. Language testing revealed that the children in Ana and Luisa's class made more than the expected gains in Spanish vocabulary over the year, and improved as well in English vocabulary despite the fact that their formal exposure to English was limited to 30 minutes a day of ESL. Finally, Bronson and Fetter's comparisons of these Spanish-speaking 3-year-olds to Spanish speakers in English-medium classrooms in the same Head Start program revealed them to be more socially competent and to score higher on task mastery.

In short, the experience of the adult participants and the test data strongly support the effectiveness of native-language preschool instruction in promoting children's overall development and documents the absence of negative effects on English development. Ana and Luisa taught a Spanish-language 3-year-old classroom for a 2nd year, with considerable interest from parents who had heard about the first year's experience. During the 2nd year, they became consulting teachers to their colleagues, because there was general recognition within the program that they were doing a very effective job of teaching and organizing their classroom. Given these successes, one might have expected the model to become a permanent option in the Witham Head Start program and to expand to more classrooms.

Unfortunately, neither of those things happened. The innovation was brief and limited, and both Ana and Luisa were back teaching in English-medium classrooms after 2 years. There was simply insufficient support from the administration of the Witham Head Start and insufficient data as to the value of the program to be able to keep it alive. The termination of the Language Diversity Project also meant that expectation of support and resources from Harvard associated with the intervention dwindled. Like many educational experiments, this remained a demonstration that never rose to the level of becoming standard practice.

The story of the Spanish-language classroom in Witham has been repeated dozens of times. A similar case studied by Wagenaar (1993) in the Netherlands was a preschool program delivered in Moroccan Arabic for the benefit of Moroccan children. The large numbers of Turkish and Moroccan children living in the Netherlands have very much the same achievement profile as Spanish-speaking children in U.S. schools. These children tend to live in relatively homogeneous, immigrant neighborhoods. They attend schools referred to in Holland as "black schools," emphasizing the paucity of ethnic Dutch children in them. They live in families in which the parents tend to maintain the ancestral language; many of the mothers are monolingual and have limited literacy skills in either the L1 or in Dutch.

The program Wagenaar (1993) studied started with 3-year-olds, this being the age at which public preschool normally begins in the Netherlands. It was conducted in Moroccan Arabic and welcomed mothers to spend time in the classroom and observe or take part in the activities designed to build children's classroom participation skills as well as basic numeracy, literacy, and world knowledge.

Like the Witham native language program, the Amsterdam program was judged highly successful by participating families and teachers. The children showed considerable gains in Arabic-language skills in comparison to other Moroccan children in traditional Dutch-language programs and, again like the Witham program, showed no comparative deficits in Dutch, though they continued to test below the level of monolingual Dutch-speaking children.

Again like the Witham program, the Amsterdam program (originally intended to develop into a full-fledged bilingual program as the children entered the elementary grades) lasted only 2 years. Logistical challenges

that simply could not be overcome included availability of sufficient numbers of qualified teachers who were fluent in both Moroccan Arabic and Dutch, and the difficulty of either excluding from the program or serving adequately within it the minority of Berber-speaking Moroccan children, for whom the program was ill-designed. Additional contributing factors certainly included the low perceived value of Moroccan Arabic in the Netherlands, and indeed its somewhat diminished role as an academic language even in Morocco, where standard Arabic is taught as the initial language of literacy and French is the language of higher schooling.

Failure of the capacity to develop and sustain sufficient numbers of programs like the Moroccan Arabic preschool studied by Wagenaar (1993) has led Dutch educators to abandon attempts at native-language schooling and to develop instead Dutch-language enrichment preschool programs designed for nonnative speakers. Three such programs that have been studied in some detail are the Dutch adaptation of the Israeli home-based program called HIPPY and the center-based programs Kaleidoskoop (a Dutch adaptation of HighScope) and Piramide. These three programs are notable for their minimization of explicit attention to the linguistic and cultural knowledge the children bring with them. They operate on a simple target language/target culture model: There are certain skills and capacities that children who will be successful in school need to have, and because their home does not naturally provide them, the programs are designed to teach them. Parent participation in the center-based programs is encouraged, in part because it is thought to be a route toward the acquisition of Dutch linguistic and cultural knowledge for the mothers, who might otherwise be somewhat isolated from Dutch society. Evaluation studies have shown no significant effect of the HIPPY program in the Netherlands (Eldering & Vedder, 1993), but the two center-based programs, Piramide and Kaleidoskoop, have generated gains for participating children (Schonewille, Kloprogge, & van der Leij, 2000; Veen, Roeleveld, & Leseman, 2000).

Immigrants to the Netherlands share with the indigenous population a sense that Dutch norms need to be acquired, and that their own languages are somehow unsuited to schooling. Kook (1994) and Muysken, Kook, and Vedder (1996), describing parent-child interaction among Papiamentto-speaking immigrants to the Netherlands from the Dutch West Indies, noted that even those

mothers whose Dutch was very limited would switch to Dutch when presenting certain "academic" content to their preschool-age children, for example, numbers, shapes, and colors. Afkir (2002), in a study of low-income Moroccan mothers interacting with their kindergarten-age children, noted a similar switch from Moroccan Arabic to French for academic content; in this case as well, the mothers themselves possessed minimal skills in French. There is indeed a general sense in multicultural and/or multilingual settings that some languages are worth more than others and are more appropriate for formal tasks, for literacy, and for academic practices; this sense, which may well be unexpressed, is shared by policymakers, the public at large (as indicated by Ron Unz's success in passing referenda limiting bilingual education), many educators, and even parents who themselves have little education and minimal control over the language of power. The specifics of these consensual valuations of language are sometimes puzzling; it may not seem strange that Creole languages like Papiamentto and Haitian Kreyol, which have few native speakers and relatively brief literary traditions, easily give way before standard, national languages like Dutch and English. But why should Arabic, a language of high culture and long-standing literacy, and the fourth most widely spoken language in the world, be of less value in school than French or Dutch (a language spoken by fewer than 25 million people, almost all of whom speak another European language fairly well)? Nonetheless, Arabic has little status in Holland or in France, with severe consequences for the potential of North African immigrants in those nations to be successful students in their L2 or to maintain their L1 at high levels of proficiency or literacy.

Elementary School Programs

For elementary school programs, theory as well as the wisdom of practice would lead to the conclusion that programs that incorporate the native language have an advantage for one segment of the population: those children who are at some risk of difficulty in learning to read and who have not acquired literacy skills in their native language. The Committee on the Prevention of Reading Difficulties in Young Children (Snow et al., 1998) recommended native language literacy instruction specifically for that group; at the same time, they suggested the postponement of literacy instruction until

children had acquired some oral English and strong emergent literacy skills.

The argument presented by the Committee on the Prevention of Reading Difficulties focused on literacy outcomes as the primary goal of native language instruction; in other words, it argued from the presupposition that the basics of literacy should be taught in a way that optimizes access to meaning, and that transfer of L1 literacy skills to L2 would be more efficient than teaching L2 skills directly. As noted earlier and acknowledged by the Committee, this recommendation is not strongly supported by evaluation data, though the more scholarly and politically neutral meta-analyses of English-only versus bilingual programs (e.g., Willig, 1985) generally come out showing small positive and no negative effects for bilingual education.

Transitional Bilingual Programs

The term “transitional bilingual program” is used for programs that are designed to ease the language learner’s entry into schooling in the majority language. They are formally distinguished from various sorts of maintenance bilingual programs, which are designed to support development of oral and literacy skills in the native language with true bilingualism as the outcome. In fact, though, the classroom activities that go on in transitional versus maintenance programs may not be radically different. In each type of program, on the other hand, there is considerable heterogeneity of pedagogical approach and language use. The most common arrangement in bilingual programs of both types is that a single, bilingual teacher is responsible for the delivery of instruction in both the L1 and the L2, operating with some more or less formal guidelines for amounts of L1 and of L2. Very few programs separate language by teacher, pairing an English speaker with an other-language speaker in serving two classes. Some programs separate language by subject matter, teaching math, art, and music, for example, in English, and teaching reading, social studies, and science in the L1. Other programs prescribe use of both languages in all subjects, for example, presenting new material in the native language and then teaching it again in English to provide the relevant English vocabulary. Alternatively, teaching might go on primarily in English, with use of the native language to repeat and reinforce lessons that some children struggle with. Sometimes literacy is taught first in the native language and subsequently in English, but most often literacy is taught simultaneously in both languages

but at different times of day. Some programs even prescribe that every teacher utterance be produced in both English and the children’s L1—an approach almost certain to lead students to ignore half of what is said.

Two-Way Bilingual Programs

Some educators (e.g., Christian, 1994) have made the more millennial argument that bilingual education is of value not just as a way of reducing risk for L2/C2 learners, but as a way of promoting bilingualism. Maintenance programs, for example, are designed not only to teach English and transfer students into mainstream classrooms as quickly as possible, but to teach literacy, language arts, and content in both the native language and in English, with the goal of producing highly proficient bilinguals. A particular approach to maintenance of L1 skills for L2 learners is represented by two-way bilingual (also called two-way immersion) programs, in which L2/C2 learners and English-only students study together in classrooms where half the instruction is provided in English and half in the other language.

Evidence about the conditions under which two-way programs are successful for all their students is accumulating (Cazabon, Lambert, & Hall, 1998; Howard, Christian, & Genesee, 2004). The major challenge in such programs is not the acquisition of English by the language minority students, but the acquisition of the other language by the English speakers. Creating conditions under which English speakers devote time and energy to L2 learning is not easy (another symptom of the high status of English), and the obstacles to keeping the other language robust in such programs are many. What are these obstacles? They range from within-classroom effects to the consequences of school, district, and statewide policies. They can be overcome only by ensuring that changes are made at all four of these levels of organization simultaneously.

One study of fourth- and fifth-grade classrooms in a two-way bilingual school (Carrigo, 2000) documented the many classroom-level contexts that led to use of English, even during the part of the school day designated as Spanish time. When groups of native English speakers were working together, they were very unlikely to speak in Spanish, even if their work involved Spanish texts; teachers interacting with such groups often accommodated to their language choice. When student groups included both native English and native Spanish speakers, again there was a strong tendency for peer and teacher talk to be in English; this reflected both the

fact that the Spanish speakers were more proficient in English than the English speakers were in Spanish, and that English was the high-status language among the students. Only in small groups where all the students were native Spanish speakers did group work and teacher talk reliably occur in Spanish. Although the Spanish-speaking students had access to quite sophisticated Spanish-language use during these interactions, they were not very frequent, and native English speakers had few opportunities to participate in Spanish-rich discussions.

The principal of another two-way school, which we call Clemente, recognized a similar problem in her school: The teachers deviated massively from the planned use of Spanish in the higher grades, reverting to almost 100% English. The teachers reported that many of the children in their classes simply couldn't understand Spanish, whereas everyone could understand English. How can one explain this outcome in a school that had provided systematic Spanish and English instruction from kindergarten? Several factors emerged as relevant. First, Clemente was a Success for All school, and the Success for All program, with its required daily 90-minute literacy block, was delivered entirely in English. Thus, the 50–50 split between Spanish and English started only after the most intensive teaching of the day had ended. Second, the Clemente School and the district in which it was located were under considerable pressure to show adequate improvement on the mandated statewide test. The superintendent required in-class test preparation programs be used in third and higher grades in all the schools, such as Clemente, which were in danger of showing inadequate progress. The test preparation activities absorbed at least 90 minutes a day between January and April and were, of course, all carried out in English. Third, Clemente was located in a very mixed neighborhood, not a homogeneously Latino or Spanish-speaking part of town. Every year, in every grade, new students were enrolled whose parents were not seeking a two-way program but had picked Clemente for convenience. These English-only speakers were unable, if they entered in third or fourth grade, to follow instruction offered in Spanish. All these factors led to a situation in which Clemente was offering a two-way program in name only. In kindergarten through second grade, the program was perhaps 30% Spanish, and in third and higher grades perhaps 15% Spanish. Thus, it was not surprising that many English-speaking children failed to learn much Spanish, and that Spanish speakers were soon opting as

well for the default language, English, for in- and out-of-classroom interactions.

What factors are associated with better adherence to the principles of two-way programs? First, the sociolinguistic reality that English is more highly valued than other languages has to be recognized and acknowledged in program designs; programs are more successful if they counteract that reality by making the other language unavoidable. They can do this by instituting preschool programs that are delivered entirely in the other language; such programs function as enrichment for the other-language speakers and as immersion L2 settings for English speakers. They can adopt so-called 90–10 or 80–20 designs, in which kindergarten instruction is heavily weighted to the other language, with a gradual shift to a 50–50 balance of language use by third grade. Some programs find that they still need to reinforce the other language by offering afterschool and/or summer school activities that are highly engaging and monolingual, banning the use of English in these settings.

Second, the natural tendency to accommodate to the less proficient speakers of a language has to be counteracted. Two-way programs should be able to exclude monolingual English speakers as new entrants after kindergarten or grade 1, and transfer to other programs students who are not making expected progress in the L2 within the program. Two-way programs need extra resources so they can offer L2 courses for parents, both in English for the immigrant parents and in the other language for English-only parents. How can parents help with homework, after all, if they don't speak both of the languages in which their child is studying?

Third, the value of bilingual outcomes should be acknowledged by the district and the community, for example, by reporting children's scores on tests administered in the other language as well as in English, by establishing some level of other-language proficiency as a high school graduation requirement, and by featuring the two-way programs as high-status magnet programs rather than treating them as remedial.

Supporting Second Language/Second Culture Learners in Predominantly English Instruction

We made the argument that students could transfer knowledge acquired in their L1 and C1 to be more efficient and effective L2/C2 learners. But we also presented evidence that transfer is neither automatic nor inevitable. Transfer is more or less likely, and more or less helpful, as a function of the L1-L2 and C1-C2

relationships, the specific L2/C2 learning task, the degree of metacognitive capacity of the learner, and the skill of the teacher. Many students simply fail to recognize or exploit knowledge they possess that could help them solve L2/C2 problems. Of course, this specific problem of ensuring that learners transfer knowledge from a well-established to a novel domain of functioning is ubiquitous in education. But it is particularly acute for the L2/C2 learner, who is in the position of having to learn more than the monolingual student, and to catch up with monolingual levels of functioning in less time. Helping L2/C2 learners meet or even surpass the academic achievement of their monolingual classmates requires figuring out how to help them turn their L1/C1 knowledge into an asset through transfer.

One such attempt was the Vocabulary Improvement Project (VIP), a vocabulary intervention designed to enrich fourth- and fifth-grade Spanish-speaking English-language learners' academic vocabulary in English (L2) through helping them make use of their vocabulary and linguistic knowledge in L1 and promoting L1-L2 transfer (August, Carlo, Lively, McLaughlin, & Snow, 2005; Carlo et al., 2004; Lively, August, Carlo, & Snow, 2003). The VIP was initially designed in accordance with research indicating that vocabulary knowledge was one of the key predictors of students' performance in reading comprehension; furthermore, vocabulary knowledge sufficient to ensure comprehension of moderately complex texts creates opportunities for new vocabulary learning (Fukkink & de Glopper, 1998). The VIP focused on teaching children strategies for word learning as much as new vocabulary items. Those strategies, furthermore, were directed at various aspects of lexical knowledge, including morphology (affixes, frequently occurring Latin and Greek roots), recognizing multiple meanings of words, thinking about semantic associations (e.g., superordinates, antonyms, near synonyms), and the metalinguistic knowledge required to give definitions (Lively et al., 2003). That is, the VIP not only taught *words*, but also taught *about words*, so that the children could both develop skills to infer word meanings independently and develop curiosity about words. What is more, by teaching cognate use and previewing each lesson in Spanish before introduction in English, the VIP encouraged Spanish-speaking English-language learners to use their L1 knowledge to improve their vocabulary knowledge and text comprehension.

After the 15-week intervention, introducing 10 to 12 target words each week for 30 to 45 minutes, 4 days a

week, the VIP was found to improve children's performance in reading comprehension, word knowledge, and metalinguistic analysis of novel vocabulary items (Carlo et al., 2004; Dressler, 2000). Both the English-language learners and the monolingual English speakers showed improvement, but the English-language learners did not improve at a faster rate; in other words, the curriculum was effective but, in the short run at least, did not contribute to closing the gap between English-language learners and their monolingual classmates.

The VIP undertaking provides a salutary lesson about the relation of applied and basic research to practice, and vice versa (see Selman & Dray, Chapter 10, this *Handbook*, this volume). This project was conceived as one in which we collaborated with teachers to design the curriculum. Two 3-day meetings were held at which participating researchers and teachers shared insights from the research literature and from classroom practice and developed ideas about how best to promote vocabulary development. Although those meetings were energizing, they did not in fact generate a usable curriculum. Most of the participating teachers represented themselves as already paying a lot of attention to vocabulary development in their classes, but the techniques they suggested (giving children dictionaries, repeating English words with Spanish phonology so as to remember the spelling, using word walls) were neither innovative nor sufficiently effective. Thus, having failed with at least that approach to seeking inspiration from practice, the research team reverted to the traditional transmission model; we reviewed the basic and applied research about vocabulary acquisition, designed the curriculum on that basis, carefully observed its implementation and collected information from the teachers using it about its flaws, and then produced an improved design for the next year of the study.

Reverting to practice-embedded work in studying the implementation taught us a crucial lesson: This curriculum makes a very great demand on teacher knowledge. Several of the teachers would have required considerable professional development to ensure that they understood enough about linguistics and second-language acquisition to implement the curriculum faithfully (White, 2000). For example, doing a good job with the lessons devoted to promoting cognate use required some knowledge of Latin, Spanish, or another Romance language, which many of the teachers did not have. Some understanding of the morphological structure of English was presupposed in the lessons we designed. Indeed, we also presupposed (incorrectly, in a few cases) that the teach-

ers would already know the correct pronunciation and use of the words taught in the curriculum. Knowledge about English, knowledge about linguistics, and cross-linguistic knowledge were all needed if teachers were to optimize the learning the VIP was designed for. Valuable opportunities for the teachers, especially those in diverse classrooms, to understand the exact linguistic and metalinguistic challenges their English-language learners are going through must occur in combination with supplying good teacher manuals and a well-designed curriculum.

Despite its success in promoting positive L1-L2 transfer in Spanish-speaking English-language learners as well as supporting vocabulary and reading comprehension in monolingual English speakers, the intervention has not survived as an intact instructional program in any of the classrooms where it was introduced. It has generated a published curriculum designed for fourth-, fifth-, and sixth-grade English-language learners (Lively et al., 2003); a larger-scale evaluation of the effectiveness of the curriculum is, of course, needed.

Another curriculum that aimed to promote English-language learners' academic performance by being sensitive to their linguistic and cultural background was designed by the Chèche Konnen Center for teaching science to Haitian Creole-speaking upper-elementary and middle school English-language learners. Previous studies (e.g., O. Lee & Fradd, 1996) had concluded that Haitian children were nonverbal and incompetent in science classes. Based on an understanding of the essentially oral Haitian culture and of the common Haitian practice of *Bay Odyans* ("chatting" or "science argumentation"), the research team of the Chèche Konnen Center encouraged the use of such discourse during science classes, supported the use of the students' L1, Haitian Creole, and incorporated students' existing knowledge into science teaching. Thus, the program not only supported bilingualism by encouraging the use of L1, but also showed sensitivity to the C1 by making use of their C1 discourse practice. The research team found that the Haitian students provided with a culturally familiar setting showed growth in learning behaviors and science knowledge similar to that of the mainstream students (Ballenger, 2000; Hudicourt-Barnes, 2003). More rigorous and large-scale evaluations of this approach to science instruction for Haitian immigrants are needed.

The Chèche Konnen project differed from traditional approaches to teaching Haitian children both in the contexts created for learning and in the assessment procedures used. O. Lee & Fradd's (1996) study used tradi-

tional testing, whereas the Chèche Konnen classroom used discourse-embedded assessments. Thus, curriculum design that utilizes English-language learners' L1 and C1 in academic content areas may need to be supplemented, not just by teacher professional development, but also by language- and culture-sensitive measures to assess English-language learners' growth and development in learning.

CONCLUSION

We have sketched the challenges that becoming literate poses to all learners, then elaborated evidence that learning to read is a particular challenge for the L2/C2 learner. There were two themes in our analysis. The first is the complexity of the challenges posed, both to newcomers in a society and to the locals who are responsible for teaching, working with, or interacting with the newcomers, by the need to learn each others' languages, literacies, discourse patterns, and culturally prescribed ways of operating. We have argued that, if L2/C2 learners are to catch up with monolinguals in the academic, linguistic, and literacy skills needed for success in school and in the workplace, educational procedures are needed that enhance transfer, thus exploiting the knowledge of the L1 and C1 that learners bring with them. The second theme is the need, in complex and multifaceted domains like second-language learning and education for language minorities, for practice-embedded and practice-inspired research to complement the contributions of traditional basic and applied research. The fastest route to understanding what educational treatments work best to ensure language and literacy acquisition for various subgroups of L2 learners is to study successful practice, to build on the wisdom accumulated by successful practitioners, and to systematize that wisdom to be able to test it and make it public.

Learning Is Situated and Collaborative 125

Summary 126

Mathematics education is incontestably one of the most representative examples of the subject matter orientation in instructional and developmental psychology. As shown by Kilpatrick (1992; see also Ginsburg, Klein, & Starkey, 1998), mathematics education and psychology have been intertwined throughout the past century, but for a large part of that era the approaches from both sides were complementary rather than symbiotic. On the one hand, psychologists used mathematics as a domain for studying and testing theoretical issues of cognition and learning; on the other hand, mathematics educationists often borrowed and selectively used concepts and techniques from psychology. Sometimes the mutual attitude was critical. For instance, Freudenthal (1991) criticized psychological research for disregarding the specific nature of mathematics as a domain and of mathematics teaching; others, like Davis (1989) and Wheeler (1989), reproached psychologists for taking mathematics education as a given and uncontroversial, without questioning its current goals and practices. However, especially since the 1970s, an increasingly symbiotic and mutually fertilizing relationship between both groups has emerged, facilitated by the growing im-

CONCLUSIONS 145

REFERENCES 146

part of the cognitive movement in psychology and by the creation of interactive forums such as the International Group for the Psychology of Mathematics Education founded in 1976. Today, the domain of mathematics learning and instruction has become a fully fledged and interdisciplinary field of research and study, aiming at a better understanding of the processes underlying the acquisition and development of mathematical knowledge, skills, beliefs, and attitudes, as well as at the design—based on that better understanding—of powerful mathematics teaching-learning environments.

A parallel trend is the rapprochement in past decades between developmental and cognitive psychology. For a long time in the history of psychology, both subdisciplines adhered to different, even conflicting paradigms. Whereas developmentalists considered development as the necessary prerequisite, and sometimes even the final goal of education, learning and instructional psychologists believed that cognitive development in general is not the prerequisite but the result of education (De Corte & Weinert, 1996). In contrast to these extreme positions, there has developed, especially since the last 2 decades of the preceding century, a strong movement

toward a synthesis of the concepts of development, learning, instruction, and the interactive mind. As argued by De Corte and Weinert:

First of all, there is convincing theoretical and empirical evidence that not only the relationship between development and learning but also the relationship between instruction and learning is very complicated. Maturational precursors, implicit learning, and self-organizing processes that spontaneously integrate new information with already available knowledge all mean that cognitive development always entails more than the sum of explicit learning processes. In addition more must be learned than can be taught. These restrictions on the importance of explicit learning do not mean that school learning and deliberate practice are unimportant for cognitive development. Quite the opposite: to a considerable degree cognitive development consists in the acquisition of expertise in a variety of content domains. (p. xxvii)

As a result of these trends, the boundaries between developmental and instructional psychology, but also between those subdisciplines of psychology and research in mathematics education, have become increasingly blurred. Consequently, in this chapter, we do not attempt to make clear distinctions between or to classify investigations in those different domains.

Taking into account space restrictions, but especially the vast amount of research on mathematics learning and teaching that is now available, a comprehensive and all-inclusive coverage of the literature is beyond the scope of this chapter. Whereas school mathematics involves arithmetic, algebra, measurement, and geometry, as well as data handling and probability, we focus on arithmetic only, a focus that reflects the preponderance of current psychological and educational research on mathematics education, as well as our own research interests. In our discussion of learning and teaching arithmetic, we give special emphasis to whole number arithmetic and word problem solving, topics that have been stressed in reform documents issued over the past decade (e.g., National Council of Teachers of Mathematics [NCTM], 2000) because of their importance for the acquisition of basic competence in mathematics. Our review is also selective with regard to age range, focusing on primary school children, although some attention will be paid to lower secondary school students.

Finally, we have taken into account the excellent review on the development of children's mathematical

thinking by Ginsburg, Klein, et al. (1998) in the previous edition of the *Handbook of Child Psychology*. For instance, we do not discuss the history of the field because their chapter offers a brief but very informative overview. For complementary information on issues and topics that are not reviewed here, we refer readers especially to the following sources: *The Development of Mathematical Skills*, edited by Donlan (1998); the report published by the National Research Council (NRC; 2001a), *Adding It Up: Helping Children Learn Mathematics*, edited by Kilpatrick, Swafford, and Findell; *The Development of Arithmetic Concepts and Skills: Constructing Adaptive Expertise*, edited by Baroody and Dowker (2003); *Second International Handbook of Mathematics Education*, edited by Bishop, Clements, Keitel, Kilpatrick, and Leung (2003); and the forthcoming *Second Handbook of Research on Mathematics Teaching and Learning*, edited by Lester (in press). Although our account of the domain of mathematical learning and thinking is selective in terms of mathematical content and age range, we have aimed at international representativeness of the work discussed, albeit the focus still is mostly on numerical thinking in Western societies.

As a framework for reviewing the selected literature on the development of mathematical thinking and learning, and for the presentation and discussion of research-based instructional interventions, we use a model for the design of powerful environments for learning and teaching mathematics that is structured according to four interrelated components (De Corte, Verschaffel, & Masui, 2004):

1. *Competence*: This part of the framework analyzes and describes the components of mathematical competence or proficiency; it answers the question: What has to be learned to acquire mathematical competence?
2. *Learning*: This component focuses on the characteristics of productive mathematics learning and developmental processes; it addresses the question: What kind of learning/developmental processes should be induced in students to facilitate their acquisition of competence?
3. *Intervention*: This part of the framework elaborates principles and guidelines for the design of powerful environments for mathematics learning and instruction; it should answer the question: What are appropriate instructional methods and environments to

elicit and maintain in students the required learning and developmental processes?

4. *Assessment*: This component of the model refers to forms and methods of assessment for monitoring and improving mathematics learning and teaching; the question here is: Which types of instrument are necessary to assess students' mastery of components of mathematical competence and, thus, their progress toward proficiency?

In a systematic discussion of the research literature, it is useful to distinguish among those four components of the Competence, Learning, Intervention, Assessment (CLIA) model. In the reality of curriculum development, designing learning environments, and classroom practices, the components of the framework are narrowly intertwined. For instance, stressing conceptual understanding rather than the acquisition of routine procedures as a component of competence has strong implications for the kind of learning activities in which students should get involved, as well as for the instructional interventions to induce in them those activities. Obviously, assessing conceptual understanding in mathematics requires different questions and tasks than checking to see if students can perform routine procedures. These interactive relationships among the CLIA components will become more apparent throughout this chapter.

COMPONENTS OF MATHEMATICAL COMPETENCE

Taking into account the literature of the past 15 to 20 years (see, e.g., Baroody & Dowker, 2003; De Corte, Greer, & Verschaffel, 1996; NCTM, 1989, 2000; NRC, 2001a; Schoenfeld, 1985, 1992), becoming competent in mathematics can be conceived of as acquiring a mathematical disposition:

Learning mathematics extends beyond learning concepts, procedures, and their applications. It also includes developing a disposition toward mathematics and seeing mathematics as a powerful way for looking at situations. Disposition refers not simply to attitudes but to a tendency to think and to act in positive ways. Students' mathematical dispositions are manifested in the way they approach tasks—whether with confidence, willingness to

explore alternatives, perseverance, and interest—and in their tendency to reflect on their own thinking. (NCTM, 1989, p. 230)

Building up and mastering such a disposition requires the acquisition of five categories of cognitive, affective, and conative components:

1. A well-organized and flexibly accessible domain-specific knowledge base involving the facts, symbols, algorithms, concepts, and rules that constitute the contents of mathematics as a subject matter field.
2. Heuristics methods, that is, search strategies for problem solving that do not guarantee but significantly increase the probability of finding the correct solution because they induce a systematic approach to the task. Examples of heuristics are decomposing a problem into subgoals and making a graphic representation of a problem.
3. Metaknowledge, which involves knowledge about one's cognitive functioning (metacognitive knowledge, e.g., believing that one's cognitive potential can be developed and improved through learning and effort) and knowledge about one's motivation and emotions that can be used to deliberately improve volitional efficiency (e.g., becoming aware of one's fear of failure when confronted with a complex mathematical task or problem).
4. Self-regulatory skills, which embrace skills relating to the self-regulation of one's cognitive processes (metacognitive skills or cognitive self-regulation; e.g., planning and monitoring one's problem-solving processes) and skills for regulating one's volitional processes/activities (metavolitional skills or volitional self-regulation; e.g., keeping up one's attention and motivation to solve a given problem).
5. Positive beliefs about oneself in relation to mathematical learning and problem solving (self-efficacy beliefs), about the social context in which mathematical activities take place, and about mathematics and mathematical learning and problem solving.

We know from past research that knowledge and skills that students have learned are often neither accessible nor usable when necessary to solve a problem at hand (Cognition and Technology Group at Vanderbilt, 1997). Building a disposition toward skilled learning

and thinking should help to overcome this phenomenon, which Whitehead already in 1929 labeled “inert knowledge.” To overcome this inertia, it is necessary that these different kinds of knowledge, skills, and beliefs are acquired and mastered in an *integrated way*, resulting in the development of the intended disposition. According to Perkins (1995), two crucial aspects of such a disposition are *sensitivity* to situations in which it is relevant and appropriate to use acquired knowledge and skills and the *inclination* to do so. Perkins argues that these aspects are both determined by the beliefs a person holds. For instance, one’s beliefs about what counts as a mathematical context and what one finds interesting or important have a strong impact on the situations one is sensitive to and whether or not one engages in them.

This view of mathematical competence is quite consonant with the conception of mathematical proficiency as elaborated in the report of the NRC (2001a) which defines proficiency in terms of five interwoven strands: conceptual understanding, computational fluency, strategic competence, adaptive reasoning, and productive disposition. Conceptual understanding and procedural fluency are the two most important aspects of a well-organized and flexibly accessible domain-specific knowledge base. Conceptual understanding refers to “comprehension of mathematical concepts, operations, and relations” and procedural fluency to “skill in carrying out procedures flexibly, accurately, efficiently, and appropriately” (p. 5). Strategic competence is defined as “ability to formulate, represent, and solve mathematical problems” (p. 5); this obviously implies heuristic strategies but also aspects of cognitive self-regulation. Adaptive reasoning, viewed as the “capacity for logical thought, reflection, explanation, and justification” (p. 5), involves especially skills in cognitive self-regulation (see also p. 118). Finally, a productive disposition is conceived of as a “habitual inclination to see mathematics as sensible, useful, and worthwhile, coupled with a belief in diligence and one’s efficacy” (p. 5); this strand of proficiency converges with the positive beliefs mentioned earlier, but it also relates to the sensitivity and inclination aspects of a mathematical disposition.

The conceptualization of mathematical proficiency in the report of the NRC (2001a) is thus well in line with our elaboration of the competence component of the CLIA framework. Both perspectives embody also what Hatano (1982, 1988; see also Baroody, 2003) has called

adaptive expertise, that is, the ability to apply meaningfully acquired knowledge and skills flexibly and creatively in a large variety of situations, familiar as well as unfamiliar. Nevertheless, some aspects of our analysis of competence are not, or at least not explicitly, included or articulated in the definition of proficiency in the NRC report, namely, metaknowledge and especially volitional self-regulation skills, which are essential to stay concentrated on a task and to sustain and persevere in achieving it (Corno et al., 2002). A major point on which both perspectives on mathematical competence do strongly agree is that the different components involved are interwoven and, therefore, need to be acquired integratively. In fact, the interdependency of the five strands outlined earlier is the leitmotif of the report: “Learning is not an all-or-none phenomenon, and as it proceeds, each strand of mathematical proficiency should be developed in synchrony with the others. That development takes time” (NRC, 2001a, p. 133).

This standpoint has very important implications from a developmental perspective. Indeed, it means that from the very beginning of mathematics education, attention has to be paid to the parallel and integrated acquisition in children of the different components of competence. In this respect, we endorse the following point of view of the NRC (2001a, p. 133) report: “One of the most challenging tasks faced by teachers in prekindergarten to grade 8 is to see that children are making progress along every strand and not just one or two.”

In the next part of this section, we focus on several components of competence by reviewing a selection of the recent literature that has contributed to unravel their development in children. Thereby we will take into account the interdependency of the different strands of proficiency: number sense, single-digit computation, and multidigit arithmetic, which constitute major aspects of the domain-specific knowledge involved in the primary school mathematics curriculum; word problem solving, in which domain-specific knowledge but also heuristic strategies and self-regulation skills and even beliefs all interactively play an important role; and mathematics-related beliefs, a topic that only recently has attracted the interest of researchers. Most of these topics received relatively little attention in the chapter on the development of children’s mathematical thinking in the previous edition of this *Handbook* (Ginsburg, Klein, et al., 1998), which focused more on development during infancy, toddlerhood, and the preschool years.

Number Sense

In the reform documents for mathematics education issued in different countries over the past decades, it has been stressed that the elementary mathematics curriculum should pay substantial attention to the development of number concepts and numeration skills (see, e.g., Australian Education Council, 1990; Cockcroft, 1982; NCTM, 1989). One of the most typical aspects of the reform documents in this respect is the emphasis they put—already in the early grades of primary school—on number sense (e.g., NCTM, 1989); this is not at all surprising as it typifies the current view of learning mathematics as a sense-making activity.

McIntosh, Reys, and Reys (1992, p. 3) describe number sense as follows:

Number sense refers to a person's general understanding of number and operations. It refers to a person's general understanding of number and operations along with the ability and inclination to use this understanding in flexible ways to make mathematical judgments and to develop useful strategies for handling numbers and operations. It reflects an inclination and an ability to use numbers and quantitative methods as a means of communicating, processing and interpreting information. It results in, and reciprocally derives from, an expectation that numbers are useful and that mathematics has a certain regularity.

Further discussions and analyses have resulted in listings of the essential components of number sense (McIntosh et al., 1992; Sowder, 1992), descriptions of students displaying (lack of) number sense (Reys & Yang, 1998), and an in-depth theoretical analysis of number sense from a psychological perspective (Greeno, 1991a).

Probably the most comprehensive and most influential attempt to articulate a structure that clarifies, organizes, and interrelates some of the generally agreed upon components of basic number sense has been provided by McIntosh et al. (1992). In their model, they distinguish three areas where number sense plays a key role: number concepts, operations with number, and applications of number and operation:

1. The first component, “knowledge of and facility with numbers,” involves subskills such as a sense of orderliness of number (“Indicate a number on an empty number line, given some benchmarks”), multiple representations for numbers ($\frac{3}{4} = 0.75$), a sense of rela-

tive and absolute magnitude of numbers (“Have you lived more or less than 1,000 days?”), and a system of benchmarks (recognizing that the sum of two 2-digit numbers is less than 200).

2. The second component, called “knowledge of and facility with operations,” involves understanding the effect of operations (knowing that multiplication does *not* always make bigger), understanding mathematical properties (e.g., commutativity, associativity, and distributivity, and intuitively applying these properties in inventing procedures for mental computation), and understanding the relationship between operations (the inverse relationships between addition and subtraction and between multiplication and division) to solve a problem such as $11 - 9 = \underline{\quad}$ by means of indirect addition, or to solve a division problem such as $480/8$ by multiplying $8 \times \underline{\quad} = 480$.
3. The third component, “applying knowledge and facility with numbers and operations to computational settings,” involves subskills such as understanding the relationship between problem contexts and the necessary computation (e.g., “If Skip spent \$2.88 for apples, \$2.38 for bananas, and \$3.76 for oranges, could Skip pay for this fruit with \$10?” can be solved quickly and confidently by adding the three *estimated* quantities rather than by *exact* calculation), awareness that multiple strategies exist for a given problem, inclination to utilize an efficient representation and/or method (not solving $(375 + 375 + 375 + 375 + 375)/5$ by first adding the five numbers and then dividing the answer by 5), and inclination to review data and results (having a natural tendency to examine one's answer in light of the original problem).

Several researchers have documented the problems children experience with the different aspects of number sense. For instance, Reys and Yang (1998) investigated the relationship between computational performance and number sense among sixth- and eighth-grade students in Taiwan. Seventeen students were interviewed about their knowledge of the different aspects of number sense from the theoretical framework mentioned here. Students' overall performance on number sense was lower than their performance on similar questions requiring written computation. There was little evidence that identifiable components of number sense, such as use of benchmarks, were naturally used by Taiwanese students in their decision making.

In line with his situative view of cognition, Greeno (1991a; see also Sowder, 1992) has suggested the following metaphor for developing number sense. He characterized it as an environment, with the collection of resources needed for knowing, understanding, and reasoning all at different places within this environment: “Learning in the domain, in this view, is analogous to learning to get around in an environment and to use the resources there in conducting one’s activities productively and enjoyably” (p. 45).

People who have developed number sense can move around easily within this environment because of their access to the necessary resources. Teaching becomes the act of “indicating what resources the environment has, where they can be found, what some of the easy routes are, and where interesting sites are worth visiting” (p. 48).

Given that number sense is conceptualized in such a way, it is evident that, according to Greeno (1991a), Reys and Yang (1998, p. 227), and many others, the development of number sense “is not a finite entity that a student has or does not have but rather a process that develops and matures with experience and knowledge.” This development results from a whole range of mathematical activities on a day-by-day basis within each mathematics lesson, rather than from a designated set or subset of specially designed activities (Greeno, 1991a; Reys & Yang, 1998).

According to many authors, estimation is closely connected to number sense (or to numeracy). For instance, Van den Heuvel-Panhuizen (2001, p. 173) starts her didactical treatise of estimation as follows: “Estimation is one of the fundamental aspects of numeracy. It is the preeminent calculation form in which numeracy manifests itself most explicitly.” Besides the fact that it is pervasively present in the daily lives of both children and adults, estimation is also important because it is related to and constitutive of other conceptual, procedural, strategic, and attitudinal aspects of mathematical ability (Siegler & Booth, in press; Sowder, 1992; Van den Heuvel-Panhuizen, 2001). In her review of the literature on estimation up to the early 1990s, Sowder differentiated three forms of estimation: computational estimation (performing some mental computation on approximations of the original numbers of a required computation), measurement estimation (estimating the length or area of a room), and numerosity estimation (estimating the number of items in a set, such as the number of people in a theater). In a more recent overview of

the literature, Siegler and Booth identify a fourth category, number line estimation (translating numbers into positions on number lines, such as a 0–100 or a 1–1,000 number line). For all these types of estimation, the older and more recent research, which is excellently reviewed in the works cited earlier, shows that both children and adults use varied estimation strategies, that the variety, efficiency, sophistication, and adaptivity of these strategies increase with age and experience, and that estimation is a domain wherein all aspects of a mathematical disposition are integratively involved.

The preceding discussion clearly shows the dispositional nature of number sense, involving not only aspects of capacity but also aspects of inclination and sensitivity; it also illustrates that number sense remains a vague notion and that its relationships with other aspects of arithmetic competence need further clarification. As stated in NCTM’s (1989, p. 39) *Curriculum and Evaluation Standards for School Mathematics*, number sense is “an intuition about numbers that is drawn from all varied meanings of numbers.” Nowadays, it is very common in the mathematics education community to agree that this intuition is important; however, it is hard to define and even harder to operationalize in view of the research. And recently there has been a rash of more or less related terms, such as “numeracy” and “mathematical literacy,” also with little definitional precision. Indeed, in most cases where we have encountered it, number sense is defined so broadly that it includes problem solving but also most, if not all, other skills that constitute a mathematical disposition (McIntosh et al., 1992). Although we acknowledge its power in curricular reforms, we have some doubts about its usefulness for scientific research unless its specific meaning is articulated in a more clear and consistent way.

Single-Digit Computation

The domain of single-digit addition and subtraction is undoubtedly one of the most frequently investigated areas of numerical cognition and school mathematics. Much work in the domain has been done from a cognitive/rationalist, especially an information-processing perspective. Numerous older and more recent studies provide detailed descriptions of the progression in children of orally stated single-digit additions (e.g., $3 + 4 = \underline{\quad}$): from the earliest concrete counting-all-with-materials strategy; over several types of more advanced counting strategies (such as counting-all-

without-materials, counting-on-from-first, and counting-on-from-larger, and derived-fact strategies) that take advantage of certain arithmetic principles to shorten and simplify the computation; to the final state of “known facts” (for extensive reviews of this research, see Baroody & Tiilikainen, 2003; Fuson, 1992; NRC, 2001a; Thompson, 1999).

Similar levels for subtraction have been described, although this developmental sequence is somewhat less clearly defined (Thompson, 1999).

These and other studies document how, at any given time during this development, an individual child uses a variety of addition strategies, even within the same session and for the same item (for an overview, see Siegler, 1998). Even older students and adults do not always perform at the highest developmental level of “known fact use” but still demonstrate use of a range of different procedures even for simple addition problems (Siegler, 1998).

The exact organization of the store of arithmetic facts in subjects having reached the final stage of this developmental process is a special area of research in numerical cognition (for an overview, see Ashcraft, 1995; Dehaene, 1993). Most of this research has been done with adults rather than with elementary school children. Most models share the notion that in the “expert fact retriever,” arithmetic facts such as $2 + 3 = 5$ are memorized in and automatically retrieved from a stored associative network or lexicon (Ashcraft, 1995). Well-known “problem size effects” (i.e., the fact that the time needed to solve single-digit addition problems increases slightly with the size of the operands) and “tie effects” (i.e., the fact that response time for ties such as $2 + 2$ remains constant or increases only moderately with operand size) are considered in this common view as reflecting the duration and difficulty of memory retrieval. According to Ashcraft (1995; Ashcraft & Christy, 1995), both effects faithfully reflect the frequency with which arithmetic facts are acquired and practiced by individuals. However, it is quite generally accepted that not all experts’ knowledge of single-digit arithmetic is mentally represented in separate and independent units. Part of their knowledge about simple addition seems to be stored in rules (e.g., $N + 0 = N$) rather than as isolated facts (e.g., $1 + 0 = 1$, $2 + 0 = 2$). A related assumption is that not all problems are represented. For instance, for each commutative pair of problems (e.g., $3 + 5$ and $5 + 3$), there might be only one representational unit in the network.

It is well known that the developmental process from counting to fact retrieval does not proceed smoothly for all children. Single-digit arithmetic among children with mathematical difficulties or learning problems has also attracted a lot of research. Generally speaking, this research shows that learning-disabled children and others having difficulty with mathematics do not use procedures that differ from the progression described here. Rather, they are just slower than others in moving through it (NRC, 2001a; Torbeyns, Verschaffel, & Ghesquiere, 2005). Especially the last step of arithmetic facts mastery seems to be very difficult for them, and for some of these children, these retrieval difficulties appear to reflect a highly persistent, perhaps lifelong, deficit rather than merely a temporary developmental delay (Geary, 2003).

Several other studies have addressed the relationship between declarative and procedural knowledge by investigating which kind of knowledge develops before the other. As far as single-digit addition and subtraction is concerned, this question has focused on the relationship between children’s understanding of certain mathematical principles, especially commutativity, and their progression toward more efficient counting strategies (e.g., the counting-on-from-larger strategy, otherwise known as the *min* strategy) based on these mathematical principles (for extensive reviews of this literature, see Baroody, Wilkins, & Tiilikainen, 2003; Rittle-Johnson & Siegler, 1998). This research indicates that conceptual and procedural knowledge are positively correlated, but also that most children understand the commutativity concept before they generate the procedure(s) based on it. This latter finding seems to favor, at least for the domain of single-digit addition, the “concepts first” above the “skills first” view. However, whereas in previous decades the debate about the relationship between conceptual and procedural knowledge was dominated by proponents of these two camps, most researchers now adhere to a more moderate perspective. They assume, on the one hand, that the relationship between procedural and conceptual knowledge develops more concurrently and/or iteratively than suggested by both opposite views and, on the other hand, that the nature of this relationship may differ among different mathematical (sub)domains (Baroody, 2003; Rittle-Johnson & Siegler, 1998).

Although the research concerning the development of children’s strategies for multiplying and dividing single-digit numbers is less extensive than for single-digit addition and subtraction, there is a growing body of studies

in this domain, too (e.g., Anghileri, 1999; Butterworth, Marschesini, & Girelli, 2003; LeFevre, Smith-Chant, Hiscock, Daley, & Morris, 2003; Lemaire & Siegler, 1995; Mulligan & Mitchelmore, 1997; Steffe & Cobb, 1998). As for single-digit addition and subtraction, this research documents how, generally speaking, children progress from concrete (material-, fingers-, or paper-based) counting-all strategies, through additive-related calculations (repeated adding and additive doubling), pattern-based (e.g., multiplying by 9 as by $10 - 1$), and derived-fact strategies (e.g., deriving 7×8 from $7 \times 7 = 49$), to a phase of learned multiplication products. However, there is less consistency between the names and the characterizations of the different categories than for addition and subtraction. As for these two operations, research on multiplication and division has shown that multiplicity and flexibility of strategy use are basic features of people doing simple number combinations, even for older children and adults (LeFevre et al., 2003). Here, too, research is unequivocal about the exact features of the organization and the functioning of the multiplication facts store and, more particularly, to what extent (part of) experts' knowledge about the multiplication table is stored in rules ($0 \times N = 0$, $1 \times N = N$, $10 \times N = N0$, etc.) rather than as strengthened associative links between particular mathematical expressions and their correct answers. Based on a recent study with third and fifth graders solving multiplication items with the larger operand either placed first ($7 \times 3 = \underline{\quad}$) or second ($3 \times 7 = \underline{\quad}$), Butterworth et al. (2003, p. 201) concluded:

The child learning multiplication facts may not be passive, simply building associative connections between an expression and its answer as a result of practice. Rather, the combinations held in memory may be reorganized in a principled way that takes into account a growing understanding of the operation, including the commutativity principle, and, perhaps, other properties of multiplication.

Baroody (1993) arrived at a similar conclusion based on a study on the role of relational knowledge in the development of mastering multiplication basic fact knowledge, and especially of knowledge about the addition doubles in learning multiplication combinations involving 2 (2×6 , 2×11 , $2 \times 50 \dots$).

Probably the most ambitious and most influential attempt to model this development and this variety of strategy use in single-digit arithmetic from an

information-processing perspective is found in the subsequent versions of the computer model of strategy choice and strategy change in the domain of simple addition developed by Siegler and associates. We briefly describe the latest version of the Strategy Choice and Discovery Simulation (SCADS; Shrager & Siegler, 1998; see also Siegler, 2001; Torbeyns, Arnaud, Lemaire, & Verschaffel, 2004). Central in SCADS is a database with information about problems and strategies that plays a key role in the strategy choice process. The first type of information, information about problems, consists of problem-answer associations, that is, associations between individual problems and potential answers to these problems, which differ in strength. The second type of information includes global, featural, problem-specific, and novelty data about each strategy available in the database. Whenever SCADS is presented with a problem, it activates the global, featural, and problem-specific data about the speed and accuracy of each of the available strategies. The model weights these data in terms of the amount of information they reflect and how recently they were generated. Weighted efficiency and novelty data for each strategy provide the input for stepwise regression analyses, which compute the projected strength of the different strategies on the problem: The strategy with the highest projected strength has the highest probability to be chosen. In case the initially chosen strategy does not work, another strategy with less projected strength is chosen, and this process continues until a strategy is chosen that meets the model's criteria. An important advantage of SCADS (compared to its predecessors) is that it also discovers new strategies and learns about them. It does so through representing each strategy as a modular sequence of operators (rather than just a unit) and by maintaining a working memory trace of the strategy's execution (rather than just recording speed and accuracy data). A metacognitive system uses the representation of the strategies and the memory traces to formulate new strategies based on the detection of redundant sequences of behavior and the identification of more efficient orders of executing operators. SCADS evaluates these proposed strategies for consistency with a "goal sketch," which indicates the criteria that legitimate strategies in the domain of simple addition must meet. If the proposed strategy violates the conceptual constraints specified by the goal sketch filters, it is abandoned. If the proposed strategy is in accord with the

conceptual constraints (approved strategies), SCADS adds it to its strategy repertoire. The newly discovered strategy thus modifies the model's database and, consequently, influences future strategy choices. According to the developers of SCADS, its performance on single-digit additions and on additions with one addend above 20 is highly consistent with the strategy choice and discovery phenomena that they observed in their studies with young children (Shrager & Siegler, 1998; Siegler & Jenkins, 1989; see also Siegler, 2001).

Siegler's strategy choice model has been tested for simple addition and also, although to a much less fine-grained extent, for multiplication. Siegler and Lemaire (1997) report a longitudinal investigation of French second graders' acquisition of single-digit multiplication skills. Speed, accuracy, and strategy data were assessed three times in the year when children learned multiplication. The data showed improvements in speed and accuracy, which reflected four different aspects of strategic changes that generally accompanied learning: origin of new strategies, more frequent use of more efficient strategies, more efficient execution of each strategy, and more adaptive choices among available strategies. According to the authors, these findings support a number of predictions of the SCADS model.

Siegler's (2001) model is considered by many as among the strongest proofs of the success of the information-processing paradigm, and it has influenced and still influences a lot of research in the domain of single-digit arithmetic. Nevertheless, this model also has its critics. First, although SCADS involves a large number of strategies, its direct application field is rather restricted. Future models will need to incorporate a wider range of strategies, such as the decomposition-to-10 strategy (e.g., $8 + 7 = (8 + 2) + (7 - 2) = 15$) or the tie strategy (e.g., $6 + 7 = (6 + 6) + 1 = 13$; Torbeyns et al., 2005), as well as the extension from single-digit to multidigit addition. The further elaboration of the model for other operations is also necessary. According to some scholars (e.g., Cowan, 2003), this may only be a matter of time; others are more skeptical about the ease with which the application range of computer models like SCADS can be meaningfully broadened to include related task domains (Baroody & Tiilikainen, 2003). More important, however, are the criticisms of the model coming from other, more recent theoretical perspectives. Starting from a constructivist and social-learning theoretical framework and from a broader data

set, Baroody and Tiilikainen performed a very critical analysis of Siegler's model of early addition performance and its underlying assumptions. These authors argue that the operation of SCADS is at odds with several key phenomena about the development and flexibility of children's addition strategies. For instance, Baroody and Tiilikainen collected evidence that even children who apparently have constructed a goal sketch sometimes used strategies that do not conform to a valid addition strategy specified in the goal sketch whereas SCADS never executes illegal strategies. Another important criticism of the model is that little or no attention is given to the social and instructional context in which the development of arithmetic skills takes place. Indeed, it seems incontrovertible to assume that the occurrence and the frequency, efficiency, and adaptivity with which certain strategies are used by children will depend heavily on the nature of instruction. And by instruction we mean more than the frequency of an arithmetic fact in an elementary school mathematics textbook (Ashcraft & Christy, 1995), the number of times a particular item has been shown, or the number of times a child has received positive or negative feedback for a particular item. For instance, several researchers (Hatano, 1982; Kuriyama & Yoshida, 1995) who examined the developmental paths of addition solution methods used by Japanese children have reported that they typically move more quickly than U.S. children do from counting-all methods to derived-fact and known-fact methods without passing through a clearly identifiable stage of more efficient counting strategies. Interestingly, many Japanese children use the number 5 as an intermediate anchor to think about numbers and to do additions and subtractions, before starting to do sums by means of retrieval or using 10 as an anchor in their derived-fact strategies. According to these authors, these developmental characteristics of Japanese children are closely related to a number of cultural and instructional supports and practices, such as the emphasis on using groups of five in the early arithmetic instruction in general and in abacus instruction in particular. Similarly, among classes of Flemish children, Torbeyns et al. (2005) found an unusually frequent, efficient, and adaptive use of a tie strategy on sums above 10, that is, solving almost-tie sums such as $7 + 8 = \underline{\quad}$ by means of $(7 + 7) + 1 = \underline{\quad}$, rather than by the decomposition-to-10 strategy: $(7 + 3) + 5 = \underline{\quad}$. In those classes, a new textbook series was used that put great emphasis on

the deliberate and flexible use of multiple solution strategies rather than on the mastery of the decomposition-to-10 strategy as the only acceptable approach to sums above 10.

Commenting on Baroody and Tiilikainen's (2003) very critical analysis of SCADS, and on the "schema-based view" they present as a more valuable alternative, Bisanz (2003) remarks that, although it is quite clear how SCADS works, this schema-based view, which speaks of a "web of conceptual, procedural, and factual knowledge," is not described in equally great detail. He concludes rightly, "When accounting for data, an unspecified model (like Baroody's) will always have an advantage over a relatively well-specified model, because the latter is constrained by its details" (p. 442). But even if Baroody and Tiilikainen's model lacks the specificity of SCADS, it certainly points to the complex mutual relationship between different kinds of knowledge (conceptual and procedural) in the development of single-digit arithmetic, as well as to the crucial role of the broader sociocultural and instructional contexts in which this development occurs.

In sum, the available research over the past decade has convincingly documented that acquiring proficiency with single-digit computations involves much more than rote memorization. This domain of whole number arithmetic demonstrates (a) how the different components of arithmetic skill (strategies, principles, and number facts) contribute to each other; (b) how children begin with understanding of the meaning of operations and how they gradually develop more efficient methods; and (c) how they choose adaptively among different strategies depending on the numbers involved (NRC, 2001a). Researchers have made considerable progress in describing these phenomena, and there are now sophisticated computer models that fit to some extent with the available empirical data. But we are nevertheless still remote from a full understanding of the development of expertise in this subdomain (Cowan, 2003). One of the most important tasks for further research relates to how these different components interact and, more precisely, exactly when and how the development of one component promotes the development of another. As argued convincingly by Siegler and others (Siegler, 2001; Torbeyns et al., 2004), further research on this issue requires the application of so-called microgenetic methods, which involve the repeated examination of children's factual, conceptual, and procedural knowledge during the whole learning process.

Another largely unresolved issue concerns the impact of cultural and instructional factors beyond the simple ones dealing with the amount of practice and reinforcement of arithmetic responses that are implemented in Siegler's computer simulation model. Remarkably, many of the available computer models seem to assume that there is a kind of universal taxonomy and/or developmental sequence of computational strategies, which is fundamentally independent of the nature of instruction or the broader cultural environment. It seems indeed plausible that some elements of this development are strongly constrained by general factors other than the instructional and cultural context wherein this development occurs, such as the inherent structure of mathematics and the unfolding of certain cognitive capacities in early childhood. However, other developmental aspects look less constrained and much more dependent on children's experiences with early mathematics at home and at school, such as the provision of cultural supports and practices as sources to move quickly beyond counting-based methods, or the immersion in a classroom climate and culture that encourages and praises flexibility.

Multidigit Arithmetic

Whereas existing theory and research offer a rather comprehensive picture of how children learn to add and subtract with small numbers, the literature about what concepts and strategies should be distinguished and how they develop over time is much more limited in the domain of multidigit arithmetic.

During the past decade, a number of studies from many different countries have documented the frequent and varied nature of children's and adults' use of informal strategies for mental addition and subtraction that depart from the formal written algorithms taught in school (Beishuizen, 1999; Carpenter, Franke, Jacobs, Fennema, & Empson, 1998; Cooper, Heirdsfield, & Irons, 1996; Jones, Thornton, & Putt, 1994; Reys, Reys, Nohda, & Emori, 1995; Thompson, 1999; Verschaffel, 1997). For instance, in the United States, Carpenter et al. (1998) did a longitudinal study investigating the development of children's multidigit addition and subtraction in relation to their understanding of multidigit concepts in grades 1 through 3. Students were individually interviewed five times on a variety of tasks involving straightforward, result-unknown addition and subtraction word

problems with two-digit numbers for the first three interviews and three-digit numbers in the last two interviews. During the same interviews, children were individually administered five tasks measuring their knowledge of base-10 number concepts, together with a task wherein they had to apply a specific invented strategy to solve another problem and two unfamiliar (missing addend) problems that required some flexibility in calculation. It is important to note that all students were in classes of teachers who were participating in a 3-year intervention study designed to help them understand and build on children's mathematical thinking in line with reform-based principles. The emphasis of this intervention was on how children's intuitive mathematical ideas emerge to form the basis for the development of more formal concepts and procedures. Teachers learned about how children solve problems using base-10 materials and about the various invented strategies children often construct. The researchers identified the following categories of strategies:

- Modeling or counting by 1s.
- Modeling with 10s materials.
- Combining-units strategies (otherwise called decomposition or split strategies), wherein the 100s, 10s, and units of the different numbers are split off and handled separately (e.g., $46 + 47$ is determined by taking $40 + 40 = 80$ and $6 + 7 = 13$, answer $80 + 13 = 93$).
- Sequential strategies or jump strategies, wherein the different values of the second number are counted up or down from the first unsplit number (e.g., $46 + 47$ is determined by taking $46 + 40 = 86$, $86 + 7 = 93$).
- Compensating strategies or varying strategies, wherein the numbers are adjusted to simplify the calculation (e.g., $46 + 47 = (45 + 45) + 1 + 2 = 93$).
- Other invented mental calculation strategies.
- Algorithms (correct as well as buggy ones) wherein the answer is not found by means of mental calculation with numbers but by applying a taught algorithm on digits.

The study showed that, under favorable circumstances, children can invent mental calculation strategies for addition and subtraction problems. Also, buggy algorithms occurred more frequently among children who started out working algorithmically than among children who used invented mental strategies before or at the

same time that they used standard algorithms. Students who used mental calculation strategies before using standard algorithms demonstrated better knowledge of base-10 number concepts and were more successful in extending their knowledge to new situations than students who used standard algorithms before applying mental calculation strategies. Finally, the data suggest that there is no explicit sequence in which the three basic categories of mental calculation strategies (sequential, combining units, and compensating) develop for addition; the majority of students applied all three, and the order in which they occurred was mixed. For subtraction, the sequential method was most often used, but some compensation strategies were observed, too.

Similar findings about the development of students' mental calculation strategies for multidigit addition and subtraction, in close relation to the development of their conceptual knowledge, were reported by Fuson et al. (1997) and by Hiebert and Wearne (1996). In both studies, these findings were obtained in nonconventional, reform-based classrooms. The latter authors followed children from the first to the fourth grade. They assessed conceptual understanding by asking children to identify the number of 10s in a number, to represent the value of each digit in a number with concrete materials, and to make different concrete representations of multidigit numbers. Procedural knowledge was assessed through performance on two-digit addition and subtraction story problems, which could be solved either by the standard algorithm or by an invented procedure. The size of the numbers used in the tests differed as the children grew older. Across assessment periods, children who demonstrated higher levels of conceptual understanding obtained higher scores on the procedural measures. As a second kind of support for the close relationship between procedural and conceptual knowledge, Hiebert and Wearne found that early conceptual understanding predicted not only concurrent but also future procedural skill.

Several researchers have documented that children also can invent strategies for multiplying and dividing multidigit numbers and have described some strategies they use. However, less progress has been made in characterizing such inventions than for the domain of multidigit addition and subtraction. We summarize next the main findings from an analysis by Ambrose, Baek, and Carpenter (2003) of children's invented multidigit multiplication and division procedures and the concepts and

skills they depend on. We stress that these inventions did not take place in a vacuum, but in the context of a reform-based instructional environment that allowed and even stimulated children to construct, elaborate, and refine their own mental strategies rather than forcing them to follow a uniform, standardized trajectory for mental and/or written arithmetic. Very similar analyses have been reported by Anghileri (1999) and Thompson (1999) in the United Kingdom with children being taught according to the principles of the National Numeracy Strategy and by Treffers (1987) and Van Putten, Van den Brom-Snijders, and Beishuizen (2005) in the Netherlands with children being taught according to the principles of Realistic Mathematics Education.

Ambrose et al. (2003) classified children's mental calculation strategies for multiplication problems into four categories: direct modeling, complete number strategies, partitioning number strategies, and compensating strategies. A child using a *direct modeling strategy* models each of the groups using concrete manipulatives or drawings. Among these direct modeling strategies, the most elementary ones involve the use of individual counters to directly represent problems (identical to those used with single-digit numbers). As children develop knowledge of base-10 number concepts, they begin to use base-10 materials rather than individual counters to directly model and solve the problem. A second category, *complete number strategies*, describes strategies based on progressively more efficient techniques for adding and doubling. The most basic one is simply repeated addition. Others involve doubling, complex doubling, and building up by other factors. A child using the *partitioning number strategy* will split the multiplicand or multiplier into two or more numbers and create multiple subproblems that are easier to deal with. This procedure allows children to reduce the complexity of the problem and to use multiplication facts they already know. Distinction is made between strategies wherein a number is partitioned into nondecade numbers, strategies wherein a number is partitioned into decade numbers, and strategies wherein both numbers are partitioned into decade numbers. Finally, a child using a *compensating strategy* will adjust both multiplicand and multiplier or one of them based on special characteristics of the number combination to make the calculation easier. Children then make corresponding adjustments later if necessary. Ambrose et al. present a similar taxonomy for division. Many children in the study developed their mental calculation strategies for multidigit

numbers in a sequence from direct modeling to complete number, to partitioning numbers into nondecade numbers, and to partitioning numbers into decade numbers. Moreover, children's strategies for solving multidigit multiplication problems varied with their conceptual knowledge of addition, units, grouping by 10, place value, and properties of the four basic operations.

Our analysis of these studies revealed also how these researchers investigated the development of both procedural and conceptual knowledge. For the analysis of conceptual knowledge, investigators relied on a model developed by Fuson (1992; see also Fuson et al., 1997). This framework is called the UDSSI triad model, after the names of the five conceptual structures (unitary, decade, sequence, separate, integrated) distinguished in that model. Each conception involves a triad of two-way relationships among number words, written number marks, and quantities. Each of these relationships is connected to the other two. According to the model, children begin with a unitary multidigit conception, in which quantities are not differentiated into groupings, and the number word and number marks are not differentiated into parts. So, for 15 doughnuts, for example, the 1 is not related to "teen" in "fifteen" and the quantities are not meaningfully separable into 10 doughnuts and 5 doughnuts. In the most sophisticated conception, the integrated sequence-separate 10s conception, bidirectional relationships are established between the 10s and the 1s component of each of the three parts (i.e., number words, marks, quantities) of the sequence-10s and the separate-10s conceptions. This integrated conception allows children considerable flexibility in approaching and solving problems using two-digit numbers.

Fuson et al. (1997) acknowledge that this developmental model is deceptively neat in several respects. First, there are qualitative and quantitative differences depending on the language used. The European number words require some decade conception, and the written marks require some conception of separate 10s and 1s. For full understanding of the words and marks, European children need to construct all five of the UDSSI multidigit conceptions. But children speaking Chinese-based number words, for instance, that are regular and name the 10s, have a much easier task. Second, children learn the six relationships for a given number (or set of numbers) at different times and may not construct the last triad relationship for all numbers up to 99 for one kind of conception before the first triad relationships

for another conception are construed. Third, not all children construct all conceptions; these constructions depend on the conceptual supports experienced by individual children in their classroom and outside of school. In this respect, it is important to note that besides these five conceptual structures, Fuson's framework also contains a sixth, inadequate conception, called the "concatenated single-digit conception," which refers to the interpretation and treatment of multidigit numbers as single-digit numbers placed adjacent to each other, rather than using multidigit meanings for the digits in different positions. According to Fuson (1992, p. 263), the use of this concatenated single-digit meaning for multidigit numbers may stem from classroom experiences "that do not sufficiently support children's construction of multiunit meanings, do require children to add and subtract multidigit numbers in a procedural, rule-directed fashion, and do set expectations that school mathematics activities do not require one to think or to access meanings."

Finally, children who have more than one multidigit conception may use different conceptions in different situations or combine parts of different triads in a single situation. For instance, even among children who already have a more meaningful conception available, the vertical instead of a horizontal presentation of an addition or subtraction problem may seduce them into using a concatenated single-digit conceptual structure. So children's multiunit conceptions do not conform to a uniform and stage-like model (Fuson et al., 1997).

We now turn to some comments on this framework. First, the empirical basis of the latest version of the model, as presented here, is somewhat unspecific. It remains unclear which aspects of this development are shaped by specific characteristics of the innovative learning environments in which it was observed, and which aspects are shaped by more general factors that are largely outside the control of instruction. Second, Fuson et al.'s (1997) model focuses on only one aspect of children's growing understanding of numbers and number relationships when they start exploring and operating on multidigit numbers (Fuson, 1992; Jones et al., 1994; Treffers, 2001), namely, their base-10 structure. Fuson (1992) herself points to the fact that besides this "collection-based" interpretation of numbers, there is also the "counting-based" interpretation. Treffers refers to these two interpretations as, respectively, the "structuring" and the "positioning"

representation of numbers. He defines "positioning" as "being able to place whole numbers on an empty number line with a fixed start and end point. . . . Positioning enables students to gain a general idea of the sizes of numbers to be placed" (p. 104). As such, Treffers's "positioning" interpretation shows some alignment with Dehaene's (Dehaene & Cohen, 1995) theory about how numbers are internally represented in the human mind (and brain), which assumes an analogue magnitude code (a kind of mental number line) as the main, if not only, semantic representation of a number. Although several mathematics educators working in the domain of multidigit arithmetic give this counting-based or positioning interpretation a prominent place in their experimental curricula, textbooks, and instructional materials (see, e.g., Beishuizen, 1999; Selter, 1998; Treffers, 2001), we are not aware of any ascertaining study that describes in a broad and systematic way the development of this latter aspect of children's growing conceptual knowledge of numbers and its relationship to the other aspect of multidigit number development.

To summarize, whereas in the 1970s and 1980s research focused on children's solutions of arithmetic problems involving relatively small whole numbers, researchers afterward paid more attention to problems that involve multidigit calculations. Significant progress has been made in identifying and characterizing the different concepts and strategies that children construct to calculate with multidigit numbers besides the regularly taught standard algorithms for written computation. Most classifications of children's procedures for operating on multidigit numbers distinguish among three basic categories of strategies of mental arithmetic:

1. Strategies where the numbers are primarily seen as objects in the counting row and for which the operations are movements along the counting row: further (+) or back (-) or repeatedly further (\times) or repeatedly back (\div).
2. Strategies where the numbers are primarily seen as objects with a decimal structure and in which operations are performed by splitting and processing the numbers based on this structure.
3. Strategies based on arithmetic properties where the numbers are seen as objects that can be structured in all sorts of ways and where operations take place by choosing a suitable structure and using the appropriate arithmetic properties (see also Buys, 2001).

Each of these three basic forms can be performed at different levels of internalization, abbreviation, abstraction, and formalization. Moreover, each of these categories can be found in each of the four arithmetic operations.

The description of the past decade's research on multidigit mental arithmetic has pointed to the invented nature of some of these procedures of mental arithmetic and to the flexible or adaptive use of different strategies as a basic characteristic of expertise in multidigit arithmetic (see also Hatano, 2003). The available work has revealed the impossibility of separating the learning of the procedures for doing multidigit arithmetic from the development of base-10 number concepts as well as other, complementary conceptualizations of number. In their review of the relationship between conceptual and procedural knowledge of multidigit arithmetic, Rittle-Johnson and Siegler (1998) report several kinds of empirical evidence for this close relationship. At the same time, they refer to some research evidence (Resnick & Omanson, 1987) showing that in conventional instruction, which emphasized practicing procedures without linking this practice to conceptual understanding, the links between conceptual and procedural development are much looser. Finally, the research yielded evidence for the "dispositional nature" of multidigit arithmetic. This is convincingly documented, albeit in a negative way, by many traditionally taught children's inclination to apply their standard algorithms in a stereotyped, stubborn way, even in cases where mental arithmetic seems much more appropriate, such as for $24,000/6,000 = \underline{\hspace{2cm}}$ or $4,002 - 3,998 = \underline{\hspace{2cm}}$ (Buys, 2001; Treffers, 1987, 2001), and by their lack of self-confidence to have a go and take risks when leaving the safe path of standard algorithms (Thompson, 1999).

Word Problem Solving

Using the information-processing approach, research on the cognitive processes involved in solving one-step addition and subtraction as well as multiplication and division problems was flourishing during the 1980s and the early 1990s (for extensive and thorough reviews, see Fuson, 1992; Greer, 1992; see also Verschaffel & De Corte, 1997). This work has substantially advanced our understanding of the development of children's solution processes and activities for word problems. For in-

stance, there has been considerable agreement concerning the categorization of real-world addition and subtraction situations involving three quantities in terms of their underlying semantic structure: change, combine, and compare situations. *Change* problems refer to a dynamic situation in which some event changes the value of a quantity (e.g., Joe had 3 marbles; then Tom gave him 5 more marbles; how many marbles does Joe have now?). *Combine* problems relate to static situations where there are two parts that are considered either separately or in combination as a whole (e.g., Joe and Tom have 8 marbles altogether; Joe has 3 marbles; how many marbles does Tom have?). *Compare* problems involve two amounts that are compared and the difference between them (e.g., Joe has 8 marbles; Tom has 5 marbles; how many fewer marbles does Tom have than Joe?). Within each of these three categories, further distinctions can be made depending on the identity of the unknown quantity; furthermore, change and compare problems are also subdivided depending on the direction of the transformation (increase or decrease) or the relationship (more or less), respectively.

Using a variety of techniques, such as written tests, individual interviews, computer simulation, and eye-movement registration, extensive research on these word problems has documented children's performance on the different problem types, the diversity in the solution strategies they use to solve the problems, and the nature and origin of their errors (e.g., Verschaffel & De Corte, 1993). For instance, the psychological significance of the categorization of the word problems was convincingly shown in many studies with 5- to 8-year-old children, reporting that word problems that can be solved by the same arithmetic operation but that belong to distinct semantic categories differ substantially in their level of difficulty; this demonstrates the importance of mastering knowledge of the different semantic problem structures for competent problem solving. From a developmental perspective, this research has demonstrated that most children entering primary school can solve the most simple one-step problems (e.g., change problems with the result set unknown, or combine problems with the whole unknown) using a solution strategy based on modeling the relations and actions described in them. Later on, children's proficiency gradually develops and increases in two important directions. First, informal, external, and cumbersome strategies are progressively replaced by more formalized, abbreviated and internal-

ized, and more efficient strategies. Second, whereas initially children have a different solution method for each problem type that directly reflects the problem situation, they develop more general methods that apply to classes of problems with a similar underlying mathematical structure. Therefore, it is only in the later phases of development that children demonstrate problem-solving behavior that reflects the sequence of steps as described in models of expert problem solving: (a) representing the problem situation; (b) deciding on a solution procedure; (c) carrying out the solution procedure. Because at earlier levels of development they do not proceed through those steps, but use a solution method that directly models the situation, it is not surprising that children then solve problems correctly without first writing a corresponding number sentence (Fuson, 1992), or even without being able to write such a number sentence on request (De Corte & Verschaffel, 1985).

The research on multiplication and division word problems from the information-processing perspective during that period did not lead to a similar coherent theoretical framework as for addition and subtraction problems, but important related results were obtained (Verschaffel & De Corte, 1997). Based on a review of previous work, Greer (1992) proposed a categorization scheme representing different semantic types of multiplication and division situations. Paralleling the developmental findings for addition and subtraction, it was observed that many children can solve one-step multiplication and division problems involving small numbers before they have had any instruction about these operations. Also, here they use a large variety of informal strategies that reflect the action or relationship described in the problem situation. Likewise, the development proceeds in the direction of using more efficient, more formal, and internalized strategies. A difference from addition and subtraction that emerges from the literature, however, is that multiplicative thinking develops more slowly (Anghileri, 2001; Clark & Kamii, 1996).

Overall, the extensive body of research in the 1980s and the early 1990s relating to word problems involving the four basic operations has resulted in identifying different knowledge components of proficiency in solving such problems. This points to the significant role of domain-specific conceptual knowledge concerning semantic structures underlying additive and multiplicative problem situations, and to the diversity of strategies for solving them. Substantial progress has

been made in tracing the developmental steps that children pass through in acquiring problem-solving competence: Starting from a level that is characterized by informal, concrete, and laborious procedures, they progressively acquire more formal, abstract, and efficient strategies. Nevertheless, important issues for further inquiry remain. First, previous research that focused on the initial and middle stages of the development of additive and multiplicative concepts needs to be enlarged to more advanced developmental levels involving extension beyond the domain of positive integers (Greer, 1992; Vergnaud, 1988). Second, and as argued already in 1992 by Greer, whereas in the past the study of both conceptual fields occurred separately, future work should explicitly aim at the integration of additive and multiplicative conceptual knowledge.

A third critical comment on the research carried out in the information-processing tradition largely explains why this approach to the study of word problem solving has fallen into the background in the past decade. As argued in 1992 by Fuson, most of that research used only word problems that are restricted school versions of the real world. Indeed, researchers in this tradition have relied heavily on a narrow range of problems, namely, brief, stereotyped, contextually impoverished pieces of text that contain all the necessary numerical data and end with a clear question that can undoubtedly be answered by performing one or more arithmetic operations on these numbers. These constraints raise serious doubts about the generalizability of the theoretical assertions and the empirical outcomes (such as the importance of semantic schemata) toward solving more realistic, context-rich, and more complex problems in situations inside as well as outside the school (Verschaffel & De Corte, 1997). Therefore, researchers who stress the importance of social and cultural contexts in problem solving have engaged in investigations aimed at unraveling children's solution activities and strategies relating to more authentic and contextually embedded problems.

Well-known examples of this approach are the studies of street mathematics and school mathematics by Nunes, Schliemann, and Carraher (1993) in Recife, Brazil (see also Saxe, 1991). For example, in one study, Nunes et al. observed that young street vendors (9- to 15-year-olds) performed very well on problems in the street-vending context (such as selling coconuts), but less well on isomorphic school mathematics tasks. In addition, they found that in the street-vending situation, the children

solved the problems using informal mathematical reasoning and calculation processes that differ considerably from the formal, school-prescribed procedures they tried to use with much less success on the textbook problems. These findings show in a rather dramatic way the gap that can exist in children's experience and beliefs between the world of the school and the reality of everyday life; to bridge this gap it is thus necessary in mathematics education to take into account children's informal prior knowledge.

Another line of research on mathematics problem solving goes back to the work of Polya, who in 1945 published a prescriptive model of the stages of problem solving involving the following steps: understanding the problem; devising a solution plan; carrying out the plan; and looking back or checking the solution. In each of these steps, Polya distinguishes a number of heuristics that can be applied to the problem, such as "Draw a figure" and "Do you know a related problem?" In the early days of the information-processing approach to the study of cognition, and using emerging ideas of artificial intelligence, Newell and Simon (1972) developed the well-known General Problem Solver, a computer program that solved a variety of rather artificial, puzzle-like problems (e.g., cryptograms), applying general strategies akin to Polya's heuristics, such as means-ends analysis. But research revealed over and over that children's and students' solution processes of word problems do not at all fit the stages of Polya's model. In this respect, two important phenomena observed in students' problem solving are suspension of sense making and lack of strategic approaches to problems. We next briefly review research relating to both phenomena.

A well-known and spectacular illustration of the suspension of sense making in children's problem solving was reported by French researchers in 1980 (Institut de Recherche sur l'Enseignement des Mathématiques de Grenoble, 1980; for an extensive review of this theme, see Verschaffel, Greer, & De Corte, 2000). They administered to a group of first and second graders the following absurd problem: "There are 26 sheep and 10 goats on a ship. How old is the captain?" It turned out that a large majority of the children produced a numerical answer (mostly 36) without any apparent awareness of the meaninglessness of the problem. Similar results were obtained in Germany (Radatz, 1983) and Switzerland (Reusser, 1986) with a number of related problems. The phenomenon showed also up in the United States; the

oft-cited example comes from the Third National Assessment of Educational Progress in 1983 with a sample of 13-year-olds (Carpenter, Lindquist, Matthews, & Silver, 1983): "An army bus holds 36 soldiers. If 1,128 soldiers are being bussed to their training site, how many buses are needed?" Although about 70% of the students correctly carried out the division of 1,128 by 36, obtaining the quotient 31 and remainder 12, only 23% gave 32 buses as the answer; 19% gave as answer 31 buses, and another 29% answered 31 remainder 12. In all these examples, students seem to be affected by the belief that real-world knowledge is irrelevant when solving mathematical word problems, and this results in nonrealistic mathematical modeling and problem solving.

Using the same or similar word problems under largely the same testing conditions, this phenomenon was very extensively studied and replicated independently with students in the age range of 9 to 14 years during the 1990s, initially in several European countries (Belgium, Germany, Northern Ireland, and Switzerland), but also in other parts of the world (Japan, Venezuela; for an overview of these studies, see Verschaffel et al., 2000). In the basic study (Verschaffel, De Corte, & Lasure, 1994), a paper-and-pencil test consisting of 10 pairs of problems was administered collectively to a group of 75 fifth graders (10- to 11-year-old boys and girls). Each pair of problems consisted of a standard problem, that is, a problem that can be solved by the straightforward application of one or more arithmetic operations with the given numbers (e.g., "Steve bought 5 planks of 2 meters each. How many planks of 1 meter can he saw out of these planks?"), and a parallel problem in which the mathematical modeling assumptions are problematic, at least if one seriously takes into account the realities of the context called up by the problem statement (e.g., "Steve bought 4 planks of 2.5 meters each. How many planks of 1 meter can he saw out of these planks?"). An analysis of the students' reactions to the problematic tasks yielded an alarmingly small number of realistic responses or comments based on the activation of real-world knowledge (responding to the problem about the 2.5 m planks with 8 instead of 10). Indeed, only 17% of all the reactions to the 10 problematic problems could be considered realistic, either because the realistic answer was given, or the nonrealistic answer was accompanied by a realistic comment (e.g., with respect to the planks problem, some students gave the answer 10, but

added that Steve would have to glue together the four remaining pieces of .5 m two by two). The fact that these studies yielded very similar findings worldwide justifies the conclusion that children's belief that real-world knowledge is irrelevant when solving word problems in the mathematics classroom represents a very robust research result. Moreover, additional studies in our center (De Corte, Verschaffel, Lasure, Borghart, & Yoshida, 1999), but also by other European researchers (see Greer & Verschaffel, 1997), have shown that this misbelief about the role of real-world knowledge during word problem solving is very strong and resistant to change.

How is it possible that the results of some years of mathematics education could be the willingness of children to collude in negating their knowledge of reality? Gradually, researchers came to realize that this apparent "senseless behavior" should not be considered the result of a "cognitive deficit" in children, but should be construed as sense making of a different sort, namely, a strategic decision to play the "word problem game" (De Corte & Verschaffel, 1985). As expressed by Schoenfeld (1991, p. 340):

Such behavior is sense-making of the deepest kind. In the context of schooling, such behavior represents the construction of a set of behaviors that results in praise for good performance, minimal conflict, fitting in socially and so on. What could be more sensible than that?

Students' strategies and beliefs develop from their perceptions and interpretations of the didactic contract (Brousseau, 1997) or the sociomathematical norms (Yackel & Cobb, 1996) that determine—largely implicitly—how they behave in a mathematics class, how they think, and how they communicate with the teacher. This enculturation seems to be mainly caused by two aspects of current instructional practice: the nature of the (traditional) word problems given and the way these problems are conceived and treated by teachers. Support for the latter factor comes from a study by Verschaffel, De Corte, and Borghart (1997), where preservice elementary school teachers were asked, first, to solve a set of problems themselves and, second, to evaluate realistic and unrealistic answers from imaginary students to the same set of problems. The results indicated that these future teachers shared, though in a less extreme form, students' tendency to suspend sense making.

Research has also documented convincingly the lack of strategic aspects of proficiency in students' solution activities of word problems. When confronted with a problem, they do not spontaneously use valuable heuristic strategies (such as analyzing the problem, making a drawing of the problem situation, decomposing the problem) in view of constructing a good mental representation of the problem as a lever to understanding the problem well. For instance, in a study by De Bock, Verschaffel, and Janssens (1998), 120 12- to 13-year-old seventh graders were administered a test with 12 items involving enlargements of similar plane figures, six of which were so-called proportional, and the other six nonproportional items, as illustrated by the following examples:

- *Proportional items:* Farmer Gus needs approximately 4 days to dig a ditch around a square pasture with a side of 100 m. How many days would he need to dig a ditch around a square pasture with a side of 300 m?
- *Nonproportional item:* Farmer Carl needs approximately 8 hours to manure a square piece of land with a side of 200 m. How many hours would he need to manure a piece of land with a side of 600 m?

In line with what was predicted, the proportional items were solved very well (over 90% correct), whereas performance on the nonproportional items was extremely weak (only about 2% correct). An inspection of the answer sheets revealed that only 2% of the students spontaneously made a drawing of the nonproportional items; in other words, most 12- to 13-year-olds were not at all inclined to apply to these problems the appropriate heuristic "Make a drawing of the problem." Even the encouragement to make a drawing or the presentation of a ready-made drawing when given a second test did not significantly increase performance. Continued research using individual interviews for the in-depth analysis of the thinking processes of 12- to 13- and 15- to 16-year old students has confirmed the improper use of proportional or linear reasoning, as well as its resistance to change (De Bock, Van Dooren, Janssens, & Verschaffel, 2002).

Similar outcomes revealing the lack of use of heuristic strategies, especially in weak problem solvers, have been reported by many other scholars, even with older subjects (e.g., De Corte & Somers, 1982; Hegarty, Mayer, & Monk, 1995; Van Essen, 1991). As argued in the NRC (2001a) report, weak problem solvers often

rely on very superficial methods to solve problems. For example, when given the problem “At ARCO, gas sells for \$1.13 per gallon. This is 5 cents less per gallon than gas at Chevron. How much does 5 gallons of gas cost at Chevron?” they focus on the numbers and on the keyword “less,” which triggers the wrong arithmetic operation, in this case subtraction. In contrast, successful problem solvers build a mental representation of the problem by carefully analyzing the situation described, focusing on the known and unknown quantities and their relationships.

But not being heuristic is not the only flaw in students’ (especially the weaker ones) problem-solving approach. Maybe even more important is the absence of metacognitive activities during problem solving. Indeed, research has clearly shown that the use of cognitive self-regulation skills—such as planning a solution process, monitoring that process, evaluating the outcome, and reflecting on one’s solution strategy—is a major characteristic of expert mathematics problem solving (e.g., Schoenfeld, 1985, 1992). Comparative studies have convincingly documented that successful problem solvers more often apply self-regulation skills than unsuccessful ones, in the United States (see, e.g., Carr & Biddlecomb, 1998; Garofalo & Lester, 1985; Silver, Branca, & Adams, 1980) as well as in other parts of the world. For example, in the Netherlands, Nelissen (1987) found that good problem solvers among elementary school children were better at self-monitoring and reflection than poor problem solvers; Overtoom (1991) registered analogous differences between gifted and average students at the primary and secondary school levels. De Corte and Somers (1982) observed a strong lack of planning and monitoring of problem solving in a group of Flemish sixth graders, leading to poor performance on a word problem test. In his well-known studies, Krutetskii (1976) observed differences between elementary and secondary school students of different ability levels with respect to metacognitive activities during word problem solving. In summary, there is abundant evidence showing that cognitive self-regulation constitutes a major aspect of skilled mathematical learning and problem solving, but that it is often absent, especially in weak problem solvers.

The work of Krutetskii (1976) showing differences between primary and secondary school students elicits the question of whether there are developmental differences in metacognitive awareness and skills. However, based on an analysis of a number of studies, Carr and

Biddlecomb (1998, p. 73) conclude that young as well as older children (up to middle and high school) fail in monitoring and evaluating their problem solving activities:

Taken together, metacognitive research in mathematics is similar to metacognitive research in other domains: Children can benefit from both strategy-specific knowledge and from metacognitive awareness. Metacognitive research in mathematics, however, differs in showing that the use of cognitive monitoring and evaluation frequently do not appear to develop in children even in late childhood.

This raises a challenging issue for future research: Why is there, or should there be, a difference in this respect between mathematics and other domains? Indeed, the extensive literature on metacognitive development (Kuhn, 1999, 2000) suggests that metacognitive awareness emerges in children by age 3 to 4, and that starting from there, the executive control of cognitive functioning is acquired gradually through multiple developmental transitions (Zelazo & Frye, 1998). Development does not occur as a single transition, but “entails a shifting distribution in the frequencies with which more or less adequate strategies are applied, with the inhibition of inferior strategies as important an achievement as the acquisition of superior ones” (Kuhn, 2000, p. 179; see also Siegler, 1996).

Taking into account that it is plausible that the nature and development of cognitive self-regulation skills show some generality across domains (Kuhn, 2000), this current perspective on metacognitive development presents an interesting framework for future research on the development of mathematics-related self-regulation skills, especially because enhancing metacognitive awareness and skills constitutes a major component of mathematical proficiency and, thus, an important developmental and educational goal.

The preceding discussion shows that over the past 20 years substantial progress has been made in understanding the role and development of major components of a mathematical disposition in children’s word problem solving. These components are domain-specific knowledge (conceptual understanding as well as computational fluency), heuristic strategies, and self-regulation skills. Although the available work points to the interwoven character of the different components, a challenge for future research consists in unraveling in greater detail the interactions among those strands in the acquisition and development of competence in mathematical problem solving.

Mathematics-Related Beliefs

Based on 2 decades of research, there is currently quite general agreement in the literature that beliefs that students hold about mathematics and about mathematics education have an important impact on their approach to mathematics learning and on their performance (Leder, Pehkonen, & Törner, 2002; Muis, 2004). In the *Curriculum and Evaluation Standards for School Mathematics* the NCTM echoed this point of view in 1989: “These beliefs exert a powerful influence on students’ evaluation of their own ability, on their willingness to engage in mathematical tasks, and on their ultimate mathematical disposition” (p. 233).

To acquire the intended mathematical disposition, it is thus important that students develop positive beliefs about mathematics as a domain and about mathematics education. This converges with the component of “productive disposition,” one of the five strands of mathematical proficiency proposed in the 2001 report of the NRC (2001a, p. 131): “*Productive disposition* refers to the tendency to see sense in mathematics, to perceive it as both useful and worthwhile, to believe that steady effort in learning mathematics pays off, and to see oneself as an effective learner and doer of mathematics.” However, the available research shows that today the situation in mathematics classrooms is remote from this ideal. One pertinent illustration derives from studies in which students of different ages were asked to draw a mathematician at work. In one study by Picker and Berry (2000), 476 12- to 13-year-olds from several countries (United States, United Kingdom, Finland, Sweden, and Romania) were asked to make such a drawing and to comment on it in writing. A major conclusion from the study is that in all the countries involved, the gist of the images produced by the students was that of powerless little children confronted with mathematicians portrayed as authoritarian and threatening. According to the authors, the dominant picture of a mathematician that emerged from their study is in line with the images obtained in a similar investigation by Rock and Shaw (2000) with children ranging from kindergarten through the eighth grade. As it is plausible that children’s drawings reflect their beliefs about mathematics, it is obvious that they do not perceive this domain as attractive and interesting.

Based on an analysis of the literature, De Corte, Op ’t Eynde, and Verschaffel (2002; see also Op ’t Eynde, De Corte, & Verschaffel, 2002) have made a distinction

among three kinds of student beliefs: beliefs about the self in relation to mathematical learning and problem solving (e.g., self-efficacy beliefs relating to mathematics), beliefs about the social context (e.g., the social norms in the mathematics class), and beliefs about mathematics and mathematical learning and problem solving. With respect to the last type, it has been shown that, probably as a consequence of current educational practices, students of a wide range of ages and abilities acquire beliefs relating to mathematics that are naive, incorrect, or both, but that have mainly a negative or inhibitory effect on their learning activities and approaches to mathematics tasks and problems (Muis, 2004; Schoenfeld, 1992; Spangler, 1992). From a certain perspective, the research reported earlier on the suspension of sense making in solving word problems is also an illustration of these phenomena. In other words, the available data are in line with the bleak situation that emerged from the studies of Picker and Berry (2000) and Rock and Shaw (2000). According to Greeno (1991a), most students learn from their experiences in the classroom that mathematics knowledge is not something constructed by the learner, either individually or in a group, but a fixed body of received knowledge. In a similar way, Lampert (1990) characterizes the common view about mathematics as follows: Mathematics is associated with certainty and with being able to quickly give the correct answer; doing mathematics corresponds to following rules prescribed by the teacher; knowing math means being able to recall and use the correct rule when asked by the teacher; and an answer to a mathematical question or problem becomes true when it is approved by the authority of the teacher. She also argues that those beliefs are acquired through years of watching, listening, and practicing in the mathematics classroom. A case study by Boaler and Greeno (2000), this time at the secondary school level, likewise suggests that students’ problematic beliefs result more or less directly from the actual curriculum and classroom practices and culture.

Convincing empirical evidence for the claim that students are afflicted by such beliefs has been reported by Schoenfeld (1988) in an article with the strange title “When Good Teaching Leads to Bad Results: The Disasters of ‘Well-Taught’ Mathematics Courses.” Schoenfeld made a year-long intensive study of one 10th-grade geometry class with 20 students, along with periodic data collections in 11 other classes (210 students altogether) involving observations, interviews with teachers

and students, and questionnaires relating to students' perceptions about the nature of mathematics. The students scored well on typical achievement measures, and the mathematics was taught in a way that would generally be considered good teaching. Nevertheless, it was found that students acquired debilitating beliefs about mathematics and about themselves as mathematics learners, such as "All mathematics problems can be solved in just a few minutes" and "Students are passive consumers of others' mathematics." It is obvious that such misbeliefs are not conducive to a mindful and persistent approach to new and challenging problems. Other strange beliefs that have been observed in students, and that are to a large extent responsible for the lack of sense making when doing word problem solving, are "Mathematics problems have one and only one right answer" and "The mathematics learned in school has little or nothing to do with the real world" (see, e.g., Schoenfeld, 1992).

With regard to beliefs about the self, it has been shown that self-efficacy beliefs are predictive of performance in mathematics problem solving in university students (Pajares & Miller, 1994). However, this seems to be the result of a developmental trend that mirrors an evolution in the nature and complexity of these beliefs. For instance, a study by Kloosterman and Cougan (1994) on a sample of 62 students in grades 1 to 6 suggests that students' confidence beliefs and liking of mathematics in the first two grades of elementary school are independent of their achievement levels, but that by the end of elementary school, these beliefs are related to performance, and that low achievers, besides having low confidence, start to dislike mathematics. Wigfield et al. (1997) also found that in the beginning of primary school, children view mathematics as important and themselves as competent to master it (see also NRC, 2001a). But later during primary school, their competence beliefs decrease. Middleton and Spanias (1999) point to the junior high school level as the crucial stage where students' beliefs about mathematics become more influential; unfortunately, a large number of students start developing more negative beliefs about the self in relation to mathematics (see also Muis, 2004; Wigfield et al., 1997).

As already stressed, several authors have argued that the negative mathematics-related beliefs of students of different ages are largely induced by current educational practices. However, although anecdotal observations and a few case studies point in that direction, this must be considered a plausible hypothesis in need of further

research. Therefore, a major challenge for continued inquiry is the systematic study of the interplay between students' beliefs and instructional intervention, focusing on the design of interventions that can facilitate the acquisition of the intended productive disposition. This type of research would at the same time contribute to tracing in a more detailed way the development of mathematics-related beliefs in students. Indeed, as is the case for general epistemological beliefs (i.e., beliefs about knowing and knowledge; see Hofer & Pintrich, 2002), there is a need for better research-based knowledge about the nature and the processes of development of mathematics-related beliefs and about the internal and contextual factors that induce change in those beliefs in students (see also Muis, 2004).

Summary

The preceding selective review of research relating to components of mathematical competence shows that over the past decades, substantial progress has been made in unraveling major and educationally relevant aspects of their nature and development. The discussions have also shown the interdependency of the distinct components of proficiency in mathematics, for instance, the interconnectedness of conceptual and procedural knowledge in computation skills; the integration of domain knowledge, heuristic strategies, self-regulation skills, and beliefs in problem solving; and the complexity of number sense.

However, throughout this analysis of major components of a mathematical disposition, it has also become clear that important unanswered questions call for continued inquiry in view of the elaboration of a more encompassing and overarching theoretical framework of the development of mathematical competence. For instance, a crucial and still largely unresolved question with respect to the development of several components, such as basic conceptual and procedural knowledge structures, is to what degree they are either biologically prepared and, thus, more or less universal schemas, or are acquired in and attuned to situational contexts (see, e.g., Resnick, 1996). Whether a conceptual structure is subjected mainly to the first or to the second trend has important implications for teaching: It constrains or facilitates its sensitivity for instructional intervention. A related topic for further investigation is the more fine-grained unraveling of the interactions among the different components of mathematical competence. Future research must address more intensively the development

of competence in other subdomains of mathematics, such as rational numbers, negative numbers, proportional reasoning, algebra, measurement, and geometry. Illustrative in this respect are the following quotes from the NRC (2001a) report, *Adding It Up: Helping Children Learn Mathematics*:

Moreover, how students become proficient with rational numbers is not as well understood as with whole numbers. (p. 231)

Compared with the research on whole numbers and even on noninteger rational numbers, there has been relatively little research on how students acquire an understanding of negative numbers and develop proficiency in operating with them. (p. 244)

LEARNING MATHEMATICS: ACQUIRING THE COMPONENTS OF COMPETENCE

The learning component of the CLIA model should provide us with an empirically based description and explanation of the processes of learning and development that must be elicited and kept going in students to facilitate in them the acquisition of the intended mathematical disposition and the components of competence involved in it. Research over the past decades has made progress in that direction and has resulted in the view of mathematics learning as the active and cumulative construction in a community of learners of meaning, understanding and skills based on modeling of reality (see, e.g., De Corte et al., 1996; Fennema & Romberg, 1999; Nunes & Bryant, 1997; Steffe, Nesher, Cobb, Goldin, & Greer, 1997). This conception implies that productive mathematics learning has to be a self-regulated, situated, and collaborative activity.

Learning as Cumulative Construction of Knowledge and Skills

The view that learning is a cumulative and constructive activity has nowadays become common ground among educational psychologists in general, and among mathematics educators in particular, and there is substantial empirical evidence supporting it (e.g., NRC, 2000; Simons, Van der Linden, & Duffy, 2000; Steffe & Gale, 1995). What is essential in the constructivist approach to learning is the mindful and effortful involvement of learners in the processes of knowledge and skill acquisition in interaction with the environment and building on their prior knowledge. What needs to be constructed is the process of doing mathematics rather than the mathe-

matical content (Greer, 1996). This is well illustrated in the work of Nunes et al. (1993) with Brazilian street vendors referred to earlier. In one case, the interviewer, acting as a customer, bought from a 12-year-old vendor 10 coconuts at 35 cruzeiros a piece. After the interviewer said, "I'd like 10. How much is that?" there was a pause and then the vendor reacted as follows: "Three will be 105; with three more that will be 210. [Pause] I need four more. That is . . . [pause] 315. . . . I think it is 350" (p. 19). This cumbersome but accurate calculation procedure was clearly invented by the street vendor himself. Indeed, third graders in Brazil learn to multiply any number by 10 by just putting a zero to the right of that number.

In our own work, we observed in first graders a great variety of solution strategies for one-step addition and subtraction problems (Verschaffel & De Corte, 1993). Many of these strategies were never explicitly taught in school, but they were invented by the children themselves. For example, to solve the difficult change problem "Pete had some apples; he gave 5 apples to Ann; now Pete has 7 apples; how many apples did Pete have in the beginning?" some children successfully applied a kind of trial-and-error strategy: They estimated the size of the initial amount and checked their guess by subtracting it by 5 to see if there were 7 left; if not, they made a new guess and checked again.

But the constructive nature of learning is also evidenced in a negative way in the misconceptions and defective procedures that many learners acquire in a variety of content domains, including mathematics. A well-known illustration of the latter kind of erroneous inventions are the so-called buggy algorithms, that is, systematic procedural errors made by children on multi-digit arithmetic operations, such as subtracting the smaller digit from the larger one in each column regardless of position, as in the following example:

$$\begin{array}{r} 543 \\ - 175 \\ \hline 432 \end{array}$$

Based on task analysis and using computer simulation, it has been shown that such bugs can be predicted as constructions of the child who is faced with an impasse because conditions are encountered beyond the currently mastered procedures (VanLehn, 1990).

A well-documented misconception is the idea that multiplication always makes bigger. There is, for instance, overwhelming evidence from studies with

students of different ages (from 12- to 13-year-olds up to preservice teachers) supporting the most obvious manifestation of this misconception, known as the multiplier effect: When given the task to choose the operation to solve a multiplication problem with a multiplier smaller than 1, almost 50% of the preservice teachers and almost 70% of the 12- to 13-year-olds made an incorrect choice (mostly division instead of multiplication; Greer, 1988; see also De Corte, Verschaffel, & Van Coillie, 1988; Greer, 1992). Remarkable from a developmental perspective is the persistence of this multiplier effect over a broad age range. As argued by Hatano (1996, p. 201), “Procedural bugs and misconceptions are taken as the strongest pieces of evidence for the constructive nature of knowledge acquisition, because it is very unlikely that students have acquired them by being taught.”

Notwithstanding the evidence showing that students construct their own knowledge, even in learning environments that are implicitly based on an information-transmission model, today we cannot pretend to have a well-elaborated constructivist learning theory. What Fischbein argued in 1990 still largely holds true, namely, “the need for a more specific definition of constructivism as a psychological model for mathematical education” (p. 12). For instance, current constructivist approaches to learning do not provide clear and detailed guidelines for the design of teaching-learning environments (Greer, 1996; see also Davis, Maher, & Noddings, 1990). This standpoint is echoed in a recent contribution by Cobb, Confrey, diSessa, Lehrer, and Schauble (2003) stating that general orientations to education, such as constructivism, often fail to offer detailed guidelines for organizing instruction. The authors present the following illustration:

The claim that invented representations are good for mathematics and science learning probably has some merit, but it specifies neither the circumstances in which these representations might be of value nor the learning processes involved and the manner in which they are supported. (p. 11)

Indeed, it is important to stress that the view of learning as an active process does not imply that students’ construction of their knowledge cannot be supported and guided by suitable interventions by teachers, peers, and educational media (see, e.g., Grouws & Cebulla, 2000). Thus, the claim that productive learning is accompanied by good teaching still holds true. Moreover, as argued in the recent volume *Beyond Constructivism* (Lesh &

Doerr, 2003), there are distinct categories of instructional objectives in mathematics education, and not all of them have to be discovered and constructed autonomously by the learners.

The present state of the art thus calls for continued theoretical and empirical research aimed at a deeper understanding and a more fine-grained analysis of the nature of constructive learning processes that are conducive to the acquisition of worthwhile knowledge, (meta)cognitive strategies, and affective components of skilled performance, and of the role and nature of instruction in eliciting and facilitating such learning processes.

Learning Is Increasingly Self-Regulated

If the process and not the product of learning is the focus of constructivism, this also implies that constructive learning has to be self-regulated. Indeed, self-regulation “refers to the degree that individuals are metacognitively, motivationally, and behaviorally active participants in their own learning process” (Zimmerman, 1994, p. 3). It is a form of action control characterized by the integrated regulation of cognition, motivation, and emotion (De Corte, Verschaffel, & Op ’t Eynde, 2000; see also Boekaerts, 1997). Research has shown that self-regulated learners in school are able to manage and monitor their own processes of knowledge and skill acquisition; that is, they master and apply self-regulatory learning and problem-solving strategies on the basis of self-efficacy perceptions in view of attaining valued academic goals (Zimmerman, 1989). Skilled self-regulation enables learners to orient themselves to new learning tasks and to engage in the pursuit of adequate learning goals; it facilitates appropriate decision making during learning and problem solving, as well as the monitoring of an ongoing learning and problem-solving process by providing their own feedback and performance evaluations and by keeping themselves concentrated and motivated. It has also been established in a variety of content domains, including mathematics, that the degree of students’ self-regulation correlates strongly with academic achievement (Zimmerman & Risemberg, 1997). The importance of self-regulation for mathematics learning has been stressed, especially by reflective activities, for instance, by Nelissen (1987). During learning, the student has to continuously make decisions about the next steps to be taken, for example, looking back for a formula or theorem, reconsidering a problem situation from a different perspective or restructuring it, or making an estimation of the expected outcome.

Moreover, it is necessary to monitor learning processes through intermediate evaluations of the progress made in acquiring, understanding, and applying new knowledge and skills, as well as of one's motivation and concentration on the learning task.

However, as we reported in the section on word problem solving, many students, especially the weaker ones, do not master appropriate and efficient cognitive self-regulation skills that facilitate their learning of new knowledge and skills and enhance their success in mathematical problem solving. In some ways, this is not so surprising. Indeed, observing current teaching practices in mathematics classrooms, one often has the impression that regulating students' learning and problem solving appropriately is considered to be the task of the teacher. This induces the beliefs mentioned earlier, namely, that mathematics is a fixed body of knowledge received from the teacher and that doing mathematics is following the rules prescribed by the teacher. At the same time, as shown earlier, students often develop inappropriate self-regulating learning activities that result in defective algorithmic procedures and/or misconceptions.

On a more positive note, the literature shows that the self-regulation of learning can be enhanced through appropriate guidance (see, e.g., Schunk, 1998; Zimmerman, 2000). We will come back to this in the section on intervention.

Learning Is Situated and Collaborative

The idea that learning and cognition are situated activities was strongly put forward in the late 1980s in reaction to the then dominant cognitive view of learning and thinking as highly individual and purely mental processes occurring in the brain and resulting in encapsulated mental representations (J. S. Brown, Collins, & Duguid, 1989). This cognitive view is in line with Sfard's (1998) acquisition metaphor of learning focused on individual enrichment through acquiring knowledge, skills, and so on. In contrast, the situated perspective converges with the participation metaphor: It stresses that learning is enacted essentially in interaction with social and cultural contexts and artifacts, and especially through participation in cultural activities and contexts (Greeno & the Middle School Mathematics through Applications Project Group, 1998; Lave & Wenger, 1991; see also Bruner, 1996; Greeno, Collins, & Resnick, 1996; Sfard, 1998). This situated conception of learning and cognition is nowadays quite widely shared in the

mathematics education community. The calculation procedure invented by the Brazilian street vendor in the realistic context of his business is a nice illustration of this view. It also is representative of the outcomes of a series of ethnomathematical studies of the informal calculation procedures and problem-solving strategies of particular groups of children and adults who are involved in specific everyday cultural practices of business, tailoring, weaving, carpentry, grocery, packing, cooking, and so on (Nunes, 1992; for a summary, see De Corte et al., 1996).

Although the situated nature of learning has been documented especially well in studies carried out in everyday contexts, it is obvious that situatedness applies to school learning as well. For instance, the young street vendors in the study by Nunes et al. (1993) who were so successful in using informal invented strategies and procedures when selling coconuts did not do well when solving isomorphic textbook problems in school. There they tried, without much success, to apply the formal procedures learned in the mathematics lessons. The work on the suspension of sense making when doing school word problems can be considered another line of evidence for the importance of the social and cultural situatedness of mathematical thinking and learning (Lave, 1992).

The situated perspective on learning has fueled and supported the movement toward more authentic and realistic mathematics education, although it has to be added that such an approach to mathematics teaching and learning was already introduced and developed earlier by several groups of mathematics educators; the most typical example in this respect is probably Freudenthal, who developed and implemented, together with his collaborators, Realistic Mathematics Education in the Netherlands in the 1970s (see, e.g., Streefland, 1991; Treffers, 1987).

Of special importance from an educational perspective is that the situativity view of learning and cognition has obviously also contributed to emphasis on the importance of collaboration for learning. In fact, because it emphasizes the social and participatory character of learning, the situated perspective implies the collaborative nature of learning. This means that effective learning is not a purely solo activity, but essentially a distributed one; that is, the learning efforts are distributed over the individual student, his or her partners in the learning environment, and the technological resources and tools that are available. In the past, this idea was embraced broadly by mathematics educators. For

instance, Wood, Cobb, and Yackel (1991; see also Cobb & Bauersfeld, 1995) consider social interaction essential for mathematics learning, with individual knowledge construction occurring throughout processes of interaction, negotiation, and cooperation.

There is no doubt that the available literature provides substantial evidence supporting the positive effects of collaborative learning on the cognitive as well as the social and affective outcomes of learning (see, e.g., Good, Mulryan, & McCaslin, 1992; Mevarech & Light, 1992; Salomon, 1993a). In the cognitive domain, the significance of interaction, collaboration, and communication lies especially in their requiring insights, strategies, and problem-solving methods to be made explicit. This not only supports conceptual understanding, it also fosters the acquisition of heuristic strategies and metacognitive skills. Therefore, a shift toward more social interaction and participation in mathematics classrooms would represent a worthwhile move away from the traditional overemphasis on individual learning that prevails, as shown in a study by Hamm and Perry (2002). Studying the classroom discourse processes and participatory structures in six first-grade classrooms, they found that five out of the six teachers did not grant any authority to their students and did not create a classroom community in which students participated in mathematical discourse and analysis; even the one teacher who invited her students to take some responsibility as members of a mathematical community still mainly reinforced herself as the source of mathematical authority rather than the classroom community. But one should also avoid falling into the trap of the other extreme. Indeed, stressing the importance for learning of collaboration, interaction, and participation does not at all deny that students can and do develop new knowledge individually. As argued by Salomon (1993b), distributed and individual cognitions interact during productive learning (see also Salomon & Perkins, 1998; Sfard, 1998).

Summary

The preceding discussion shows that recent research provides substantial evidence supporting the view that productive mathematics learning is a constructive, progressively more self-regulated, and situated process of knowledge building and skill acquisition involving ample opportunities for interaction, negotiation, and collaboration. Therefore, it seems self-evident that we

should take these basic characteristics of this conception of learning as major guidelines for the design of curricula, textbooks, learning environments, and assessment instruments that aim at fostering in students the acquisition of a mathematical disposition as defined in the previous section of this chapter.

But, notwithstanding this positive overall result of past inquiry, numerous issues and problems have to be addressed in future research. We stressed the need to further unravel the nature of constructive learning processes and the role of instructional interventions in eliciting such processes. Continued research should also aim at tracing the development in students of self-regulatory skills, and at unpacking how and under what instructional conditions students become progressively more self-regulated learners. Similarly, it is necessary to get a better understanding of how collaborative work in small groups influences the learning and thinking of students of different ages, of the role of individual differences on group work, and of the processes that are at work during group activities.

DESIGNING POWERFUL MATHEMATICS LEARNING ENVIRONMENTS

The preceding sections elucidated the ultimate objective of mathematics education, developing a mathematical disposition, as well as major characteristics of learning processes that can facilitate the acquisition of the different components of such a disposition. All this leads us to the important and challenging question relating to the intervention component of the CLIA model: How can powerful mathematics learning environments be designed for inducing in students the intended learning activities and processes, and by so doing, fostering in them the progressive development and mastery of a mathematical disposition?

Over the past 15 years, scholars in the domain of mathematics education have been addressing this challenge mainly by using intervention studies, such as in constructional research (Becker & Selter, 1996), and design experiments (Cobb et al., 2003) or design-based research (Sandoval & Bell, 2004b). Becker and Selter define constructional research “as research that is connected with suggestions on how teaching ought to be or *could* be, to put it slightly more moderately. . . . [It is] concentrating on the development of theoretically

founded and empirically tested practical *suggestions* for teaching” (p. 525). According to Cobb et al.:

Design experiments entail both “engineering” particular forms of learning and systematically studying those forms of learning within the context defined by the means of supporting them. This designed context is subject to test and revision, and the successive iterations that result play a role similar to that of systematic variation in experiments. (p. 9)

It is important to stress that this type of research intends to advance theory building about learning from instruction, besides contributing to the innovation and improvement of classroom practices (Cobb et al., 2003; De Corte, 2000). In this respect, Sandoval and Bell (2004a, pp. 199–200) characterize design-based research as “theoretically framed, empirical research of learning and teaching based on particular designs of instruction.” From a theoretical perspective, then, a major task bears on the development and validation of a coherent set of guiding principles for the design of powerful mathematics learning environments.

Due to space restrictions, we can discuss only a very small selection from the extensive number of projects that have been or still are being carried out (see, e.g., Becker & Selter, 1996), focusing on primary education and choosing examples that are in line with the constructivist perspective on learning discussed earlier. Specifically, two studies are reviewed in some detail: a learning environment for mathematical problem solving in the upper primary school (Verschaffel et al., 1999) and a program of classroom teaching experiments aiming at better understanding the development of social and sociomathematical norms in the lower grades of the primary school (Cobb, 2000; Yackel & Cobb, 1996). Besides the distinction in grade level and the geographical spread over both sides of the Atlantic, the two examples differ in two other respects. Whereas our intervention focuses on word problem solving, the work of Cobb and his coworkers relates to mental calculation with whole numbers, thus representing two distinct aspects of mathematical competence. In addition, both studies contrast and complement each other interestingly from a methodological perspective. The first one is a relatively well-controlled investigation looking for treatment effects, with some attention to differences between teachers in implementing the intervention but providing little sense of the processes that produce different outcomes; Cobb’s investigations have a more longitudinal charac-

ter and pay closer attention to the ongoing processes of learning and teaching in the mathematics classroom.

A Learning Environment for Mathematical Problem Solving in Upper Primary School Children

Parallel with the rethinking of the objectives and the nature of mathematics education by researchers in the field, initiatives have been implemented in many countries to reform and innovate classroom practices (see, e.g., NCTM, 1989, 2000). This has also been the case in the Flemish part of Belgium. Since the school year 1998 to 1999, new standards for primary education became operational (Ministerie van de Vlaamse Gemeenschap, 1997). For mathematics education, these standards embody an important shift that is in line with the view of mathematical competence as defined by de-emphasizing the teaching and practicing of procedures and algorithms, and instead stressing the importance of mathematical reasoning and problem-solving skills and their application to real-life situations and problems, as well as the development of positive attitudes and beliefs toward mathematics. To implement the new standards, the Department of Education of the Flemish Ministry commissioned the present project from our center, aimed at the design and evaluation of a powerful learning environment that can elicit in upper primary school students the constructive learning processes for acquiring the intended mathematical competence (for a more detailed report, see Verschaffel et al., 1999).

Taking into account the literature discussed in the previous sections, a set of five major guidelines for designing a learning environment was derived from our present understanding of a mathematical disposition (the first component of the CLIA model) and the characteristics of constructive learning processes (the second CLIA component):

1. Learning environments should initiate and support active, constructive acquisition processes in *all* students, thus also in the more passive learners and independent of socioeconomic status and/or ethnic diversity. However, the view of learning as an active process does not imply that students’ construction of their knowledge cannot be guided and mediated by appropriate interventions. Indeed, the claim that productive learning involves good teaching still holds true. In other words, a powerful learning environment

is characterized by a good balance between discovery and personal exploration, on the one hand, and systematic instruction and guidance, on the other, always taking into account individual differences in abilities, needs, and motivation among learners.

2. Learning environments should foster the development of self-regulation strategies in students. This implies that external regulation of knowledge and skill acquisition through systematic instructional interventions should be gradually removed so that students become more and more agents of their own learning.
3. Because of the importance of context and collaboration for effective learning, learning environments should embed students' constructive acquisition activities in real-life situations that have personal meaning for the learners, that offer ample opportunities for distributed learning through social interaction, and that are representative of the tasks and problems to which students will have to apply their knowledge and skills in the future.
4. Because domain-specific knowledge, heuristic methods, metaknowledge, self-regulatory skills, and beliefs play complementary roles in competent learning, thinking, and problem solving, learning environments should create opportunities to acquire general learning and thinking skills embedded in the mathematics content.
5. Powerful learning environments should create a classroom climate and culture that encourages students to explain and reflect on their learning activities and problem-solving strategies. Indeed, fostering self-regulatory skills requires that students become aware of strategies, believe that they are worthwhile and useful, and finally master and control their use (Dembo & Eaton, 1997).

Aims of the Learning Environment

The aims of our learning environment were twofold. The first aim was the acquisition of an overall cognitive self-regulatory strategy for solving mathematics application problems. This consisted of five stages and involved a set of eight heuristic strategies that are especially useful in the first two stages of that strategy (see Table 4.1). Acquiring this strategy involves (a) becoming aware of the different phases of a competent problem-solving process (awareness training); (b) being able to monitor and evaluate one's actions during the different phases of the solution process (self-regulation training); and (c) gaining mastery of the eight heuristic strategies

Table 4.1 The Competent Problem-Solving Model Underlying the Learning Environment

| | |
|---|--|
| Step 1: Build a Mental Representation of the Problem | Heuristics: Draw a picture. |
| | Make a list, a scheme, or a table. |
| | Distinguish relevant from irrelevant data. |
| | Use your real-world knowledge. |
| Step 2: Decide How to Solve the Problem | Heuristics: Make a flowchart. |
| | Guess and check. |
| | Look for a pattern. |
| | Simplify the numbers. |
| Step 3: Execute the Necessary Calculations | |
| Step 4: Interpret the Outcome and Formulate an Answer | |
| Step 5: Evaluate the Solution | |

(heuristic strategy training). The five stages of this strategy for cognitive self-regulation parallel the models proposed by Schoenfeld (1985) and Lester, Garofalo, and Kroll (1989).

The second aim was the acquisition of a set of appropriate beliefs and positive attitudes with regard to mathematics learning and problem solving (e.g., "Mathematics problems may have more than one correct answer"; "Solving a mathematics problem may be effortful and take more than just a few minutes").

Major Characteristics and Organization of the Learning Environment

The five design principles were applied in an integrated way in the learning environment. This resulted in an intervention characterized by the following three basic features:

1. *A varied set of complex, realistic, and challenging word problems.* These problems differed substantially from the traditional textbook problems and were carefully designed to elicit the application of the intended heuristics and self-regulatory skills that constitute the model of skilled problem solving. The example that follows illustrates the type of problems used in the learning environment:

School Trip Problem*

The teacher told the children about a plan for a school trip to visit the Efteling, a well-known amusement park

*The problem is not presented in its original format because it takes a lot of space. Moreover, translating it from Flemish to English is somewhat cumbersome.

in the Netherlands. But if that would turn out to be too expensive, one of the other amusement parks might be an alternative.

Each group of four students received copies of folders with entrance prices for the different parks. The lists mentioned distinct prices depending on the period of the year, the age of the visitors, and the kind of party (individuals, families, groups).

In addition, each group received a copy of a fax from a local bus company addressed to the principal of the school. The fax gave information about the prices for buses of different sizes (with a driver) for a 1-day trip to the Efteling.

The first task of the groups was to determine whether it was possible to make the school trip to the Efteling given that the maximum price per child was limited to 12.50 euro.

After finding out that this was not possible, the groups received a second task: They had to find out which of the other parks could be visited for the maximum amount of 12.50 euro per child.

2. *A series of lesson plans based on a variety of activating and interactive instructional techniques.* The teacher initially modeled each new component of the metacognitive strategy; a lesson consisted of a sequence of small-group problem-solving activities or individual assignments, always followed by a whole-class discussion. During all these activities, the teacher's role was to encourage and scaffold students to engage in and to reflect on the kinds of cognitive and metacognitive activities involved in the model of competent mathematical problem solving. These encouragements and scaffolds were gradually withdrawn as the students became more competent and took more responsibility for their own learning and problem solving. In other words, external regulation was faded out as students became more self-regulated learners and problem solvers.

3. *Interventions explicitly aimed at the establishment of new social and sociomathematical norms.* A classroom climate was created that is conducive to the development in students of appropriate beliefs about mathematics and mathematics learning and teaching and to students' self-regulation of their learning. Social norms are general norms that apply to any subject matter domain and relate, for instance, to the role of the teacher and the students in the classroom (e.g., not the teacher alone, but the whole class will decide which of the different learner-generated solutions is the optimal one after an evaluation of the pros and cons of the distinct alternatives). Sociomathematical norms, on the other hand, are specific to stu-

dents' activity in mathematics, such as what counts as a good mathematical problem, a good solution procedure, or a good response (e.g., sometimes a rough estimate is a better answer to a problem than an exact number; Yackel & Cobb, 1996).

The learning environment consisted of a series of 20 lessons designed by the research team in consultation and cooperation with the regular class teachers, who themselves did the teaching. With two lesson periods each week, the intervention was spread over about 3 months. Three major parts can be distinguished in the series of lessons:

1. Introduction to the content and organization of the learning environment and reflection on the difference between a routine task and a real problem (1 lesson).
2. Systematic acquisition of the five-step regulatory problem-solving strategy and the embedded heuristics (15 lessons).
3. Learning to use the competent problem-solving model in a spontaneous, integrated, and flexible way in so-called project lessons involving more complex application problems (4 lessons). The School Trip Problem is an example of such a lesson.

Teacher Support and Development

Because the class teachers taught the lessons, they were prepared for and supported in implementing the learning environment. The model of teacher development adopted reflected our views about students' learning by emphasizing the creation of a social context wherein teachers and researchers learn from each other through continuous discussion and reflection on the basic principles of the learning environment, the learning materials developed, and the teachers' practices during the lessons (De Corte, 2000). Moreover, taking into account that the mathematics teaching-learning process is too complex to be prespecified and that teaching as problem solving is mediated by teachers' thinking and decision making, the focus of teacher development and support was not on making them perform in a specific way, but on preparing and equipping them to make informed decisions (see also Carpenter & Fennema, 1992; Yackel & Cobb, 1996). Taking this into account, the teachers received the following support materials to enhance a reliable and powerful implementation of the learning environment: (a) a general teaching guide containing an extensive description of the aims, content, and structure of the learning environment; (b) a list of 10 guidelines

comprising actions that they should take before, during, and after the individual or group assignments, complemented with worked-out examples of each guideline (see Table 4.2); (c) a specific teacher guide for each lesson, containing the overall lesson plan but also specific suggestions for appropriate teacher interventions and examples of anticipated correct and incorrect solutions and solution methods; and (d) all the necessary concrete materials for the students.

Procedure and Hypotheses

The effectiveness of the learning environment was evaluated in a study with a pretest-posttest-retention test design. Four experimental fifth-grade classes (11-year-olds) and seven comparable control classes from 11 different elementary schools in Flanders participated in the study. These seven classes were comparable to the experimental classes in terms of ability and socioeconomic status, and during the 4-month period they followed an equal number of lessons in word problem solving. Interviews with the teachers of these classes and analyses of the textbooks used provided us with a good overall view of what happened in those control classes. This indicated that the teaching with respect to word problem solving was representative of current instructional practice in Flemish elementary schools (see De Corte & Verschaffel, 1989).

Table 4.2 General Guidelines for the Teachers Before, During, and After the Group and Individual Assignments

Before

1. Relate the new aspect (heuristic, problem-solving step) to what has already been learned before.
2. Provide a good orientation to the new task.

During

3. Observe the group work and provide appropriate hints when needed.
4. Stimulate articulation and reflection.
5. Stimulate the active thinking and cooperation of all group members (especially the weaker ones).

After

6. Demonstrate the existence of different appropriate solutions and solution methods for the same problem.
 7. Avoid imposing solutions and solution methods onto students.
 8. Pay attention to the intended heuristics and metacognitive skills of the competent problem-solving model, and use this model as a basis for the discussion.
 9. Stimulate as many students as possible to engage in and contribute to the whole-class discussion.
 10. Address (positive as well as negative) aspects of the group dynamics.
-

Three pretests were collectively administered in the experimental as well as the control classes: a standardized achievement test (SAT) to assess fifth graders' general mathematical knowledge and skills, a word problem test (WPT) consisting of 10 nonroutine word problems, and a beliefs attitude questionnaire (BAQ) aimed at assessing students' beliefs about and attitudes toward (teaching and learning) word problem solving. In addition, students' WPT answer sheets for each problem were carefully scrutinized for evidence of the application of one or more of the heuristics embedded in the problem-solving strategy. Besides these collective pretests, three pairs of students of equal ability from each experimental class were asked to solve five nonroutine application problems during a structured interview. The problem-solving processes of these dyads were videotaped and analyzed by means of a self-made schema for assessing the intensity and the quality of students' cognitive self-regulation activities.

By the end of the intervention, parallel versions of all collective pretests (SAT, WPT, and BAQ) were administered in all experimental and control classes. The answer sheets of all students were again scrutinized for traces of the application of heuristics, and the same pairs of students from the experimental classes as prior to the intervention were subjected again to a structured interview involving parallel versions of the five nonroutine application problems used during the pretest. Three months later, a retention test (a parallel version of the collective WPT used as pretest and posttest) was also administered in all experimental and control classes. To assess the implementation of the learning environment by the teachers of the experimental classes, a sample of four representative lessons was videotaped in each experimental class and analyzed afterward for an "implementation profile" for each experimental teacher.

A major hypothesis was that as a result of acquiring the self-regulatory problem-solving strategy, the experimental students would significantly outperform the control children on the WPT, and that this would be accompanied by a significant increase in the use of heuristics. Furthermore, it was anticipated that the frequency and the quality of the self-regulation activities in the dyads would substantially grow.

Results

We summarize here the major results of this intervention study. Although no significant difference was found between the experimental and control groups on

the WPT during the pretest, the former significantly outperformed the latter during the posttest, and this difference in favor of the experimental group was maintained in the retention test. However, it should be acknowledged that in the experimental group, students' overall performance on the posttest and retention tests was not as high as anticipated (i.e., the students of the experimental classes still produced only about 50% correct answers on these tests). In the experimental group, there was a significant improvement in students' beliefs about and attitudes toward learning and teaching mathematical problem solving, whereas in the control group there was no change in students' reactions to the BAQ from pretest to posttest. Although there was no difference in the pretest results on the SAT between the experimental and the control group, the results on the posttest revealed a significant difference in favor of the former group, indicating some transfer effect of the intervention toward mathematics as a whole. A qualitative analysis of the students' response sheets of the WPT revealed a dramatic increase from pretest to posttest and retention test in the manifest use of some of the heuristics that were specifically addressed and discussed in the learning environment; in the control classes, there was no difference in students' use of heuristics between the three testing times. In line with this result, the videotapes of the problem-solving processes of the dyads revealed substantial improvement in the intensity and quality with which the pairs from the experimental classes applied certain—but not all—(meta)cognitive skills that were specifically addressed in the learning environment. Both findings are indicative of a substantial increase in students' ability to self-regulate their problem-solving processes. Although there is some evidence that students of high and medium ability benefited more from the intervention than low-ability students, the statistical analysis revealed at the same time that all three ability groups contributed significantly to all the positive effects in the experimental group. This is a very important outcome, because it suggests that through appropriate intervention, one can also improve the cognitive self-regulatory skills of the weaker children. Finally, the positive effects of the learning environment were not observed to the same extent in all four experimental classes; actually, in one of the four classes, there was little or no improvement on most of the process and product measures. Analysis of the videotapes of the lessons in these classes indicated substantial differences in the extent to which the four

experimental teachers succeeded in implementing the major aspects of the learning environment. For three of the four experimental classes, there was a good fit between the teachers' implementation profiles and their students' learning outcomes.

Strengthening the Learning Environment with a Technology Component

The results of the previous study encouraged us to combine in a subsequent investigation the theoretical ideas and principles relating to socioconstructivist mathematics learning and to teachers' professional development with a second strand of theory and research focusing on the (meta)cognitive aspects of computer-supported collaborative knowledge construction and skill building (De Corte, Verschaffel, Lowyck, Dhert, & Vandeput, 2002). Taking into account the available empirical evidence showing that computer-supported collaborative learning (CSCL) is a promising lever for the improvement of learning and instruction (Lehtinen, Hakkarainen, Lipponen, Rahikainen, & Muukkonen, 1999), we enriched the learning environment designed in the previous study with a CSCL component. We chose Knowledge Forum (KF), a software tool for constructing and storing notes, for sharing notes and exchanging comments on them, and for scaffolding students in their acquisition of specific cognitive operations and particular concepts (Scardamalia & Bereiter, 1998). As in the preceding study, students solved the problems in small groups; afterward, they exchanged their solutions through KF and could comment on each other's solutions before a whole-class discussion was held. In the last stage of this study, the small groups generated problems themselves, which were also exchanged through KF; each group solved at least one problem posed by another group and sent its solution to that group for comments.

The learning environment was implemented in two fifth-grade and two sixth-grade classes of a Flemish primary school over a period of 17 weeks (2 hours per week). Although this study was less well-controlled than the previous one (e.g., there was no control group), the findings point in the same direction, showing that it is possible to create a high-powered computer-supported learning community for teaching and learning mathematical problem solving in the upper primary school. Of special importance is that the teachers were very enthusiastic about their participation and involvement in the investigation. Their positive appreciation related to the approach to the teaching of problem solving as well as

the use of KF as a supporting tool for learning; for instance, they reported several positive developments observed in their students, such as a more mindful and reflective approach to word problems. The learning environment was also enthusiastically received by most of the students. At the end of the intervention, they expressed that they liked this way of doing word problems much more than the traditional approach. Many of the children also reported learning something new, both about information technology and about mathematical problem solving.

Summary

By combining in these intervention studies a set of carefully designed word problems, a variety of activating and interactive teaching methods (strengthened by a technology component in the second one), and the adoption of new social and sociomathematical classroom norms, a learning environment was created that aimed at the development in students of a mindful and self-regulated approach toward mathematical problem solving. In terms of the components of a mathematical disposition, the learning environment focused selectively on heuristic methods, cognitive self-regulation skills, and, albeit rather implicitly, positive beliefs about learning mathematics problem solving. As anticipated, the results show that the intervention had significant positive effects on students' performance in problem solving, their use of heuristic strategies, and their cognitive self-regulation. Moreover, in the first study, the learning environment also had a favorable influence, albeit to a lesser extent, on their beliefs about learning and teaching mathematics. Taking into account the rather short period of the intervention, this last result is not at all surprising; indeed, beliefs and attitudes do not change overnight. However, a recent study in Italy by Mason and Scriveri (2004) in which a learning environment was designed and implemented with a more explicit focus on fostering students' beliefs obtained similar good results as our study, but the outcomes were especially positive with respect to the development of students' mathematics-related beliefs.

Notwithstanding the positive outcomes of these studies, some critical comments need to be made that point at issues for continued research (for a more detailed discussion, see Verschaffel et al., 1999). First of all, due to the quasi-experimental design of the studies, the complexity of the learning environment, and the small experimental group, it is not possible to establish the rel-

ative importance of the distinct components of the intervention in producing its positive effects; in fact, it is plausible that it is the combination of the different aspects of the design, the content, and the implementation of the learning environment that is responsible for those effects. From a methodological perspective, this is often considered a weakness of teaching experiments, criticized for their lack of randomization and control (see, e.g., Levin & O'Donnell, 1999). To overcome this criticism and make a stronger contribution to theory building, one could conduct randomized classroom trial studies (Levin & O'Donnell, 1999) involving larger numbers of experimental classes, in which different versions of complex learning environments are systematically contrasted and compared in terms of identification and differentiation of the aspects that contribute especially to their power and success. However, as argued by Slavin (2002, p. 17), one should be aware of "the fact that randomized experiments of interventions applying to entire classrooms can be extremely difficult and expensive to do and are sometimes impossible."

Furthermore, some problematic aspects of the learning environment designed and implemented in these studies may explain why no stronger effects were achieved; they point to suggestions for further inquiry. First, the components of the model of competent problem solving might be reformulated in terms that are more understandable and accessible to children, and that at the same time better reflect the cyclical nature of a solution process. Second, the third basic pillar of the learning environment, the establishment of a new classroom climate through the introduction of new social and sociomathematical norms, was not implemented in this study in a sufficiently systematic and effective way. Besides the short duration of the intervention, this may also explain the rather weak impact of the intervention on students' attitudes and beliefs. Third, with respect to the instructional techniques, an issue that needs to be further addressed is how to organize and support small-group work so that all students—including the shy and low-ability ones—participate and collaborate in a task-oriented way.

Finally, although the observed outcomes are promising, we should realize that in several respects we are still far removed from the intended large-scale implementation in educational practice of the underlying conception of mathematics learning and teaching. First, the intervention was restricted to only a part of the mathematics curriculum, namely, word problem solving; for a

sustained innovation, the whole mathematics curriculum, and even the entire school program, should be modeled after the socioconstructivist perspective on learning environments (see also Cognition and Technology Group at Vanderbilt, 1996). Second, the studies have shown that practicing a learning environment such as the ones designed in our project is very demanding and requires drastic changes in the role of the teacher. Instead of being the main, if not the only source of information, as is often still the case in average educational practice, the teacher becomes a “privileged” member of the knowledge-building community who creates an intellectually stimulating climate, models learning and problem-solving activities, asks thought-provoking questions, provides support to learners through coaching and guidance, and fosters students’ agency in and responsibility for their own learning. Broadly scaling up this new perspective on mathematics learning and teaching into educational practice is not a minor challenge. Indeed, it is not just a matter of acquiring a set of new instructional techniques, but calls for a fundamental and profound change in teachers’ beliefs, attitudes, and mentality and, therefore, requires intensive professional development and cooperation with in-service mathematics teachers (see also Cognition and Technology Group at Vanderbilt, 1997; Gearhart et al., 1999).

Developing Social and Sociomathematical Norms

In the previous subsection, we remarked that in our intervention study, one characteristic of the learning environment was not very well implemented, namely, the establishment of new social and sociomathematical norms. It is plausible that this flaw in the actualization of the learning environment accounts to a large extent for the poor effects on students’ mathematics-related beliefs. The work of Cobb and his colleagues (Cobb, 2000; Cobb, Gravemeijer, Yackel, McClain, & Whitenack, 1997; Cobb, Yackel, & Wood, 1989; McClain & Cobb, 2001; Yackel & Cobb, 1996) over the past 15 years has focused on conducting design experiments in the lower grades of the primary school that explicitly aimed at developing novel social and sociomathematical norms that can enhance students’ mathematics-related beliefs.

The theoretical stance of Cobb’s work, called the *emergent view*, conceives of “mathematical learning as both a process of active individual construction and a process of enculturation” (Cobb et al., 1997, p. 152). By stressing the individual as well as the social aspects of

learning, this view is closely related to our socioconstructivist perspective.

The methodological approach used by Cobb (2000) is the classroom teaching experiment, an extension to the level of the classroom of the constructivist teaching experiment in which the researcher himself or herself acts as teacher interacting with students either one-on-one or in small groups. The aim of the classroom teaching experiment, or design experiment, is to study students’ mathematics learning in alternative learning environments designed in collaboration with teachers. By so doing, this design can reveal “the implications of reform as they play out in interactions between teachers and students in classrooms” (p. 333).

Social and Sociomathematical Norms, and Beliefs as Their Correlates

The rather subtle distinction between social norms and sociomathematical norms, referred to in the previous subsection, can be clarified through some examples. The expectation that students explain their solution strategies and procedures is a social norm, whereas being able to recognize what counts as an acceptable mathematical explanation is a sociomathematical norm. Similarly, the rule that when discussing a problem one should come up with solutions that differ from those already presented is a social norm; knowing and understanding what constitutes mathematical difference (see later discussion) is a sociomathematical norm. Stated more generally, social norms apply to any subject matter domain of the curriculum; sociomathematical norms are domain-specific in the sense that they bear on normative aspects of students’ mathematical activities and discussions (Yackel & Cobb, 1996).

Social and sociomathematical norms constitute the key constructs of the following interpretive framework put forward by Cobb (2000; see also Cobb et al., 1997) for analyzing the classroom microculture. According to Cobb and his colleagues, this framework represents both reflexive perspectives of the emergent view. The *social perspective* refers to interactive and collective classroom activities; the *psychological perspective* focuses on individual students’ activities during and contributions to the collective classroom practices resulting in beliefs: beliefs about one’s own role as a learner, about the role of the teacher and one’s colearners, and about the general nature of the mathematical activity as correlates of the social norms; and mathematical beliefs and values as correlates of the sociomathematical norms. As Table 4.3

Table 4.3 An Interpretive Framework for Analyzing Individual and Collective Activity at the Classroom Level

| Social Perspective | Psychological Perspective |
|----------------------------------|--|
| Classroom social norms | Beliefs about our own role, others' roles, and the general nature of mathematical activity |
| Sociomathematical norms | Specifically mathematical beliefs and values |
| Classroom mathematical practices | Mathematical conceptions and activity practices |

Source: From "Mathematizing and Symbolizing: The Emergence of Chains of Signification in One First-Grade Classroom" (pp. 151–233), by P. Cobb, K. Gravemeijer, E. Yackel, K. McClain, and J. Whitenack, in *Situated Cognition: Social, Semiotic, and Psychological Perspectives*, D. Kirshner and J. Whitson (Eds.), 1997, Mahwah, NJ: Erlbaum. Reprinted with permission.

shows, the social component of the framework involves a third aspect, classroom mathematical practices, which refers to taken-as-shared mathematical practices established by the classroom community. Cobb (2000, p. 324; see also Cobb et al., 1997) gives the following example:

In the second-grade classrooms in which my colleagues and I have worked, various solution methods that involve counting by ones are established mathematical practices at the beginning of the school year. Some of the students are also able to develop solutions that involve the conceptual creation of units of 10 and 1. However, when they do so, they are obliged to explain and justify their interpretations of number words and numerals. Later in the school year, solutions based on such interpretations are taken as self-evident by the classroom community. The activity of interpreting number words and numerals in this way has become an established mathematical practice that no longer stands in need of justification. From the students' point of view, numbers simply are composed of 10s and 1s—it is a mathematical truth.

As is shown in the "Psychological Perspective" column of Table 4.3, the mathematical interpretations, conceptions, and activities of individual students are considered the psychological correlates of those classroom practices; their relationship is also conceived as reflexive.

Research Method

The interpretive framework was used over the past years in a number of teaching experiments in lower primary classrooms (first, second, and third grades) in which attempts were made to help and support teachers in radically changing their mathematics teaching practices. This implies that the researchers are present in the classroom during all the lessons of the experiment. Also, the

participating teachers become members of the research and development team. The duration of the experiments can vary from just a few weeks to an entire school year.

A variety of data are collected throughout the experiments. Video recordings of the lessons are made using two cameras, one focused mainly on the teacher, but sometimes on individual children who explain their reasoning and problem solving; the other camera tapes students while they are involved in discussions about a math task. Other data sources are copies of students' written work, field notes relating to the daily lessons, reports of the daily and weekly planning and debriefing sessions of the researchers together with the teacher, the teacher's diary, and videotapes of individual interviews with students. The method used to analyze those data is in line with the constant comparison method of B. G. Glaser and Strauss (1967) as applied in ethnographic studies. It consists of the cyclic comparison of data against conjectures derived from the preceding analysis: Issues that arise from watching the video recordings of a lesson are documented and clarified through a process of conjecture and refutation, and the trustworthiness of the final outcome can be checked against the original data tapes (McClain & Cobb, 2001; for a more detailed account, see Cobb & Whitenack, 1996).

Illustrative Results

Classroom teaching experiments were usually carried out with teachers who followed an inquiry approach to teaching and learning. The instructional tasks and problems, as well as the instructional strategies, are prepared and planned in collaboration and consultation with the teacher. The instructional strategies are very much in accordance with those applied in our own intervention study: whole-class discussions of problems led by the teacher and collaborative small-group work followed by whole-class discussions in which students explicate, argue for, and justify their strategies and solutions elaborated during the small-group activities.

The illustration of the development of social norms described later is taken from a study in a second-grade classroom. In the beginning of the school year, the teacher quickly realized that the students did not meet his expectation that they would easily explain for the whole class how they had approached and solved tasks and problems. Apparently, this expectation contradicted their belief acquired during the previous school year, in the first grade, that the only source of the right solution method and the correct answer is the teacher. To deal

with these conflicting expectations, the teacher started using a procedure called the renegotiation of classroom social norms. As a result, different social norms relating to whole-class discussion were overtly considered, negotiated, and thus socially constructed through interaction in the classroom. Examples are explaining and justifying solutions, trying to understand others' explanations, expressing agreement and disagreement, and questioning alternatives when conflicting interpretations and solutions are put forward (Cobb et al., 1989). Their contributions to the social construction of the classroom social norms in the renegotiation process initiates in students developments and changes in their beliefs about their role and the role of the teacher and their fellow students in the mathematics classroom, and about the nature of mathematics. Therefore, these beliefs are considered the psychological correlates of the classroom social norms.

Whereas Cobb and his colleagues initially focused on general social norms in elaborating a social perspective on classroom activities, in the mid-1990s this was complemented by a growing attention to domain-specific norms that permeate and regulate classroom discourse, that is, norms that are specific to activities and interactions in the mathematics classroom (Yackel & Cobb, 1996; see also Voigt, 1995). Examples of such sociomathematical norms are what counts as a different mathematical solution, a sophisticated solution, an insightful solution, an elegant solution, an efficient solution, and an acceptable solution.

The mathematical difference norm and its significance was first identified in inquiry-oriented classrooms where teachers regularly solicited students to offer a different approach or solution to a task, and rejected some reactions as not being mathematically different. It was obvious that the students had no idea what a mathematically different answer could be, but became aware of it during interactions in the course of which some of their contributions were accepted and others rejected. It was thus through their reactions to the teacher's invitation to offer different solutions that students learned what mathematical difference means and also contributed to install and define the mathematical difference norm in their classroom. This shows that, as is the case for social norms, sociomathematical norms also emerge and are socially constructed through negotiation between teacher and students.

The following episode of a lesson in a second-grade classroom shows how a teacher initiates the interactive

development of a mathematically different solution (Yackel & Cobb, 1996, pp. 462–463):

The number sentence $16 + 14 + 8 = \underline{\quad}$ has been posed as a mental computation activity.

Lemont: I added the two 1s out of the 16 and [the 14] . . . would be 20 . . . plus 6 plus 4 would equal another 10, and that was 30 plus 8 left would be 38.

Teacher: All right. Did anyone add a little *different*? Yes?

Ella: I said 16 plus 14 would be 30 . . . and add 8 more would be 38.

Teacher: Okay! Jose? *Different*?

Jose: I took two 10s from the 14 and the 16 and that would be 20 . . . and the I added the 6 and the 4 that would be 30 . . . then I added the 8, that would be 38.

Teacher: Okay! It's almost similar to—(addressing another student) Yes? *Different*? All right.

Here, the teacher's response to Jose suggests that he is working out for himself the meaning of *different*. However, because he does not elaborate for the students how Jose's solution is similar to those already given, the students are left to develop their own interpretations. The next two solutions offered by students are more inventive and are not questioned by the teacher.

Rodney: I took one off the 6 and put it on the 14 and I had . . . 15 [and] 15 [would be] 30, and I had 8 would be 38.

Teacher: Yeah! Thirty-eight. Yes. *Different*?

Tonya: I added the 8 and the 4, that was 12. . . . So I said 12 plus 10, that would equal 22 . . . plus the other 10, that would be 32—and then I had 38.

Teacher: Okay! Dennis—*different*, Dennis?

Throughout such interactions the students progressively learned the meaning of mathematical difference as they observed that their teacher accepted solutions that consist of decomposing and recomposing numbers in a variety of ways but rejected responses that only more or less repeat solutions already presented. The episode demonstrates clearly how normative aspects of mathematical activity emerge and are constituted during classroom discourse. Correlatively with the installation of those sociomathematical norms, students develop at the individual level mathematics-related beliefs and values that

enable them to become progressively more self-regulated in doing mathematics.

The initial work on sociomathematical norms from which the preceding episode is taken (Yackel & Cobb, 1996) documents through a post hoc analysis how such normative aspects of mathematical activity emerge. In a more recent classroom teaching experiment, more explicit attempts were undertaken, in collaboration between a teacher and the research team, to proactively foster the establishment of certain sociomathematical norms, thus simultaneously enhancing children's mathematics-related beliefs. In addition, this work focused on tracing the emergence of one sociomathematical norm from another throughout the classroom discourse.

Based on video data of lessons during the first 4 months of a school year, McClain and Cobb (2001) showed what first-grade teachers could do to evoke and sustain the development of sociomathematical norms at the classroom level and mathematics-related beliefs in individual children that are in line with the mathematical disposition advocated in current reform documents. One task given to the children was to figure out how many chips were shown on an overhead projector on which an arrangement of, for instance, five or seven chips was displayed. The objective was to elicit reasoning about the task and initiate a shift in students from using counting to find the answer to more sophisticated strategies based on grouping of chips. The results show how the mathematical difference norm developed in the classroom through discussions and interactions focused on the task, but later evolved into a renegotiation of the norm of a sophisticated solution. Indeed, solutions based on grouping of chips were seen not only as different from, but also as more sophisticated than counting. Similarly, from the mathematical difference norm emerged the norm of what counts as an easy, simple or efficient way to solve a problem: Some of the solutions that were accepted as being different were also considered easy or efficient, but others not. In the same way as in the previous study, students' individual beliefs about mathematics and mathematics learning were influenced in parallel with the emergence of the sociomathematical norms, and this contributed to their acquisition of a mathematical disposition.

Summary

Conducting classroom teaching experiments in collaboration with teachers as an overall research strategy, and using the interpretive framework discussed here for the

in-depth qualitative analyses of video recordings of lessons (complemented with field notes and interview data), Cobb and his colleagues have shown how social and sociomathematical norms in the microculture of lower primary grades' mathematics classrooms emerge, evolve, and further develop throughout interactions between teacher and students, and also how these norms then regulate continued classroom discourse and contribute to the creation of learning opportunities for students and teacher. Besides this theoretical orientation, the work has a major pragmatic goal, namely, understanding and designing, in close collaboration with teachers, classroom learning environments that are in accordance with the basic tenets of current reform documents.

According to Cobb (2000, p. 327), the methodological issue of generalizability is of utmost importance, but the notion is not used here in the traditional sense that ignores specific features of the particular cases of the set to which a proposition generalizes: "Instead, the theoretical analysis developed when coming to understand one case is deemed to be relevant when interpreting other cases. Thus, what is generalized is a way of interpreting and acting that preserves the specific characteristics of individual cases."

Cobb (2000) concedes that the classroom teaching experiment that focuses on problems and reform issues at the classroom level is not the panacea that fits all research questions and problems. Due to the focus on the classroom as a community of learners, this type of experiment is less appropriate for investigating and documenting mathematical learning and thinking of individual students. For the same reason, the classroom teaching experiment is not well suited for studying reform issues that relate to the broader context of the school and the community, for which different approaches, such as ethnographic methods, are more strongly indicated.

Referring to the first limitation signaled by Cobb (2000), and taking into account the available publications, it seems to us that indeed this work falls short of operationalizing the psychological perspective of the interpretive framework. A major point in this respect relates to the claim that correlatively with the establishment of new social and sociomathematical norms embedded in the classroom practices, the mathematics-related beliefs of individual students develop. However, those beliefs are not at all operationalized and assessed in the reports of the experiments, although it might not be too difficult to do so.

As already remarked with regard to the previous intervention study, the second restriction of this classroom teaching experiment also raises concern about the crucial issue of upscaling promising practices that are in line with the intended reform of math education. Still, the two intervention projects support in different ways the viewpoint that it is possible to create and implement novel learning environments that induce in children learning processes that facilitate the acquisition of important components of mathematical competence as described in the beginning of this chapter.

Other projects in which innovative instructional interventions have been designed, based on similar principles, have reported converging findings. We mention here only two examples, again geographically spread over both sides of the Atlantic. In the so-called Jasper Project, learning of mathematical problem solving in the upper primary school is anchored in meaningful and challenging environments (Cognition and Technology Group at Vanderbilt, 1997, 2000). Although this project resembles our own intervention study in terms of grade level and mathematical focus, it goes far beyond it in several respects. First, anchored instruction of mathematical problem solving has been studied more intensively and over a longer period of time. Second, it involves a strong technological component, using videodisc technology to present problems. Third, efforts have been undertaken toward a more large-scale implementation of anchored instruction.

The second example, referred to earlier, is Realistic Mathematics Education (RME), which was initiated by Freudenthal and developed in the Netherlands in the 1970s. Underlying this approach to mathematics education is Freudenthal's (1983) didactic phenomenology, which involves a reaction against the traditional idea that students should first acquire the formal system of mathematics, with applications to come afterward. According to Freudenthal, this is contrary to the way mathematical knowledge has been gathered and developed, that is, starting from the study of phenomena in the real world. We refer readers to Treffers (1987), Streefland (1991), and Gravemeijer (1994) for more detailed information about the basic ideas of RME, as well as for examples of design experiments wherein these ideas have been successfully implemented and tested with respect to different aspects of the elementary school curriculum. Interesting to mention here is that in a 1-year RME-based intervention study relating to mental calculation with numbers up to 100, Menne (2001) found not

only that second graders at the end of the school year achieved one or more mastery levels higher than at the beginning of the school year, but also that this remarkable progression applied particularly to the weaker students, who mainly belonged to the group of children from non-Dutch backgrounds.

ASSESSMENT: A TOOL FOR MONITORING LEARNING AND TEACHING

The assessment component of the CLIA model is concerned with the design, construction, and use of instruments for determining how powerful learning environments are in facilitating in students the acquisition of the different aspects of a mathematical disposition. This implies that those instruments should be aligned with this view of the ultimate goal of mathematics education and with the nature of mathematics learning as discussed earlier.

Assessments of mathematics learning can either be internal or external. Internal assessments are organized by the teacher in the classroom, formally or more informally; external, usually large-scale assessments come from outside, organized at the district, state, national, or even international level using standardized tests or surveys (NRC, 2001a; Silver & Kenney, 1995). As argued by the NRC (2001b), assessments in both the classroom and a large-scale context can be set up for three broad purposes: to assist learning and teaching, to measure achievement of individual students, and to evaluate school programs. Stated somewhat differently, Webb (1992) has distinguished the following purposes of assessing mathematics: to provide evidence for teachers on what students know and can do; to convey to students what is important to know, do, and believe; to inform decision makers within educational systems; and to monitor performance of the educational system as a whole. With respect to classroom assessment, we argue that, considered within the CLIA framework, the major purpose is to use assessment *for* learning, which means that it should provide useful information for students and teachers to foster and optimize further learning (Shepard, 2000; see also Shepard, 2001). Sloane and Kelly (2003) contrast assessment *for* learning, or formative assessment, with assessment *of* learning, the goal of which is to determine what students can achieve and whether they attain a certain achievement or proficiency level. They describe this as high-stakes testing, a topic

recently heavily debated in relation to the No Child Left Behind Act of 2001 (see, e.g., the special issue of *Theory into Practice* edited by Clarke & Gregory in 2003). Before focusing on classroom assessment, we address large-scale assessment, which mostly, but not necessarily, takes the form of high-stakes testing.

Large-Scale Assessment of Mathematics Learning

The massive use of standardized tests in education has always been more customary in the United States than in Europe. The 2001 No Child Left Behind Act and the related quest for accountability have even increased this practice, and also intensified the debates about the effectiveness and desirability of high-stakes testing (see, e.g., Amrein & Berliner, 2002; Clarke & Gregory, 2003). Especially since the beginning of the 1990s, the traditional tests have been criticized (see, e.g., Kulm, 1990; Lesh & Lamon, 1992; Madaus, West, Harmon, Lomax, & Viator, 1992; Romberg, 1995; Shepard, 2001). But although research has resulted in improvements in the underlying theory and the technical aspects of achievement assessment, R. Glaser and Silver (1994, p. 401) have argued, “Nevertheless, at present, much of this work is experimental, and the most common practices in the current assessment of achievement in the national educational system have changed little in the last 50 years.”

Analyses of widely used standardized tests show that there is a mismatch between the new vision of mathematical competence, as described earlier, and the content covered by those tests. Due to the excessive use of the multiple-choice format, the tests focus on the assessment of memorized facts, rote knowledge, and lower-level procedural skills. They do not sufficiently yield relevant and useful information on students’ abilities in problem solving, in modeling complex situations, in communicating mathematical ideas, and in other higher-order components of mathematical activity and a mathematical disposition. A related criticism points to the one-sided orientation of the tests toward the products of students’ mathematics work, and the neglect of the processes underlying those products (De Corte et al., 1996; Masters & Mislavy, 1993; Silver & Kenney, 1995).

An important consequence of this state of the art is that assessment often has a negative impact on the implemented curriculum, the classroom climate, and instructional practices, dubbed the WYTIWYG (What You Test Is What You Get) principle (Bell, Burkhardt, & Swan, 1992). Indeed, the tests convey an implicit mes-

sage to students and teachers that only facts, standard procedures, and lower-level skills are important and valued in mathematics education. As a result, teachers tend to “teach to the test”; that is, they adapt and narrow their instruction to give a disproportionate amount of attention to the teaching of the low-level knowledge and skills addressed by the test, at the expense of teaching for understanding, reasoning, and problem solving (Frederiksen, 1990; R. Glaser & Silver, 1994).

An additional major disadvantage of the majority of traditional evaluation instruments is that they are disconnected from learning and teaching. Indeed, also due to their static and product-oriented nature, most achievement measures do not provide feedback about students’ understanding of basic concepts, or about their thinking and problem-solving processes. Hence, they fail to provide relevant information that is helpful for students and teachers in terms of guiding further learning and instruction (De Corte et al., 1996; R. Glaser & Silver, 1994; NRC, 2001b; Shepard, 2001; Snow & Mandinach, 1991). In this respect, Chudowsky and Pellegrino (2003, p. 75) question whether large-scale assessments can be developed that can both measure and support student learning, and they argue:

We set forth the proposition that large-scale assessments can and should do a much better job of supporting learning. But for that to happen, education leaders will need to rethink some of the fundamental assumptions, values, and beliefs that currently drive large-scale assessment practices in the United States. The knowledge base to support change is available but has to be harnessed.

Indeed, apart from the previous intrinsic criticisms of traditional standardized achievement tests, a major issue of debate is their accountability use as high-stakes tests, that is, their mandatory administration for collecting data on student achievement as a basis for highly consequential decisions about students (e.g., graduation), teachers (e.g., financial rewards), and schools and school districts (e.g., accreditation). According to the No Child Left Behind Act, this accountability use should result in the progressive acquisition by all students of a proficiency level in reading and mathematics. However, a crucial question is whether current testing programs really foster and improve learning and instruction, and there are serious doubts in this regard. In a study by Amrein and Berliner (2002) involving 18 states, it was shown that there is no compelling evidence at all for increased student learning, the intended out-

come of those states' high-stakes testing programs. Moreover, there are many reports of unintended unfavorable consequences, such as increased dropout rates, negative impact on minority and special education children, cheating on examinations by teachers and students, and teachers leaving the profession. In addition, students tend to focus on learning for the test at the expense of the broader scope of the standards.

For large-scale assessments to indeed foster and improve student learning, as set forth by Chudowsky and Pellegrino (2003), we will have to move away from the rationale, the constraints, and the practices of current high-stakes testing programs (Amrein & Berliner, 2002; NRC, 2001b). As one example, we briefly review an alternative approach to large-scale testing developed recently in the Flemish part of Belgium (for a more detailed discussion, see Janssen, De Corte, Verschaffel, Knoors, & Colémont, 2002).

In the preceding section of this chapter, we presented a study by our center in which we designed a learning environment for mathematical problem solving that is aligned with the new standard for primary education in Flanders that became operational in the school year 1998 to 1999. In a subsequent project, also commissioned by the Department of Education of the Flemish Ministry, we developed an instrument for the national assessment of the new standards of the entire mathematics curriculum. The instrument was used to obtain a first, large-scale baseline assessment of students' attainment of those curriculum standards at the end of primary school. The aim was thus not to evaluate individual children or schools as a basis for making high-stakes decisions, but to get an overall picture of the state of the art of achievement in mathematics across Flanders. The instrument consists of 24 measurement scales, each representing a cluster of standards and covering as a whole the entire mathematics curriculum relating to numbers, measurement, and geometry.

Item response theory was used for the construction of the scales. Using a stratified sampling design, a fairly representative sample of 5,763 sixth graders (12-year-olds) belonging to 184 schools participated in the investigation. Taking into account the aim of the assessment, it was not necessary to have individual scores of all students, and a population sampling approach could be used "whereby different students take different portions of a much larger assessment, and the results are combined to obtain an aggregate picture of student achievement" (Chudowsky & Pellegrino, 2003, p. 80). This approach

also allows for cover of the total breadth of the curriculum standards. Specifically, the instrument involved 10 booklets, each containing about 40 items belonging to two or three of the 24 measurement scales; to get booklets that were somewhat varied, the measurement scales in each booklet represented distinct mathematical contents (e.g., the items in booklet 2 related to percentages and problem solving). Each booklet was administered to a sample of more than 500 sixth graders. Four different item formats were used: short answer (67%), short answer with several subquestions (14%), multiple choice (11%), and product and process questions (8%). Especially the last type addressed higher-order skills by asking for a motivation or an explanation for the given answer. Figure 4.1 shows an example of each of the four item formats.

Estimating the proportion of students in three categories summarized performance on each of the 24 scales: insufficient, sufficient, and good mastery. Briefly stated, the results of this assessment were as follows. Scales about declarative knowledge and those involving lower-order mathematical procedures were mastered best. The scales relating to more complex procedures (e.g., calculating percentages; calculating perimeter, area, volume), and those that address higher-order thinking skills (problem solving; estimation and approximation) were not so well mastered. The latter finding is not so surprising as those scales relate to standards that are relatively new in the Flemish mathematics curriculum. It is also interesting to mention that few gender differences in performance were observed.

It is the intention of the Department of Education of the Flemish Ministry to organize such a large-scale assessment of mathematics education periodically in the future. As the present assessment was carried out recently, it is too early to see if it has an impact on mathematics learning and teaching. However, the potential is obviously there. Indeed, because this assessment covers the entire curriculum, its findings are a good starting point for continued discussion and reflection on the standards in and among all education stakeholders (policymakers, teachers, supervisors and educational counselors, parents, students). Also due to the breadth of such an assessment approach, it uncovers those (sets of) standards that are insufficiently mastered. In doing so, the assessment provides relevant feedback to practitioners (curriculum designers, teachers, counselors) by identifying those aspects of the curriculum that need special attention in learning and instruction; researchers could

a. Short-answer format

Ann buys a coat of 4.500 BF for 3.600 BF.
 With how many percent is the price reduced?
 _____ %

b. Short-answer format with several subquestions

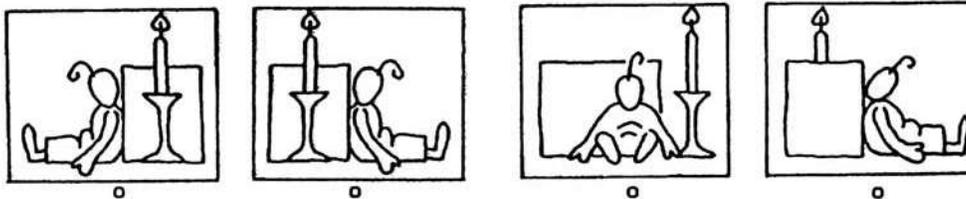

Put the following numbers in the table:
 250 3564 816 2845 1991 1702

Note: Some numbers may not fit into the table, or may fit in several columns.

| divisible through 2 | divisible through 3 | divisible through 5 | divisible through 9 | divisible through 10 |
|---------------------|---------------------|---------------------|---------------------|----------------------|
| | | | | |

c. Multiple-choice format

Three of these pictures are made of the same situation.
 One picture does not belong here.
 Color the round below this picture.

d. Product and process question

Chantal wants to buy a pair of Tiger sneakers and saw these ads in the local paper.

| | |
|--|--|
| <p>Family Shoe Center</p> <p>Bottom prices every day</p> <p>Tiger sneakers only 1200 BF</p> | <p>Van Dierens shoe shop</p> <p>This week only</p> <p>Sales: Tiger sneakers 1100 BF</p> |
|--|--|

The Family Shoe Center is within walking distance.
 To go to Van Dierens shoe shop Chantal has to take the bus. That would cost 80 BF
 for a one-way ticket.

If Chantal wants to spend as little money as possible, at which shop should she buy her sneakers?

Answer: _____

Explain why.

Answer: _____

Figure 4.1 Examples of an item for each item format.

also focus intervention research of the kind discussed in the previous section on those weaknesses in students' competence. A third advantage of the alignment of the assessment and the curriculum is that the often heard complaint about teaching and learning to the test can largely be avoided, especially if appropriate counseling and follow-up care is provided after the results are published. Moreover, because the Ministry does not intend to use the results for the evaluation of individual teachers or schools, and because scores of individual children, classes, and schools are not published, the negative consequences of high-stakes testing are also avoided.

Classroom Assessment

Notwithstanding the relevance and importance of large-scale, external assessments, these necessarily need to be supplemented by internal classroom testing. Large-scale tests are a form of summative evaluation: They measure achievement after a longer period of instruction covering a more or less extensive part of the curriculum of a subject matter domain. It is obvious that assessment *for* learning, that is, to assist and support learning in the classroom, needs to be formative in nature: Teachers need to continually collect evaluative information during the instructional process about students' progress in understanding and mastering knowledge and skills as a basis for guiding and supporting further learning, and, if needed, for providing on-time corrective help and instruction for individual students or groups of students. Such formative assessments also provide students themselves with informative feedback as a basis for monitoring and regulating their own learning (see, e.g., NRC, 2001b; Shepard, 2001). Whereas external assessments are useful and important for the large-scale monitoring of trends in mathematics education, classroom assessment intends to provide information on an ongoing day-to-day basis to improve student learning, taking into account the strengths and weaknesses of the class as a group as well as of the individual students.

In view of fulfilling their expected role in supporting and fostering learning, classroom assessment instruments should be well aligned with the full breadth of the learning goals or standards, similarly to large-scale tests. And because classroom assessment is much more focused on learning of and instruction for one specific group of students (as a group but also as individual children), it should provide, even more than large-scale tests, diagnostic information about students' conceptual understanding and about their thinking processes and

solution strategies for tasks and problems. This is a condition sine qua non for teachers to guide further learning and instruction, especially for adapting teaching appropriately to the needs of the learners (De Corte et al., 1996; R. Glaser & Silver, 1994; Shepard, 2001).

A very simple example from our own research can illustrate the importance of this diagnostic information. In a study on children's solution processes of numerical addition and subtraction problems (De Corte & Verschaffel, 1981), an item such as $\underline{\quad} - 12 = 7$ elicited mainly the two wrong answers 18 and 5. Both responses are incorrect, but the underlying erroneous solution processes are totally different: The first wrong answer is due to a rather technical error in executing the arithmetic operation; the second mistake is conceptual in nature and points to a lack of understanding of the equal sign. By tracing children's solution processes and strategies, one can derive their level of understanding; this information is necessary for designing individually adapted remedial instruction.

Another striking example of the usefulness of identifying students' reasoning comes from the well-known QUASAR (Quantitative Understanding: Amplifying Student Achievement and Reasoning) project. The open-ended task shown in Figure 4.2 was given to middle school students (Silver & Kenney, 1995). The classroom teachers believed that this was a straightforward task, and expected the answer "No" accompanied by the following explanation: "Yvonne takes the bus eight times a week, which would cost \$8.00. Buying the pass would

The table below shows the cost for different bus fares

| BUSY BUS COMPANY FARES | |
|------------------------|--------|
| One Way | \$1.00 |
| Weekly Pass | \$9.00 |

Yvonne is trying to decide whether she should buy a weekly bus pass. On Monday, Wednesday, and Friday, she rides the bus to and from work. On Tuesday and Thursday, she rides the bus to work but gets a ride home with her friends.

Should Yvonne buy a weekly bus pass?

Explain your answer:

Figure 4.2 Item from the QUASAR project. *Source:* From "Sources of Assessment Information for Instructional Guidance in Mathematics" (pp. 38–86), by E. A. Silver and P. A. Kenney, in *Reform in School Mathematics and Authentic Assessment*, T. A. Romberg (Ed.), 1995, Albany, NY: State University of New York Press. Reprinted with permission.

cost \$1.00 more.” But surprisingly, quite a number of students came up with the answer “Yes,” a response that in a traditional product-oriented test would be scored as incorrect. However, in their explanation, those children argued that the pass was a better deal because it could be used for other trips during the weekend by Yvonne, and even by other family members. This clearly illustrates that appropriately assessing students’ knowledge and understanding requires that one looks not only at their answers, but also at their thinking and reasoning.

The preceding discussion shows that using assessment to assist instruction requires that the two should be integrated, as envisioned by the NRC (1989, p. 69; see also NRC, 2001b; Shepard, 2001; Snow & Mandinach, 1991): “Assessment should be an integral part of teaching. It is the mechanism whereby teachers can learn how students think about mathematics as well as what students are able to accomplish.” In accordance with this perspective, Shavelson and Baxter (1992, p. 82) have rightly argued that “a good assessment makes a good teaching activity, and a good teaching activity makes a good assessment.”

One can add that from the perspective of the learner, a good assessment makes a good learning activity, and a good learning activity makes a good assessment. Taking into account the conception of learning in the CLIA model, this also implies that assessment should contain assignments that are meaningful for the learners and that offer opportunities for self-regulated and collaborative—besides individual—approaches to tasks and problems (see also Shavelson & Baxter, 1992). In line with the constructivist view of learning, the increasing proficiency in self-regulating their learning should gradually lead to students acquiring the ability to self-assess their math work. Of course, from that perspective, the criteria and expectations should be made explicit to students (see also Shepard, 2001).

To gather data about students’ performance and progress, teachers can use a variety of techniques: informal questions, seatwork and homework tasks, clinical interviews, portfolios, and more formal instruments such as teacher-made classroom tests, learning potential tests, and progress maps. The clinical interview initiated by Piaget (1952) is a very appropriate technique for acquiring insight into children’s thinking and reasoning processes while solving mathematics tasks and problems. Due to its flexible, responsive, and open-ended nature (Ginsburg, Klein, et al., 1998) it allows

for an in-depth analysis of those processes. For an excellent and practice-oriented introduction to the use of the clinical interview as a tool for formative classroom assessment, we refer readers to the teacher’s guide by Ginsburg, Jacobs, and Lopez (1998).

Another method that aims at the diagnosis of mental structures and cognitive processes is the so-called learning potential test, a concept that emerges from Vygotsky’s (1978) notion of the zone of proximal development (ZPD). The purpose of a learning potential test is to diagnose the ZPD that provides an assessment of the child’s learning ability (see, e.g., A. L. Brown, Campione, Webber, & McGilly, 1992; Hamers, Ruijsenaars, & Sijtsma, 1992). Such a test consists of three steps: a pretest, a learning phase, and a posttest. The pretest assesses the child’s entering ability with respect to the targeted problems. In the learning phase, which often takes the format of an individual interview, the tester administers a carefully designed sequence of tasks representing a continuum of increasing difficulty/transfer levels; the amount of help needed by the child for solving the successive tasks is taken as a measure of learning efficiency. Finally, a posttest is given to measure the amount of learning that has occurred throughout the session. This learning potential test thus offers a nice example of the integration of instruction and assessment.

One type of instrument that is particularly useful for classroom assessment from a developmental perspective, especially if it is theory-based, is a progress map, which describes the typical sequence of development and acquisition of knowledge and skill in a given domain of learning. As an example, we present the Number Knowledge Test developed by Griffin and Case (1997; see also NRC, 2001b). The test was originally elaborated as an instrument for testing the authors’ theory concerning the normal development in children of central conceptual structures for whole numbers. In this regard, they distinguish four stages:

1. *Initial counting and quantity schemas*: Four-year-olds can count a set of objects and have some knowledge of quantity, allowing them to answer questions about more and less when presented with arrays of objects. But they fail on such questions as “Which is more—four or five?”
2. *Mental counting line structure*: By 6 years, children are able to answer correctly the latter type of question (without objects), indicating that the two earlier structures are integrated into a mental number line,

considered by Griffin and Case as a central conceptual structure.

3. *Double counting line structure:* By 8 years, once children understand how mental counting works, they progressively form representations of multiple number lines, such as those for counting by 2s, 5s, 10s, and 100s.
4. *Understanding of full system:* By about age 10, children acquire a generalized understanding of the whole-number system and the underlying base-10 system.

Although primarily intended as a research instrument, the Number Knowledge Test has been applied in North America more and more as a diagnostic assessment tool to inform and assist arithmetic teaching. The test has already been revised to better capture 4-year-olds' understanding of number. The revised version is presented in Figure 4.3 (Griffin, 2003, 2004).

This Number Knowledge Test is administered orally and individually to children. The testing continues until a child does not answer a sufficient number of questions to proceed to the next level. It has been shown that the test yields very rich data about children's development in understanding numbers, and the instrument derives its power as an assessment tool from the underlying theory briefly outlined earlier. Although teachers often have an initial resistance to administering this individual oral test, most end up finding it very useful and worthwhile. They report that the test reveals differences in thinking among children that they were not aware of before. As a consequence, they also listen more actively to their students, and they find the results very useful for supporting and fostering children's learning.

Summary

Theoretical and empirical work over the past 15 years has resulted in important changes in the roles for assessment that are in line with a constructivist perspective on learning. The NRC (2001b, p. 4) has summarized these roles appropriately as follows:

Assessments, especially those conducted in the context of classroom instruction, should focus on making students' thinking visible to both teachers and themselves so that instructional strategies can be selected to support an appropriate course for future learning. . . . One of the most important roles for assessment is the provision of timely and informative feedback to students during instruction

and learning so that their practice of a skill and its subsequent acquisition will be effective and efficient.

Researchers in the field of learning and instruction, as well as experts in the domain of testing and psychometrics, have started endeavors, aiming at the elaboration of new approaches and procedures for the design and construction of innovative assessment devices in line with those novel roles, as well as an explicit and research-based integration of assessment and instruction (Frederiksen, Mislavy, & Bejar, 1993; Lesh & Lamon, 1992; NRC, 2001b; Romberg, 1995; Shepard, 2001).

However, only the first steps have been taken, and so we are confronted with an extensive and long-term agenda of research and dissemination (see, e.g., Snow & Mandinach, 1991). Implementation of the new perspective on assessment requires first of all breaking out of the still prevailing traditional approach to evaluation in educational practice. Policymakers, practitioners, and the public need to be convinced of the nonproductivity of, and even the harm from, the educational perspective of current high-stakes testing and of the benefits of the assessment *for* learning. This is critical because large-scale assessments in the usual standardized testing scenarios radiate on and influence classroom assessment. As argued by Amrein and Berliner (2002), it is now time to debate high-stakes testing policies more thoroughly and seek to change them if they do not do what was intended and have some unintended negative consequences as well.

A major challenge for research in the future relates to the integration of psychometric theory with current perspectives about the nature of productive learning and effective teaching. In this regard, some progress has recently been made, as illustrated by the report of the NRC (2001b), *Knowing What Students Know: The Science and Design of Educational Assessment*. But much remains to be done to develop alternative methods for the construction of new types of assessment instruments. Another important issue for research is the development of computer-based systems for assessment. Indeed, due to its wide possibilities for varied presentation of tasks and problems, its potential for adaptive testing and feedback taking into account learners' prior knowledge and skills, and its capacities for storing and processing responses, the computer can be very helpful in achieving the challenging task of elaborating and implementing the intended forms of assessment to assist and support learning and instruction.

Number Knowledge Test

Level 0 (4-year-old level): Go to Level 1 if 3 or more correct.

- 1 Can you count these chips and tell me how many there are? (Place 3 counting chips in front of child in a row.)
 - 2a (Show stacks of chips, 5 vs. 2, same color.) Which pile has more?
 - 2b (Show stacks of chips, 3 vs. 7, same color.) Which pile has more?
 - 3a this time I'm going to ask you which pile has less. (Show stacks of chips, 2 vs. 6, same color.) Which pile has less?
 - 3b (Show stacks of chips, 8 vs. 3, same color.) Which pile has less?
 - 4 I'm going to show you some counting chips. (Show a line of 3 red and 4 yellow chips in a row, as follows: R Y R Y R Y Y.) Count just the yellow chips and tell me how many there are.
 - 5 Pick up all chips from the previous question. Then say: Here are some more counting chips. (Show mixed array [not in a row] of 7 yellow and 8 red chips.) Count just the red chips and tell me how many there are.
-

Level 1 (6-year-old level): Go to Level 2 if 5 or more correct.

- 1 If you had 4 chocolates and someone gave you 3 more, how many chocolates would you have altogether?
 - 2 What number comes right after 7?
 - 3 What number comes two numbers after 7?
 - 4a Which is bigger: 5 or 4?
 - 4b Which is bigger: 7 or 9?
 - 5a This time, I'm going to ask you about smaller numbers. Which is smaller: 8 or 6?
 - 5b Which is smaller: 5 or 7?
 - 6a Which number is closer to 5: 6 or 2? (Show visual array after asking question.)
 - 6b Which number is closer to 7: 4 or 9? Show visual array after asking question.)
 - 7 How much is $2 + 4$? (OK to use fingers for counting.)
 - 8 How much is 8 take away 6? (OK to use fingers for counting.)
 - 9a (Show visual array - 8 5 2 6 - and ask child to point to and name each numeral.) When you are counting, which of these numbers do you say first?
 - 9b When you are counting, which of these numbers do you say last?
-

Level 2 (8-year-old level): Go to Level 3 if 5 or more correct.

- 1 What number comes 5 numbers after 49?
 - 2 What number comes 4 numbers before 60?
 - 3a Which is bigger: 69 or 71?
 - 3b Which is bigger: 32 or 28?
 - 4a This time I'm going to ask you about smaller numbers. Which is smaller: 27 or 32?
 - 4b Which is smaller: 51 or 39?
 - 5a Which number is closer to 21: 25 or 18? (Show visual array after asking the question.)
 - 5b Which number is closer to 28: 31 or 24? (Show visual array after asking the question.)
 - 6 How many numbers are there in between 2 and 6? (Accept either 3 or 4.)
 - 7 How many numbers are there in between 7 and 9? (Accept either 1 or 2.)
 - 8 (Show card 12 54) How much is $12 - 54$?
 - 9 (Show card 47 21) How much is 47 take away 21?
-

Level 3 (10-year-old level):

- 1 What number comes 10 numbers after 99?
 - 2 What number comes 9 numbers after 999?
 - 3a Which difference is bigger: the difference between 9 and 6 or the difference between 8 and 3?
 - 3b Which difference is bigger: the difference between 6 and 2 or the difference between 8 and 5?
 - 4a Which difference is smaller: the difference between 99 and 92 or the difference between 25 and 11?
 - 4b Which difference is smaller: the difference between 48 and 36 or the difference between 84 and 73?
 - 5 (Show card, "13, 39") How much is $13 + 39$?
 - 6 (Show card, "36, 18") How much is $36 - 18$?
 - 7 How much is 301 take away 7

Griffin, in *Mathematical Cognition*, J. M. Royer (Ed.), 2003, Greenwich, CT: Information Age Publishing. Reprinted with permission.

CONCLUSIONS

Using the CLIA framework as an organizing device, this chapter presents a selective review of research on development, learning, and instruction relating to mathematics that is relevant and looks promising in view of application in and innovation and improvement of mathematics classroom practices. This framework is in line with the new international perspectives on the goals and the nature of mathematics education as manifested in reform documents such as the *Principles and Standards for School Mathematics* (NCTM, 2000). The review is selective in terms of educational level (focusing on primary school) and mathematical content (whole number and word problem solving); in addition, the chapter has an emphasis on research on mathematics education in the Western world.

The review shows that with respect to each of the four interconnected components of the CLIA model, our empirically based knowledge has substantially advanced over the past decades. Progressively, a much better understanding has emerged concerning the components that constitute a mathematical disposition, concerning the nature of the learning and developmental processes that should be induced in students to facilitate the acquisition of competence, concerning the characteristics of learning environments that are powerful in initiating and evoking those processes, and concerning the kind of assessment instruments that are appropriate to help monitor and support learning and teaching.

An important question to ask is whether this expanding knowledge base (for a condensed review, see Grouws & Cebulla, 2000) is relevant and useful to bridging the long-standing gap between theory/research and practice and, thus, can contribute to improving mathematics education practices. The available intervention studies reviewed and referred to here, as well as others (e.g., Becker & Selter, 1996; Clements & Sarama, 2004; Lesh & Doerr, 2003), warrant some optimism. Indeed, the increasing number of success stories are building to a critical mass of results, showing that under certain conditions, carefully designed, research-based learning environments can yield learning outcomes in students that are in accordance with the current view of the goal of mathematics education as the acquisition of a mathematical disposition. Based on the research analyzed and reviewed here, but also taking into account the broader recent literature on innovative contexts for learning in and out of school (e.g., NRC,

2000; Schauble & Glaser, 1996), some major interconnected principles for designing powerful mathematics learning environments are the following:

- Learner-centered environments, that is, environments that help all students construct knowledge and skills, building on their prior knowledge and beliefs relating to mathematics.
- A focus on understanding of basic concepts and number sense and, where relevant, connecting conceptual with procedural knowledge.
- Learning new mathematical concepts and skills while problem solving.
- Stimulating active and progressively more self-regulated, reflective learning, starting from eliciting children's own productions and contributions.
- Use of tasks and problems that are meaningful to students, and when they have acquired a certain level of mastery, inviting them to generate their own tasks and problems.
- Use of interactive and collaborative teaching methods, especially small-group work and whole-class discussion to create a classroom learning community.
- Alignment of learning, instruction, and assessment to provide multiple opportunities for feedback that yield relevant information for improving teachers' instruction as well as students' learning.
- Attention to individual differences by assessing, acknowledging, and supporting diversity.

The optimism based on the available research is fueled by the observation that inquiry-based ideas are indeed gradually taking root in the mathematics education community, namely, in the reform documents worldwide and subsequently in curricula and textbooks, but also in the writings and practices of knowledgeable educational professionals. However, the optimism is tempered by two major challenging problems for future research and development that we cannot elaborate here due to space restrictions. The first issue, signaled in the section on intervention, relates to broadly *upscaling* the new perspective on learning and teaching mathematics, and the design principles for learning environments that derive from it. The second related and equally important problem concerns the *sustainability* of innovative learning environments. The solution to both problems has a serious price tag and is largely a matter for educational policy. Taking this into

account, a major answer lies in preservice and in-service teacher professional development; an excellent example in this respect is the Cognitively Guided Instruction Project (Carpenter & Fennema, 1992; Carpenter, Fennema, & Franke, 1994; for a brief overview, see Ginsburg, Klein, et al., 1998). In terms of sustainability, a major condition is meeting teachers' need for ongoing support for feedback and reflection about their teaching practices (Cognition and Technology Group at Vanderbilt, 1997). A promising approach to such continuing professional development and support is elaborated in the Lesson Study Project, the core form of in-service training for Japanese mathematics teachers (Lewis, 2002).

Although there is a long tradition of research on the development of scientific reasoning, the impact of this research on science education has been limited and not always constructive. As Metz (1995) pointed out, to the extent that research has provided any guiding picture of development to inform science education, the most enduring influence has come from outmoded misinterpretations of Piagetian research. As a consequence, even now, ideas about children and science are dominated by untested conclusions about what children *cannot* do—or worse, claims about deficits that have already been refuted by evidence, but that somehow continue to hang around like unwelcome relatives, exerting their influence on education via texts, science standards, and the beliefs of educators. These assumptions about what children cannot learn show up with particular frequency in evaluations of the “developmental appropriateness” of approaches to science education or specific

topics of study. Metz, for example, charts the influence of these assumptions on the national discussions about science standards and argues convincingly that the standards seriously underestimate young children’s capability to learn and do science.

In the previous volume of this *Handbook*, Strauss (1998) suggested several reasons why the best of developmental psychology does not always contribute to the best of science education. He proposes, among other reasons, that developmental psychology and science education share little overlap in content, focus, underlying assumptions, and methods of inquiry. However, since his chapter was published, there has been an acceleration of activity in the intersection between these two fields. Science educators have become increasingly interested in and knowledgeable about learning and development. And some developmental scholars have begun to pursue education in a more serious and committed way. For example, there are now a number of research programs, described later in the chapter, in which investigators are deeply involved not just in studying scientific thinking, but also in changing its course in contexts of education. New programs of research emphasize the coordinated

Order of authorship is alphabetical; the contribution of both authors was equal. We gratefully acknowledge the contributions of Steven McGee and Kathleen Metz, who reviewed the manuscript and offered comments that were extremely helpful.

design and study of science learning in school classrooms, consistent with a wider appreciation of the fact that studying interesting forms of scientific thinking cannot progress very far unless these forms of thinking are brought into being. As a result, research on the development of scientific reasoning is increasingly becoming entwined with the search for effective ways to catalyze and support it.

Typically, this approach to research entails designing and implementing instruction and then studying the resulting student learning over a relatively extended period of time (ideally, several years). These long time periods are required because the forms of thinking that are of interest do not emerge within a few months or even a year. The emphasis in this research is not on describing “naturally occurring” forms of thinking, whatever those may be, but on systematically testing effective ways to support the development of students’ reasoning and knowledge over the long term. In addition, many of these projects pursue a secondary interest in the professional development of the teachers who conduct the instruction or in the institutional structures of schooling that both facilitate and constrain educational potential. Because these programs take a longitudinal perspective, they offer the opportunity for a more serious test of accounts of development than do studies that last only a few days or weeks (an opportunity, however, on which it is difficult to capitalize, as we will discuss). Moreover, they are tests of development under conditions in which development is brought into being and sustained by cultural and semiotic tools. As we will explain, the field is currently struggling to decide the extent to which mechanisms of development such as language, tasks, forms of argument, and tools, need to be incorporated into theoretical and empirical accounts.

This general approach to studying development and learning, in which intervention and investigation are conducted as part of a coordinated enterprise, has been called “design experiments” or “design studies.” The merits and limitations of this approach are currently being explored and debated (Brown, 1992; Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003; Shavelson & Towne, 2002; Sloane & Gorard, 2003). However, these conversations are occurring almost exclusively within the field of education research rather than the field of development. Our interest in design studies is in their potential to shed light on both origins and pathways of development, an issue that we take up in the second sec-

tion of the chapter. In that section, we survey the landscape of contemporary design studies that are informed by and, in turn, inform our knowledge about the development of scientific thinking.

In spite of the emergence of this new research in the overlap between developmental psychology and science education, we can by no means congratulate ourselves that the fields of psychology and education have achieved a comfortable and general consensus about common goals for and conclusions about children’s learning. There appear to be two main reasons for this gap. First, not only between, but also within these fields, there are long-standing disagreements about what it means to learn or understand science. These disagreements are partly due to the lack of shared vision in our society about the purposes for education in general. More particular to *science* learning, there are also competing views of the nature of science, so that we lack consensus on the character of the phenomenon under investigation. Second, within the field of developmental psychology there are long-standing differences of opinion about the nature and mechanisms of development and how developmental research can best inform and be informed by the educational enterprise. These disagreements are also at play, and views of how best to study development color perspectives about how learning should be supported.

For example, some scholars emphasize mechanisms that are conceived primarily as internal qualities of the developing individual and especially emphasize those forms of development that appear to be universal to the human species and therefore relatively robust across varying contexts and cultures. Others have argued that psychology attends too much to explanations of development that are based on presumed inner mental processes, traits, or constraints operating at the level of the individual organism. These scholars argue that an adequate account of development needs to include the local and distal contexts that support and shape it. From this perspective, the focus of study should be on the structures, goals, and values associated with the activities that people are habitually immersed in; the kinds of tasks and problems they encounter in contexts of learning; the content and structure of their prior knowledge; their histories of learning; the cultural expectations, tools, and behavioral patterns that are part of an individual’s world; and the social and historical contexts that shape contemporary activity. Of course, this tension between

explanations based on mental qualities of individuals versus the physical and social environments is an old and ongoing story in developmental psychology, one that seems to continually reshape itself as the field evolves.

In sum, different views of science literacy and learning are at least partly the result of differences in answers to two questions: What is developing when children learn science? and What is development? Where progress is being made, it has been by reformulating and testing the implications of different answers to these enduring questions. Therefore, we begin the chapter by considering different images of the nature of science, because these images have either explicitly or tacitly guided the conduct of developmental research. The second section of the chapter revisits some familiar territory—studies of the growth of scientific reasoning—but reconsiders them in light of the images of science that they assume and also in light of longer-term studies where development is (deliberately) shaped by education. This section examines the assumptions about scientific thinking and development that inspired longer-term investigations of development and summarizes how both traditional and design approaches contribute to what we understand about learning and development.

The design studies emphasize somewhat different views of the nature of science and, taken as a group, entail a contrasting set of educational designs based on different “bets” about how to catalyze development over the long haul. This new research is important for both developmental psychologists and science educators to understand. For science educators, it is providing a beginning empirical base to inform the debates about the nature of science and resulting implications for education. For developmental psychologists, it may reframe our expectations about trajectories of cognitive development and the influences that can shape or change those trajectories.

As we will explain, classroom design studies encounter a host of challenges that laboratory research typically does not. For example, taking a long-term view of learning and development often requires a fundamental rethinking of the subject matter under consideration. Historically, decisions about what is worth teaching and learning have been informed not by knowledge about learning and development, but by politics and custom. These decisions are often strongly influenced by the organizational structure and constraints of schooling. The curricular shape of a school

discipline is laid down by historical tradition and can be very difficult to envision. The way a subject has been previously taught comes to take on canonical status as it is encapsulated in textbooks, standards, tests, and preservice teacher education, and (equally important) in the expectations of parents and the public at large. These historically entrenched views about what science learning or history learning or mathematics learning should be like can be very difficult to change (Dow, 1991), as the current “math wars” amply illustrate. Yet, as we will show, a developmental perspective, coupled with longitudinal research on learning, tends to raise fundamental questions about the status quo vision of school disciplines. Taken seriously, thinking developmentally may change the landscape considerably, both for what should be learned and for how it is learned.

The third and final major section of the chapter illustrates in greater detail how these issues play out, using as an illustrative case a design investigation conducted over 10 years by the authors. Although in principle, any of the examples in this chapter might serve as the case for this analysis, the issues we discuss in this section require exposing the way design research works under the hood, information that is usually known well only to those close to the project in question. Matters usually dismissed as “implementation” or “logistical” issues seldom appear in journals or other public presentations, but in design research they should be accounted for as part of the theory of action, rather than dismissed as side issues. The purpose of this final section is to show how this form of investigation requires researchers to find new ways of addressing research concerns such as representativeness, generalizability, and replication, which cannot always be handled in the same ways as in laboratory investigations (although closer inspection of experimental laboratory studies suggests some clear parallels, especially in new domains of research; see, e.g., Gooding, 1990).

A word on what the chapter will *not* address. There are many fields of research that bear on the issues that are discussed here. They include science education, social studies of science, semiotics, the history and philosophy of science, and cognitive models of learning and development. To avoid taking the chapter too far afield, we keep our central focus trained on classroom studies that take a developmental approach to science learning and scientific reasoning. Research in related fields is

introduced only as it bears directly on the chapter's primary focus.

IMAGES OF SCIENCE

Images of the nature of science set the stage for the study of development. They inform what researchers choose to study and suggest appropriate means of study.

We have identified three images that appear to have attracted broad research support: science-as-logic, science-as-theory, and science-as-practice. Here we briefly describe each of these views of science and then further exemplify these positions by contrasting their stance toward the idea of experiment, which is an epistemic form characteristic of and central to the practice of science.

Science-as-Logical Reasoning

Science-as-logic emphasizes the role of domain-general forms of scientific reasoning, including formal logic, heuristics, and strategies, whose scope ranges across fields as diverse as geology and particle physics. This image figures prominently in three early programs of research that have been especially influential in the way researchers conceptualize scientific thinking. These include Inhelder and Piaget's (1958) pioneering work on formal operations; the Bruner, Goodnow, and Austin (1956) studies on concept development; and Wason's (1960, 1968) four-card task studies demonstrating that people tend to avoid evidence that disconfirms their prior theories. The image of scientist-as-reasoner continues to be influential in contemporary research (Case & Griffin, 1990). Learning to think scientifically is conceived as a matter of acquiring strategies for coordinating theory and evidence (D. Kuhn, 1989), mastering counterfactual reasoning (Leslie, 1987), distinguishing patterns of evidence that do and do not support a definitive conclusion (Fay & Klahr, 1996), or understanding the logic of experimental design (Chen & Klahr, 1999; Tschirgi, 1980). These heuristics and skills are considered important targets for research and for education because they are assumed to be widely applicable and to reflect at least some degree of domain generality and transferability (D. Kuhn, Garcia-Mila, Zohar, & Andersen, 1995).

A general feature of studies conducted in this vein is that researchers often attempt to rule out the use of knowledge by relying either on unfamiliar tasks based on knowledge that children are considered unlikely to have, or on tasks that are intrinsically content lean. For example, in a study of problem-solving strategies, D. Kuhn and Phelps (1982) asked children to investigate mixtures of clear, unlabeled chemical solutions in an attempt to find out "for sure" which mixtures, when added to a mixing liquid, would reliably turn pink. The content of this problem was considered unlikely to evoke participants' prior content knowledge in ways that would either help or hinder them in solving the problem, as preadolescent children typically know little about chemical solutions. Moreover, only alphabetical labels on the test tubes identified the chemicals, and all of the chemicals were indistinguishable clear liquids. The labels were changed after every trial, making it impossible for participants to develop cumulative knowledge about the materials over time. Indeed, the authors were not interested in how children think about chemical solutions; they chose this content because they wished to understand the kinds of evidence-generation and evidence-interpretation strategies children would employ in solving problems that involve multivariable causality and, in particular, how those strategies might evolve over repeated trials as children received feedback from observable changes in the physical materials.

A point on which there is no consensus is whether these forms of reasoning should be conceived of as specialized knowledge that is difficult to acquire and that emerges only gradually over development, and in many people never appears at all (D. Kuhn et al., 1995), or alternatively, whether they are appropriately viewed as the application of problem-solving strategies that are common to all kinds of thinking (Klahr, 2000). In either case, the task for developmental researchers is to identify origins, patterns of change, and underlying mechanisms of change in skills and strategies that are presumed to be useful across a wide variety of situations and problems particular to science (and perhaps everyday thinking as well).

Science-as-Theory Change

Science-as-theory change draws from philosophical studies of science and compares individual conceptual change to broader historical trends in science, especially

the periodization (i.e., normal and revolutionary science) of science identified by T. S. Kuhn (1962). Among others, Carey (1985b) and Koslowski (1996) have suggested that disciplinary knowledge evolves in ways that typically involve the gradual accretion of new facts (e.g., Kuhn's normal science) and knowledge or, occasionally, the replacement of one idea by another. At critical junctures there may even be wholesale restructuring of the theoretical landscape (e.g., Kuhn's scientific revolutions). In this case, the entire network of concepts and their relationships is reconfigured (Chi, 1992). Not only do new concepts enter the domain; in addition, existing concepts may change their meaning in fundamental ways because the theoretical structure within which they are situated radically changes. Consider, for example, the meaning of the concept *force* or *combustion*. *Force* in Aristotelian theory is not the same concept as *force* in Newtonian theory. Note, however, that we would be unlikely to conclude that scientists who believed in the phlogiston theory or who held Aristotelian notions of force and motion were illogical, in the sense of lacking or violating important canons of reasoning. Instead, we accept that scientists of earlier times reasoned in ways that depended on their knowledge and theories. Under different assumptions about the way the world worked, different kinds of conclusions and inferences would seem quite logical, perhaps even obvious.

If the development of scientific reasoning in individuals is like the development of scientific knowledge over the course of history, the argument goes, it is best conceived not as the mastery of domain-general logic, heuristics, or strategies, but as a process of conceptual or theory change. In fact, some of the research in this tradition is aimed toward demonstrating that children's reasoning per se does not differ in important ways from adults' (e.g., Carey, 1985a; Samarapungavan, 1992).

Carey (1985a), for example, claimed that there is nothing about the power or structure of children's logic that develops, at least beyond the preschool years. In her landmark studies challenging Piaget's (1962) earlier assertions about the "magical" or "animistic" thinking of preadolescent children, Carey (1985b) demonstrated that this apparent animism did not entail failures of children's reasoning, but instead reflected their theories about properties that distinguish living organisms from nonliving objects. Her results suggested that children lack some of the fundamental biological knowledge that adults have. Even more important, the knowledge that

children do have is organized into conceptual systems (i.e., theories) that do not reflect either the overall structure or the categories typically possessed by adults. For example, when asked to provide examples of things that were "not alive," children's responses suggested that they were conflating a number of distinctions that an adult would honor into a general, undifferentiated alive/not alive opposition. As examples of things that are "not alive," children proposed organisms that had been alive but were now dead (a cat run over by a car) or extinct (dinosaurs), were representations (a drawing of an animal rather than a "real" animal) or imaginary. On the basis of responses like these (and a number of other clever experimental tasks), Carey showed that it may be a mistake to assume that when a child judges an example as "alive" or "not alive," he or she is relying on a conceptual system like the one that most adults have in mind. Carey concluded that there is no evidence that children think magically or illogically. Rather, their judgments make perfect sense given their conceptual understanding of the world. Developmental change, under this account, is conceived not as the mastery of thinking processes or a new form of logical or abstract thinking, but as changes over time in one's stock of knowledge about the meaning of terms like "alive," as children collect both first- and secondhand experience with organisms and their properties. These changes in the knowledge system accumulate, and when they reach a critical level the conceptual system restructures to accommodate the inconsistencies.

Indeed, all the relevant logical equipment can be presumed to be intact at least by the time children begin school. (Whether parts of this knowledge are already in place at birth, learned at very early ages, or governed by inborn constraints is a question being actively investigated.) Even participants in content-lean studies import knowledge in an attempt to make sense of the problems and tasks they encounter. Researchers in the science-as-logic tradition have generally acknowledged that it not really possible to rule out the influence of prior knowledge and have instead focused more directly on *how* knowledge and other factors might systematically influence participants' reasoning strategies and heuristics (D. E. Penner & Klahr, 1996; Schauble, 1990, 1996). From the theory change perspective, reasoning strategies and heuristics are tools for theory development. Epistemic commitments of theories are especially important targets for development, including, for example,

whether or not a new theory is free of contradiction, accords well with previous theoretical commitments, and accounts for evidence, both actual and potential (Posner, Strike, Hewson, & Gertzog, 1982).

Science-as-Practice

Science-as-practice is an image formulated from studies of science that emphasize observational studies of scientific activity, both in the short term (e.g., studies of activity in a particular laboratory or of a program of study) and historically (e.g., studies of laboratory notebooks, published texts, eyewitness accounts). Science-as-practice suggests that theory development and reasoning are components of a larger ensemble of activity that includes networks of participants and institutions (Latour, 1999); specialized ways of talking and writing (Bazerman, 1988); development of representations that render phenomena accessible, visualizable, and transportable (Gooding, 1989; Latour, 1990); and efforts to manage material contingency, because no theory ever specifies instrumentation and measurement in sufficient detail to prescribe practice. The alignment of instruments, measures, and theories is never entirely principled (e.g., Pickering, 1995). What the other two images of science take as foundational (reasoning and theory) together comprise only one leg of a triangle that also includes material procedures (e.g., making instruments and other contexts of observation, almost always involving machines) and models of how the material procedures function to render nature visible (Pickering, 1989).

The descriptions of science that are produced in this tradition of research suggest that science includes many different forms of practice, ranging from experiment to comparative study. For example, experimental physics tends to favor experiment as a critical form of argument, a tradition initiated several centuries ago (Sibum, 2004). As examples of this, see Shapin and Schaffer's (1985) description of the epistemic controversies aroused by Boyle's then novel experimental approach in the seventeenth century and Bazerman's (1988) description of Newton's role in the genesis of the experimental report. In contrast, even contemporary studies of evolution rely on comparative methods. For example, Van Valkenburgh, Wang, and Damuth (2004) recently tested tenets of natural selection by examining the fossil record of North American carnivores during the past 50 million years. Their argument was comparative in the sense that predictions were made

about the effects of individual selection on extinction rates of large carnivores, and these were then compared to the extant fossil record.

Each of the components of practical activity cited in social studies of science appears critical for the overall success of the enterprise. Consider, for example, inscriptions (representations that are written). Latour (1990) suggests that systems of scientific inscription share properties that make them especially well suited for mobilizing cognitive and social resources in the service of scientific argument. His candidates include (a) the literal mobility and immutability of inscriptions, which tend to obliterate barriers of space and time and thus "fix" change so that it can be an object of reflection; (b) the scalability and reproducibility of inscriptions, which guarantees their economy but preserves the configuration of relations among elements of the represented phenomenon; (c) the potential for recombining and superimposing inscriptions, operations that generate structures and patterns that might not otherwise be visible or even conceivable; and (d) the control of reference, because inscriptions "circulate" throughout a program of study, taking the place of phenomena, yet maintaining an index to the original events that inspired their creation (Latour, 1999, p. 72). Lynch (1990) adds that inscriptions not only preserve change, they edit it as well: Inscriptions both reduce *and* enhance information.

Inscriptions serve epistemic commitments. Gooding (1989) examined how patterns made by iron filings in magnetic fields were transformed into displays featuring geometric curves and lines of force. These new technologies of display helped establish a language of description for the new phenomenon of electromagnetism "while also reinforcing the scientific values it embodied" (p. 186). Similarly, Kaiser (2000, pp. 76–77) suggested that the enduring and recurrent use of Feynman diagrams in particle physics was due to the diagrams sharing visual elements with the inscriptions of paths in bubble chambers, a correspondence that appealed to realism: "Feynman diagrams could evoke, in an unspoken way, the scatterings and propagation of real particles, with 'realist' associations for those physicists already awash in a steady stream of bubble chamber photographs."

Science-as-practice emphasizes the complicated and variable nature of science. What develops, then, must include logic and theory (Dunbar, 1993, 1998) but also ways of talking about phenomena and otherwise partic-

ipating in a community of practice (Gee & Green 1998; Lemke, 1990; Warren & Rosebery, 1996); inventing and appropriating display technologies, sometimes called representational competence (diSessa, 2002, 2004; Goodwin, 1994; Greeno & Hall, 1997; Roth & McGinn, 1998); becoming initiated into the lore of managing contingency within domains, including how to construct variables when Nature does not tell (e.g., Ford, 2004; Lehrer, Carpenter, Schauble, & Putz, 2000); and appreciating the different forms of method employed in different sciences. Because science-as-practice must, by definition, include opportunities to participate in these practices, studies of development that are guided by this image typically track long-term change in environments designed to support participation in scientific practices. As Warren and Rosebery (1996) summarize:

From this perspective, learning in science cannot be reduced simply to the assimilation of scientific facts, the mastery of scientific process skills, the refinement of a mental model, or the correction of misconceptions. Rather, learning in science is conceptualized as the appropriation of a particular way of making sense of the world, of conceptualizing, evaluating, and representing the world. (p. 104)

Rethinking Images of Science: What Is Experiment?

A comparative analysis of *experiment* may serve to heighten the contrast among these images of science. Science-as-logic regards experiment as a form of reasoning dominated by a singular rationale: control of variables. To experiment is to control, and what develops is an appreciation of this logic. Experiments are valid with respect to the space of possible manipulations of variables. Science-as-theory takes a different tack, treating experiment as a “critical test” of a theory. Critical experiments under gird theory change because they have the potential to produce anomaly and thus initiate conceptual change. Science-as-practice regards experiment as a resolution of an apparent paradox (Latour, 1999). Experimental facts are made—with instruments, material, and ingenuity—and so never can be regarded simply as nature observed (Galison & Assmus, 1989). Theories thus always have a practical side. They rest on foundations of mediated activity (e.g., representations, apparatus, instrument readings, interactions with other participants, design of the experiment). Yet, this practi-

cal activity becomes less visible to those who routinely practice it. As initiates are taught to see in particular ways, the products of experiment are treated as ascendant, and the activity whereby they are made becomes transparent, so that experimental facts become unmoored from their original settings (Gooding, 1989, 1990; Shapin & Schaffer, 1985; Sibum, 2004). Thus, from the science-as-practice perspective, experiment is complex and textured.

Implications of Images of Science for Education and Development

As noted, the images of science-as-logic and science-as-theory have dominated the debate about appropriate explanations for developmental change. These two views seek their support in different forms of evidence. Moreover, they tend to be associated with different views of the most appropriate goals for science education. It is interesting that science education has also engaged in its own long-standing debate about the relative importance of scientific knowledge and theories, on the one hand, versus scientific thinking, on the other. In general, school science has tended to emphasize learning what Duschl (1990) calls “final form science,” that is, its end products: concepts, facts, and theories. However, school texts that communicate this “rhetoric of conclusions” (Schwab, 1962) often fail to reveal how that knowledge was produced. Teaching facts, concepts, and theories as final form science may leave students in the dark about the way knowledge is generated and may also distort the nature of scientific knowledge, inappropriately conveying that it is unchangeable and uncontested. Partly as a corrective to traditional textbook approaches, educators in the 1960s began to argue that the focus of education should instead be on “science process skills,” such as observing, predicting, measuring, and inferring. Indeed, one of the most influential post-*Sputnik* National Science Foundation curricula was titled *Science: A Process Approach* (American Association for the Advancement of Science, 1964). However, it quickly became evident that the learning of domain-general processes could easily become as ritualized and meaningless as the learning of textbook facts. Moreover, the application of these skills seems to be tightly tuned to particular situations, tasks, and content. They are not easily acquired in one realm and then transferred to others, even when their use would be advantageous. Perhaps for these reasons, “process skills” approaches have largely fallen out of

favor in science education research (although they still seem appealing to curriculum designers and school faculty; they appear regularly in published commercial curricula and school standards documents).

Science educators agree on the importance of helping students appreciate the epistemology of science, although there is little consensus on how to do so. National science standards, for example, emphasize the importance of providing an opportunity for students to get a taste of doing science at their own level of knowledge and expertise. Indeed, inquiry is a major theme in the National Science Education Standards (Minstrell & van Zee, 2000; National Research Council, 1996). The reference to inquiry (rather than reasoning or process skills) is intended to communicate that scientific knowledge *and* scientific thinking should be inseparable goals of education, always pursued hand in hand (Bransford, Vye, Kinzer, & Risko, 1990). In the context of developing and pursuing scientific investigations that are focused on scientific knowledge, students learn inquiry skills *and* science content. As yet, however, little agreement has been achieved on what these skills might be, the extent to which they are transferable across domains, or how (indeed, whether) their mastery can be assessed (see D. Kuhn, Black, Keselman, & Kaplan, 2000, for a discussion of these matters).

As in the education field's attempt to substitute the process/content dichotomy for an integrated emphasis on inquiry, the field of research has also increasingly acknowledged that science involves *both* characteristic ways of thinking *and* conceptual structures. In research, as in education, there has been growing interest in seeking to understand these as complementary aspects of scientific reasoning. Researchers are investigating how they coevolve and are building and testing models of thinking that coordinate these two aspects of science.

For example, Klahr and Dunbar's (1988) Scientific Discovery in Dual Spaces model describes scientific reasoning as a process of integrated search through two problem spaces: a space of hypotheses and a space of evidence. In this model, moves in each of these problem spaces affect the potential movements in the other, either by constraining potential moves or opening new possibilities. As described in much of the general research on problem solving, a scientific reasoner generates a mental representation of the problem (the "problem space"), and his or her solution of the problem is modeled as a heuristic search through that set of possibilities. In the dual search space model, goals include

generating observations that may lead to the formulation of hypotheses, finding evidence that confirms or disconfirms hypotheses that are currently being entertained, or deciding among competing hypotheses. Therefore, the model incorporates hypotheses (which presumably have their origins in beliefs, concepts, or theories), strategies for generating and evaluating evidence, and descriptions of the interactions of search in these spaces in the course of scientific reasoning. In addition to this modeling approach, researchers (Klahr, 2000; D. Kuhn, Amsel, & O'Loughlin, 1988; D. E. Penner & Klahr, 1996; Schauble, 1990, 1996) have pursued empirical studies that systematically examine the effects of prior beliefs on students' strategies and heuristics for generating and evaluating evidence (and conversely, the effects of different strategies on changes in participants' theories).

Note, however, that whether a researcher believes that "what develops" is scientific concepts, scientific reasoning, or both, an assumption common to these perspectives is that the goal is to identify the most important aspect or essence of science, so that researchers can investigate its development and educators will know what to teach. Maybe, however, there is no such kernel. Perhaps what is most important about science is not its essence or core, but its variability. The science-as-practice image suggests that sciences span multiple epistemologies and practices. Moreover, perhaps what is important with respect to development is not characterizing changes that are internal to individuals, but understanding how individuals are initiated into and participate in these variable ways of knowing and doing science. From an educational perspective, the goal in that case would be to consider which forms of practice provide the greatest educational leverage, and then to understand how to assist students in beginning to participate. Primary attention would go not to investigating the developing knowledge or logic of individuals, but to characterizing the role of the systems in which cognition occurs, with special attention given to the array of semiotic and other tools that support and mediate thought.

WHAT IS DEVELOPMENT?

These views about the appropriate focus for research and education are closely associated with perspectives on the nature and mechanisms of development. This, of course, is the "What is development?" issue introduced

earlier in the chapter. From its origins as a field and throughout its history, developmental psychology has always preferred explanations based on the internal mental properties of individuals. There seems to be a bias toward seeking some form of biological essence as the ultimate explanation for development. This has been true from the origins of the field in Gesell's maturationist accounts to today's emphasis on identifying innate knowledge and genetically predetermined constraints on learning. It has been difficult in practice to conceptualize a developmental psychology that is not deeply rooted in assumptions about maturation and teleology. Indeed, for some investigators, what defines a phenomenon as *developmental* is that it has a universal character and appears to be governed at least in part by biological predispositions. With some important exceptions, the field of developmental psychology has largely regarded context, culture, history, and education primarily as noise, or at best, as *factors* that affect the course of development. Agreeing on how to legitimately bring these concerns into the purview of developmental study remains a struggle in the field.

As an alternative, one could conceive of development as inseparable from the means that support it, so that an account of "Under what conditions?" is considered an obligatory question that an adequate explanation of development must address. This kind of perspective is useful for scholars and practitioners who are concerned not just with describing or explaining development, but also with catalyzing and supporting it, or in some cases, changing its course in particular ways. Yet in general, mainstream developmental psychology has made little progress with the thorny problem of conceptualizing development and context. Indeed, the increasing attention in the field to younger and younger children could arguably be interpreted, at least in part, as an attempt to sidestep these difficult issues of culture and context.

Research on scientific reasoning that is conducted from a psychological perspective has relied mainly on cross-sectional investigations of individuals at different ages (less frequently, amount of education is used as an independent variable). A second, less frequently pursued methodology has been to track a group of individuals over the short term, conducting dense measurements to document the onset and pattern of change (D. Kuhn, 1989; D. Kuhn et al., 1988; D. Kuhn & Phelps, 1982). However, with one exception (Bullock & Ziegler, 1999), we know of no longitudinal research on scientific rea-

soning from a psychological perspective that extends beyond several weeks in duration. Indeed, cross-sectional studies (Klahr, Fay, & Dunbar, 1993; D. Kuhn et al., 1995) seem to suggest that there is more overlap than separation across age groups in the skills or heuristics typically investigated, and that education seems to be at least as important as whatever else is implicated by looking at individuals of different ages.

Although informed by the psychological research, much of the work featured in the second section of this chapter emphasizes the role of education and other semiotic means that constitute thinking. From this perspective, science entails the deployment of a set of very broad and eclectic psychological functions, marshaled in relationship to a web of complex and varying goals, pursued by a community over a changing history, and supported and shaped by culturally developed tools and semiotics. Under this view, there is no one psychological "essence" of science. Instead, science is regarded as a complex form of human practice. The term *practice* as used here refers not to the external organization of behavior, but to patterns of activity that are initiated and embedded within goals and thoroughly saturated with human meaning and intentions. "What develops" is a capability to participate in these practices of science. Researchers who pursue this perspective do not necessarily deny that scientific thinking entails logic, epistemology, and theory change. However, they argue that what is essential to account for is how these psychological functions are constructed by, contingent on, and expressed within social contexts and mediational means. Moreover, scientific reasoning is not conceived as knowing how to design experiments *plus* understanding patterns in evidence *plus* building a consistent and coherent knowledge base about a domain. Rather, each of these functions is viewed as fundamentally contingent on the others, so studying them as a collection of independent capabilities or *skills* may generate a distorted understanding of the intact enterprise.

This perspective on research tends to turn attention to sources and forms of variability, rather than to a search for universal or general forms of cognition. Variability is conceived as being understandable (and produced) by attending to the mediational features that support and provide meaning for scientific thinking or, from an educational perspective, that can be deployed as design features to instigate and support developmental change. These features may include histories of learning, teaching, and other forms of

assistance; cultural expectations of all levels and kinds; tasks and tools; genres of writing and argument; inscriptional and notational systems; and recurrent activity structures. Note that these items are conceptualized neither as internal psychological resources nor as external environmental stimuli; rather, they are understood to be externally instantiated (i.e., they have material expression) but imbued with meaning that is conferred by people.

The perspective of this chapter is not that either the psychological or practice view is “more right” than the other. However, one advantage that the practice view holds for education is that the elements that it takes as primary are potential instruments of change. One cannot directly engineer changes in people’s psychological capabilities. Educating involves understanding and deploying tools, tasks, norms of argument, and classroom practices to bring about desired ends (Lehrer & Schauble, 2000c). Understanding how these and other designable features serve to generate and sustain cognition is, therefore, a useful goal for scholars and practitioners concerned with education.

Regardless of one’s view on development, there remain unresolved questions concerning the characterization of science that is most appropriate for school science. The next section is devoted to describing current classroom investigations in which researchers work in partnership with teachers and others in school organizational structures to craft conditions that can best support the long-term development of students’ participation in the practice of science. Each program emanates from prior developmental research, so we include these antecedents to situate the design studies. Taken collectively, the design investigations emphasize somewhat different views of scientific practice and, therefore, result in educational designs based on different bets about ways of conceiving scientific practice that serve to catalyze development. The way to understand the implication of these bets is to instantiate the designs and conduct longitudinal study on the development of student thinking that results. Debates about the best way to conceptualize scientific reasoning (for educational purposes, at least) are difficult to resolve unless the bets can be cashed in and the outcomes compared. Each approach is very likely to have both strengths and characteristic weaknesses; as in any design enterprise, these need to be evaluated as trade-offs.

CLASSROOM DESIGN STUDIES AND DEVELOPMENT

In this section, we describe current classroom studies in which scholars are working to coordinate two inter-related agendas. First, they seek to change educational practice in ways that foster the development of scientific thinking. As will become evident, each of the projects featured here exemplifies a somewhat different sense of “what develops.” Thus, there is variability in what is taken as important early origins or precursors to scientific thinking, as well as in what is supported and studied along the way. Second, as these educational change experiments come into play and evolve over time, researchers study the cognitive and other forms of development that result among participating students. An important related goal is to understand the variety of means by which development is supported (Cobb et al., 2003), reflecting a general commitment to conceiving development as a culturally supported enterprise rather than a naturally occurring phenomenon.

Of course, there have been hundreds of classroom investigations that feature attempts to support students’ scientific reasoning and knowledge. This chapter does not attempt to review all of them, or even all those that may be relevant to the development of children’s scientific thinking and knowledge. Instead, we focus on a few cases that, collectively, exemplify the landscape of design studies in science, investigations in which scholars are pursuing the study of development by trying to change it. Examples that are featured here were selected for their fit to the following criteria:

- First and most important, these are projects that are developmental in their focus. In some cases, this means that the educational intervention was constructed on a foundation of knowledge from the literature in cognitive development. In others, the project may not be directly motivated by developmental studies, but it is conceptually consistent with current findings about development and makes new contributions to our understanding of development, typically by challenging what is “known” about development. These challenges often take the form of generating forms of thinking and learning that have not been previously documented. As a group, these investigations

are concerned both with identifying early origins or precursors of valued forms of thinking, and also with documenting change over time in the target forms of reasoning. In addition to describing the classroom studies on their own terms, for each, we also briefly summarize related research from developmental psychology that shows how the project links to the mainstream concerns of that field.

- In addition to focusing on the development of children's thinking, these projects take a developmental stance toward the domain of *school science*. Each embodies a perspective about how what is taught can contribute to a broader agenda of science literacy. The view of change is long term and looks well beyond the learning of a particular skill or concept. The typical grain size of interest is what can be accomplished over years of instruction, not within a lesson or a unit. All the work described here has given careful thought to what should count as a "big idea" in science education. As we will see, at this point the research agenda for most of this work still lags far behind the conceptualization.
- In each research project presented here, education is taken seriously. That is, the educational agenda is regarded as having intrinsic value. Accordingly, schools are not regarded merely as places to find participants for research, and education is conceived as more than tasks designed to tap some psychological function. The projects are situated in schools that are not unusually privileged with respect to student populations and resources. All of them have had to grapple with the actual conditions of schools, and all have had to address the thorny problem of sustainability.

Our intent is not to catalogue all work that fits these criteria, but to provide examples that illustrate the variety and breadth in the ways that investigators are conceiving of the intersection between science and development.

Not all the scholars whose work is reflected in this section identify themselves as conducting design research, but their research shows many of the commitments that design studies exemplify. Design studies are coordinated efforts to design learning environments and then to study the transitions in teaching and learning that follow. Those studies typically take many methodological forms, from traditional experiments or quasi-experiments to descriptive or ethnographic work.

The distinguishing characteristic of this approach is not its use of any particular method, but a tight and cyclical interaction between two complementary aspects of work: instructional design and research. Working from a base of previous research, analysis of the domain, and theory, researchers plan and craft the design of a learning environment, which may vary with respect to scope. Concurrently, they conduct a careful and systematic program of research on the learning that results as the design coalesces. As the research proceeds, it produces findings that call for revisions to the design. Sometimes these changes are minor, sometimes radical. The changes, in turn, generate new questions for investigation.

An assumption of the design studies approach is that many forms of learning that are important targets of inquiry cannot, in fact, be studied unless the conditions for their generation are present. Thus, they are particularly applicable to the study of forms of development that require sustained education for their emergence. As we mentioned, each design investigation places different emphases on which practices are important to sustain over longer periods of time. Often, these "best bets" have roots in developmental approaches informed by one or more of the three images of science, although in practice, all prolonged studies are hybrids.

Supporting the Development of Scientific Reasoning

Inhelder and Piaget (1958) asserted that only at the onset of formal operations, around the beginning of adolescence, do children become capable of understanding the logic of scientific experimentation. This claim, like many others concerning presumed deficits in children's cognitive capabilities, eventually fell to evidence generated by subsequent research. Microgenetic studies conducted by D. Kuhn and her associates (1988, 1995; Schauble, 1990, 1996) confirmed that only small percentages of preadolescents initially produced valid scientific reasoning strategies or heuristics when attempting to solve multivariable problems without much guidance from adults. However, when given extended opportunities to conduct repeated trials in microgenetic designs (D. Kuhn & Phelps, 1982), most of the children in these studies began to show increasing use of more effective strategies for designing and interpreting experiments (D. Kuhn et al.,

1995; D. Kuhn, Schauble, & Garcia-Mila, 1992; Schauble, 1996). These strategies included investigating all relevant combinations of variables and their levels, controlling extraneous variation, and making inferences that are appropriately based on the available quality and quantity of evidence. Indeed, many of the participants went beyond simply beginning to use the new strategies to mastering and consolidating them. That is, they almost always used the new strategies when it was appropriate to do so; the earlier, flawed strategies were eventually abandoned altogether; and participants even transferred the new strategies to unfamiliar problems that did not share surface features with the original learning context (D. Kuhn et al., 1992).

Indeed, the origins of these heuristics are evident even as early as the preschool years. In a carefully constructed sequence of studies, Sodian, Zaitchik, and Carey (1991) demonstrated that preschoolers could consider two alternative tests of a hypothesis and reliably identify which would actually settle the question. However, their succeeding appeared to depend on a number of simplifying circumstances: that the alternatives did not confirm or challenge strongly held prior beliefs, that the number of choices and variables was kept very restricted, and that children were asked simply to evaluate alternatives rather than to propose an experimental design on their own. Nevertheless, these studies do show that at least in a rudimentary way, children can differentiate their beliefs from evidence that bears on those beliefs.

Promoting Understanding of Experimental Design via Instruction

Building from earlier findings that children can understand the logic of experimental design (Tschirgi, 1980), Chen and Klahr (1999) suggested that the kernel of a science education for children is mastery of the logic of the control of variables. They recommended that children should be taught to ignore or look behind particular content to focus on structural relationships. This is precisely what children were trained to do in Chen and Klahr's educational studies. In one investigation, students learned to evaluate the design of experiments by making judgments about the informativeness of pairs of trials presented by a researcher as a "test" of causes and effects in a multivariable context. Each trial included several potentially causal independent variables (that could be set at different levels) and an outcome variable

(also with several levels). Students understood that the point of the comparisons was to make a decision about whether one of the independent variables was causally related to the outcome.

For example, in one context, students were told that their task was to evaluate an experimental trial's utility for helping to decide which factors determine how far a ball will roll down a ramp. The experimental comparison included two small ramps that could be set at either steep or shallow angles, with starting gates set at different positions on the ramps. The ramps were fitted with a reversible insert that would produce either a rough or a smooth ramp surface. Two different test balls were provided, a golf ball and a rubber squash ball. Children observed pairs of configurations of these materials and were asked whether or not each comparison supported a definitive conclusion.

Among the trials shown to children were various forms of invalid tests. For example, the two-ramp setups might differ in multiple ways, making it impossible to tell whether one of the variables was the causal one. In such a case, a child might observe a golf ball rolled down a steep ramp with a rough surface, and the comparison case would involve a rubber ball rolled down a shallow ramp with a smooth surface. If the two conditions led to a different outcome, it would be impossible to know why, because several variables had been varied simultaneously. The 7- to 10-year-old participants in the study were shown several examples of both confounded comparisons like these and other comparisons where extraneous variation was controlled. In each case, the participant was asked to decide whether the comparison was a "good test" or a "bad test." In a training condition, participants were provided explicit feedback after each trial; the experimenter also explained why the test either was or was not flawed. Chen and Klahr (1999) reported that not only were they able to improve children's abilities to judge the informativeness of experiments and to make inferences based on them; in addition, the older children were able to transfer the strategies they had learned to novel contexts, even after a 7-month delay. Moreover, Klahr and Nigam (2004) demonstrated that children who were taught these strategies were able to use them to evaluate science fair posters a week afterward.

The instruction designed by Chen and Klahr (1999) was tightly focused on the logic of control of variables. Although science-like materials (ramps, springs, and sinking objects) were used, the logic would have been precisely the same if the tasks had borne no relationship

whatsoever to science topics. Hence, this body of work is a particularly clear example of science-as-reasoning.

Practices of Investigation as a Route to Developing Reasoning

Like Chen and Klahr (1999), Kathleen Metz (2004) emphasized developing skills and strategies important to the conduct of scientific inquiry. However, in Metz's classroom investigations, the focus on domain-general forms of reasoning was not pursued at the expense of domain-specific conceptual knowledge. Instead, children received repeated opportunities to plan, conduct, and revise related *programs* of research in the service of developing coherent conceptual structures concerning important biological ideas such as behavior and adaptation. In this sense, the practices of children were similar to those of scientists.

For nearly a decade, Metz has been pursuing classroom design research with the ultimate goal of maximizing children's capability to conduct independent inquiry. A main conjecture of her research is that the learning of skills and knowledge is best supported in contexts that maintain the integrity of the original goal-focused enterprise where those skills and knowledge originated. Therefore, research methods and strategies should be introduced to students not as disembodied skills, but as tools for pursuing real questions that children pose in domains where they have opportunities to develop significant content knowledge.

In Metz's work, children are deeply immersed in one discipline, often for a year or longer. Metz (2004) makes the case that students should concentrate intensively in a relatively small number of domains, rather than learning a little bit about a wide variety of topics. After all, one cannot conduct inquiry in a field in which one knows nothing, so a curriculum that emphasizes breadth over depth is not a good one for supporting inquiry. Properly supported, the development of content knowledge and the development of scientific reasoning should bootstrap each other.

Inquiry depends on students being able to generate fruitful questions, acquiring a repertoire of appropriate methods for investigating those questions, and developing a sense of the forms and qualities of evidence (and counterevidence) that can inform the answers. Consistent with this view, Metz's participants study one scientific domain at a time—such as animal behavior, ornithology, botany, or ecology—for an extended period in which they repeatedly encounter the core ideas

of the domain in multiple contexts. Initial investigations are carefully structured and scaffolded; subsequent inquiries are planned and conducted by the children themselves, who are increasingly given independent responsibility for the progress and evaluation of the scientific work.

For example, as an introduction to animal behavior, students in second and fourth/fifth grade began by conducting observations of a rodent confined to a small space in the center of the classroom. The fact that every child was observing the same animal meant that, inevitably, they selected different behaviors to describe, interpreted the behaviors differently, or failed to record them in a common form. These occurrences motivated debates about the need for standard ways to observe and also provoked awareness of the fact that under some conditions (such as loud talking), observation can change the behavior of the organism being observed. Children typically attribute intentions and thoughts to animals, so the observations also produced a forum for discussing the difference between observations and inferences, a distinction that Metz considered fundamental for subsequent work. In small teams, children recorded and displayed their data, and the different data displays generated a reason to talk about how data representations of different design communicate different information.

After these initial observations, students were reorganized into pairs and each pair was given their own organism to study, in this case, one or more crickets. Crickets available for observation varied both between species and within species (gender, age, etc.), raising questions about relationships between these variables and observable animal behaviors (such as chirping, fighting, or eating). Various forms of controls and research methods specific to the domains of study (e.g., time sampling as a technique commonly used in animal behavior) were introduced. To pursue the goal of building a rich knowledge base that could inform inquiry, students supplemented their direct observations with reading material, videotapes, and other media. The research teams independently generated questions about the crickets, and then the whole class compiled their questions and categorized them on a number of dimensions, including whether the questions were amenable to empirical inquiry (“Is this a question that you can collect data on?”). In some cases, students explicitly noted differences between forms of thinking in everyday contexts, as contrasted with their use in science.

For example, students concluded that in science, they might not always achieve consensus and that this was acceptable if they had good justifications for failing to agree. Students learned to recognize and mark sources of uncertainty in their developing knowledge.

Initial investigations with crickets were planned by the whole class working together and then were conducted individually by pairs working as research teams. The teacher assisted in recording and categorizing questions, summarizing observations, and developing a table that displayed classes of questions that might be investigated and methods appropriate for doing so. For subsequent investigations, both the direction and the procedures were increasingly ceded to the students. Finally, using the previously developed list of heuristics for evaluating potential questions and the class-generated list of domain-specific methods for investigating questions, each team planned and conducted its own investigation. The investigations culminated with a poster presentation in which each team presented its question, methods, and findings.

The notion of inquiry exemplified in these sequences contrasts sharply with the typical cookbook laboratory exercises in which students carefully carry out step-by-step procedures, and also with hands-on science activities and kits in which a preordained course of investigation is followed. Students in Metz's classrooms have much more (although not boundless) freedom to select their own question to pursue. This means that it is essential for curriculum designers to identify domains of study that support a wide variety of student questions, all of which, however, must be very likely to lead students directly into confrontation with one or more important scientific ideas. An important topic of Metz's research is to identify domains that have these properties. Metz's approach differs, as well, from those advocated by Chen and Klahr (1999) or D. Kuhn (1989), in which the content and surface features of inquiry tasks are considered secondary and the emphasis is on repeated practice at making logical judgments about problems with varying surface features that preserve a common underlying structure.

Metz (2000) identified five different aspects of children's knowledge that were the primary foci of this instruction: children's conceptual knowledge of the domains under investigation, their understanding of the enterprise of empirical inquiry, their knowledge of domain-specific methodologies, data representation and analysis, and tools. Careful study of the progress of chil-

dren's investigations, coupled with postinvestigation interviews of the children's research teams (Metz, 2004), provided information about children's achievement of these goals. Findings were reported for one class of second graders and one class of mixed fourth/fifth graders, both from a public elementary school in a rural area, who had participated in the first iteration of the animal behavior curriculum.

All 10 of the second-grade research teams and 14 fourth/fifth-grade teams formulated both a researchable question and a method for investigating their question, although one second-grade team initially chose a research method that was not appropriate. Most of the second graders and about half of the fourth graders relied on the class-generated heuristics for identifying a good question. Interestingly, about half of the older teams pursued questions about social behavior, although none of the younger children did. The majority of the younger children conducted studies of the effect of some variable on cricket behavior by comparing the behavior of the crickets under different conditions. In sum, children showed considerable competence at taking charge of their investigations, even coming up with sophisticated proposals for controlling extraneous variation that seem surprising, given the previous literature about children's spontaneous performance on problems that require them to produce or evaluate comparisons that involve controls (Chen & Klahr, 1999; D. Kuhn et al., 1988).

After instruction, each team was individually interviewed about their conceptualization of their question and the method used to investigate it, their findings, and whether they could think of a way to increase their confidence level in the findings. In addition, each team was asked whether they could think of any way to improve the study. In her analysis of these interviews, Metz (2004) paid particular attention to how children conceptualized the sources of uncertainty in their study and the strategies they pursued in trying to resolve the uncertainty. A few of the younger children apparently held the simple idea that the point of inquiry is to produce a desired outcome, so that what was uncertain was how to make the experiment "work," a notion that has shown up repeatedly in previous research with preadolescent children (i.e., Schauble, 1990; Tschirgi, 1980). About 25% of the children focused primarily on the possibilities of uncertainty in their data that were due to imprecision of their instruments or experimenter error. About 15% of the children (approximately equal percentages in both grades) described themselves as uncer-

tain about the generalizability of the trend in their data. The most frequent reasons given for this uncertainty were that the study was conducted within a limited range of experimental conditions or that the variability of the crickets made children uncertain that results achieved with some crickets would apply to others. Nearly 40% of the second graders and 25% of the older children were uncertain that their theory was adequate to account for the trend that they observed in the data. Finally, the most common source of uncertainty was attributed to the trend identified in the data (over 40% of the second graders and 85% of the fourth/fifth graders). In most (but not all) of these cases, children were able to propose at least one strategy to resolve the uncertainty.

In sum, the participants seemed to understand the problematic nature of knowledge in several respects: that uncertainty can enter the data generation process in a variety of ways, that what they know about their research question is mediated by the study they conducted and its inherent flaws and uncertainties, and in general, that the relationship between the world and the scientist's knowledge of it is far from straightforward, but rather complex and interpretation laden. Metz (2004, p. 282) concluded, "At least by the second-grade level, the decontextualization and decomposition of the elementary science curriculum appear to be more a function of curricular traditions than developmental need."

Instruction that is organized around self-directed investigations needs to maintain the right balance between investigation skill and the development of conceptual knowledge. But it is not always a simple matter to find that balance. In practice, teachers must be skillful to negotiate the tension between these two components and must continually work against the tendency for one to fade into the background as the other takes center stage. Metz advised extended study within a coherent domain of knowledge as a way of balancing the focus on methodology with a corresponding emphasis on the development of a rich knowledge base. Because children's knowledge built cumulatively over weeks and months, their repeated opportunities to conduct and interpret investigations not only familiarized them with a repertoire of methodologies, but also provided opportunities to construct expertise in a bounded but complex domain of investigation.

In summary, Metz's approach to supporting development of scientific reasoning has a methodological bent: It places its bets on introducing children to methods commonly employed by scientists, but it does so in con-

texts of prolonged investigation of a rich content domain. It borrows from studies of scientific practice to instantiate aspects of scientific community. Questions and investigations have both a self-directed and a communal nature. What we know less about from these studies is the nature of the conceptions children are developing about the domains under investigation. Clearly, they are developing methodological commitments akin to those of scientists. But do their evolving understandings of crickets serve as gateways to larger conceptual structures in biological sciences? And if so, how? These questions have been more explicitly addressed in research guided by science as theory development.

The Development of Theories

We contrast two programs of research, both of which are centered in theory change but that make different commitments to origins and analysis of what develops. The first, *Intentional Conceptual Change*, draws from science education and is informed by a view of science as a process of conceptual change. The second, *Pathways to Science*, as its name suggests, draws from studies of early origins of children's theories about nature and seeks to capitalize on these origins to create developmentally appropriate education.

Intentional Conceptual Change

For many years, Sister Gertrude Hennessey was the sole science teacher for grades 1 through 7 in a small parochial school in Wisconsin. As a result, she had the unusual opportunity to think about the goals and trajectory for students' scientific reasoning across all those grades of schooling. Fortunately, she had both the educational background and the wisdom to capitalize on this opportunity to pursue long-term development (she holds degrees in biology and science education). Hennessey not only planned the course of instruction and taught her students daily; she also kept detailed records and videotapes of her students' learning and conducted regular interviews of individuals, small groups, and intact classes. She pursued a structured approach to science instruction that made students' thinking visible and therefore accessible to her observation. From time to time, she collaborated with university researchers from both developmental psychology and science education to conduct cross-sectional and longitudinal studies of student learning (e.g., Beeth & Hewson, 1999; Smith, Maclin, Houghton, & Hennessey, 2000).

Hennessey (2002) regarded science learning primarily as conceptual change. However, in pursuing this characterization of science, she drew primarily on the field of science education rather than psychology. She was particularly influenced by the work of Posner and his colleagues (1982) and later revisions by Hewson and Hewson (1992), who pursued what they called a conceptual change model (CCM) to account for how students' mental representations of the world might shift from initial, naive notions to the conventionally accepted explanations of science. The CCM described conceptual change as a process by which a concept might be replaced by another, modified, or simply dropped. Critical to the conceptual change model is the assumption that the relative overall *status* of a concept for a particular learner determines whether the concept will be maintained or changed when an alternative is under consideration. Status refers to how the concept is evaluated relative to a consistent set of criteria. How an individual applies those criteria depends on his or her prior knowledge, motivation or stakes in both the new concept and those that it may replace, and ontological and epistemological commitments. Specifically, the evaluative criteria associated with status include the learner's evaluation of the concept's *intelligibility* (how comprehensible is it?), *plausibility* (is it believable?), and *fruitfulness* (how useful is it for getting things done in the world or for motivating new investigations?). A fourth factor, not directly included in status but important nonetheless in whether a concept is maintained or changed, is *conceptual coherence*, whether and how the new concept fits or fails to fit into the preexisting network of related knowledge. Hewson and Hewson used the analogy of a "conceptual ecology" to refer to the balanced interrelationships among beliefs. As in ecological systems in biology, the metaphor of conceptual ecology emphasizes the importance of interdependencies. Changing one concept is very difficult or impossible to do without changing others that are closely related. According to Hewson and Hewson, each concept occupies a niche within its conceptual ecology. Concepts, like organisms, may compete for survival within a niche. However, a concept is unlikely to be discarded or changed unless the individual becomes dissatisfied with it. Therefore, helping children clearly articulate the beliefs that they hold and, in some cases, helping them notice the inconsistencies or insufficiencies of those beliefs are reasonable strategies for a teacher who hopes to help children make conceptual progress toward accepted scientific theories.

Hennessey's instructional approach was to explicitly teach students the evaluative criteria in the Conceptual Change Model, starting with the earliest grades of instruction. Her emphasis was not primarily on learning what each criterion meant in a disembodied way, but on putting the criteria to use in the context of building their own explanations for scientific phenomena and deciding among competing explanations produced by other members of the class.

Hennessey placed a great deal of importance on students' developing metacognition, hence the emphasis on scientific reasoning as *intentional* conceptual change. Becoming aware of one's own theories and explicitly evaluating them against the conceptions proposed by peers was fundamental to her goals for students. Notice, however, that in contrast to a more general emphasis on self-regulation and self-evaluation, Hennessey's classrooms were focused on a more restricted sense of metacognition, one tightly tied to the CCM epistemology of science. Hennessey was adamant that her interest in improving metacognitive understanding was not a general, all-purpose goal for students conceived as transferable across content and disciplines. Rather, student metacognition was pursued in the service of achieving domain-specific conceptual change. Moreover, neither metacognitive development nor conceptual change was regarded primarily as an end in itself, but rather both were considered to be ways of helping students achieve the more fundamental goal of engaging with deep, domain-specific ideas in science.

Given this strong emphasis on epistemology of science, it is not surprising that Hennessey's instruction was frequently based on direct experience with the natural world. Students frequently began a unit of instruction by directly exploring a phenomenon carefully chosen to provoke surprise (again, the emphasis on anomaly in theory change), given students' likely prior beliefs and assumptions. Students worked with the phenomena, typically in a laboratory or field setting, recording questions that came up in the context of their explorations. Then, as in Metz's (2004) work, they planned and carried out investigations to answer their questions. These were more likely to be investigations with physical materials than "research" in books or online. In the course of these investigations, students were encouraged to represent their ideas in a variety of formats (charts, graphs, diagrams) and to compare their ideas with those being developed by other students. The emphasis was on first clarifying one's own ideas and then, after evaluating theories against the evidence and

against competing theories posed by others, evaluating and revising those ideas to account for anomalies experienced in the course of ongoing investigations.

In sum, the view of science portrayed in Hennessey's program was that science is a matter of developing and building progressively more adequate theories about the world. Moreover, what develops is not only the scientific theories but, equally important, students' critical standards for defending, adapting, or replacing those theories. Although Hennessey did not discuss development in depth in her published articles, she clearly had ideas about the general course of development of these metacognitive criteria. At each grade, students were expected to build on accomplishments in earlier grades, constructing a progressively more sophisticated capability to reflect on and evaluate their own theories and those of their classmates. Her goals for first graders were modest, focused primarily on helping students become adept at stating their own beliefs and providing reasons for them. By the fourth grade, students were expected to understand and apply all four criteria of intelligibility, plausibility, fruitfulness, and conceptual coherence as they evaluated their evolving beliefs. By sixth grade, students were also monitoring the beliefs of others, especially their peers, and considering the fit of competing explanations to patterns of evidence.

Hennessey's sixth graders, who at that point had received a total of a half-dozen years of instruction under her tutelage, were interviewed with an instrument previously developed by Carey and colleagues (Carey, Evans, Honda, Jay, & Unger, 1989) to ascertain their understanding of the nature of science. In this study, their performance was compared to a demographically similar group of sixth graders who were taught with a more traditional elementary program. The Nature of Science Interview (Carey et al., 1989) was designed to roughly classify students' responses with respect to their conceptual grasp of the epistemology of science. Level 1 ideas, compatible with what Carey and Smith (1993) called a *knowledge unproblematic epistemology*, reflect a belief that knowledge is certain and unproblematically true. It is a relatively simple matter to know what is true; one simply has to look (or be told). Responses classified as Level 2 reflect an understanding that scientists are concerned with explanation and testing, but nonetheless, knowledge is still regarded as true, certain, and discernible. Level 3 responses, in contrast, explicitly note that knowledge is tentative, changeable, and significant only within an interpretive framework.

In previously published research involving Massachusetts public school students (Carey et al., 1989), all seventh graders had provided interview responses that were classified as Level 1. In contrast, 83% of the students in Hennessey's classroom produced responses that were classified at least as Level 2. Smith and her colleagues found four clusters of issues that differentiated Hennessey's students from those in the comparison classroom. First, when asked about the *goals of science*, the Intentional Conceptual Change students said that scientists are involved in understanding and developing ideas. In contrast, the comparison students mentioned simply doing things and gathering information. The two classes also differed on the *type of questions that scientists ask*. Hennessey's students more frequently described questions about explanations and theories, whereas the majority of the comparison students' examples were about procedures (how to do things) or questions that Smith et al. (2000) referred to as "journalistic" (identifying who, what, where, when). When asked about the *nature and purpose of experiments*, Hennessey's students were likely to highlight testing a particular idea or to refer to the role of experiments in developing theories. The comparison students, in contrast, referred to experiments as a way to try things out or to find (unproblematic) answers to questions. Finally, when students were asked *what causes scientists to change their ideas*, many of the Intentional Conceptual Change students responded that scientists change their ideas when they are able to develop a better explanation, or pointed out in other ways that change is a response to complex evidence. In contrast, the dominant answer provided by the traditional students was that scientists decide to either keep or throw out an idea after one simple observation or experiment. Only a third of the comparison students spontaneously noted that changing a scientific idea requires hard work or careful thought.

By and large, Hennessey's students had not yet achieved a sophisticated Level 3 view that included either the logic of hypothesis testing or an acknowledgment of how framework theories entail coherent principles that shape the development of hypotheses. Yet, these findings from the Nature of Science Interviews suggested that most of her students had achieved an understanding of the epistemology of science that is quite unusual for their grade. Indeed, Smith et al. (2000) reported that they found these sixth graders' replies to be similar or superior to responses typically given by 11th graders.

Although Hennessey does not explicitly mention it, there are close conceptual ties between her Intentional

Conceptual Change project and developmental research on children's criteria for evaluating theories. Samarapungavan (1992) investigated first graders', third graders', and fifth graders' criteria for scientific rationality in a study in which children observed a phenomenon and then were asked to select which of two explanations accounted better for their observations. The pairs of explanations were constructed to be identical in surface features, but to contrast on one of four "metaconceptual criteria," as she called them. These criteria, which seem quite similar to the criteria that Hennessey emphasized, included such issues as *range of explanation* (how much of the observational data does the theory account for?), *non-ad hocness* (is the theory simple or does it include a number of added-on assumptions that are not testable?), *consistency with empirical evidence*, and *logical consistency* (internal consistency, lacking mutually contradictory claims). Samarapungavan found that even the youngest children in her sample preferred theories that met these criteria when they were choosing between competing theories that were consistent with their own prior beliefs. Even the first graders preferred the empirically and logically consistent theory to theories that were inconsistent. These children also preferred theories that could account for a broader range of observations. On the other hand, when the theory of broader range contradicted their prior beliefs, they were less likely to favor it. The most difficult criterion was the one Samarapungavan called *ad hocness*. Only the 11-year-olds reliably rejected theories that were overelaborated with special conditions or auxiliary hypotheses that could not be directly tested.

In her interpretation of these results, Samarapungavan (1992) cautioned that she thought of these criteria as heuristic only, not as definitive of the value of competing explanations. In her view, any of these criteria could legitimately be overridden by a more important concern, that is, whether the content or meaning of the new idea being considered was compatible with existing scientific ideas held with a reasonable amount of confidence (Hennessey's conceptual coherence criterion). Therefore, like Hennessey, Samarapungavan also gave highest priority to the fit between a concept and other related knowledge, or, as Hewson and Hewson (1992) might describe it, how and where a concept fit into the individual's "conceptual ecology."

Samarapungavan (1992) also pointed out the importance of understanding that although children may use these criteria in a simple forced-choice task, this does

not mean they have mastered them or even that they were consciously aware of them. Students in her studies merely chose between two options and were never asked, for example, to formulate an explanation on their own. In some cases, students' choices were consistent with one of the criteria, but they did not explicitly mention the criterion in their justification for that preference. Samarapungavan suggested that children hold some of these criteria only implicitly. Therefore, she recommended, it would be helpful to highlight these "metaconceptual dimensions" in science instruction to foster awareness of them and support their systematic use.

We turn now to a more direct kind of connection between developmental research and an educational program. In this case, the educational intervention followed directly from a major trend in developmental research. This is not very surprising, given that one of the program developers is a prominent developmental scholar who conducts research on the origins of children's concepts and theories. Preschool Pathways to Science, which we describe shortly, resulted from a collaboration between developmental researchers and educators.

Early Resources for Scientific Thinking

Shortly after the seminal work of Jean Piaget became widely known in the United States, scholars began to investigate further his findings and conclusions, especially his claims that infants and young children literally do not possess the same forms of logic that adults do. Piaget's theory held that logic must be painstakingly constructed anew by each individual as he or she grapples with the regularities of objects, space, time, and cause that (in Piaget's view) necessarily structure our experience with the world and our evolving conceptual systems. These concepts and more complex forms of intelligence are developed gradually as each person adapts to the structure of the world through his or her actions upon it.

These claims inspired a flurry of interest in identifying more precisely the cognitive resources of infants and young children. Gelman and Baillargeon (1983) summarized the research on the development of Piagetian concepts and concluded that the evidence was not consistent with the idea that there are major, domain-general qualitative shifts in children's reasoning. Rather, Gelman and Baillargeon interpreted this research as suggesting that both the nature and the development of cognitive abilities are domain specific. Moreover, given the robustness and regularity with which some domain-

specific concepts emerge, it may well be that their development is governed by mechanisms that are genetically governed. As they remarked, “One lesson of modern research in child psychology is that accounts of how development proceeds can no longer ignore the possibility that at least some of the structures that underlie our systems of knowledge are innate” (p. 220).

The notion that infants may enter the world with well-formed knowledge in some domains—or at least, may be especially prepared for ready learning in them—was influenced and informed by related work in the field of ethology. For any animal, some things are very easy to learn, whereas others are very difficult. For example, as Gallistel, Brown, Carey, Gelman, and Keil (1991) point out, pigeons learn relatively easily to peck a key to obtain food but find it difficult to learn to peck a key to avoid receiving a shock. In contrast, they easily learn to flap their wings to avoid a shock. Like pigeons, humans also seem to be genetically prepared for some forms of learning. A frequently cited example of preferential learning is the relative ease with which most infants learn their native language. Moreover, babies learn language in a remarkably orderly way; both the sequence and timing of the emergence of language components are quite consistent across children and across cultures.

Not only do babies learn certain things with relative ease; they also seem to arrive in the world already possessing forms of knowledge that are relatively complex. In contrast to Piaget, who believed that infants’ knowledge of objects developed very slowly over the first months of life, most contemporary developmentalists now believe that babies’ conceptions of objects are much like those of adults. Recall that Piaget believed that young infants do not initially integrate information that comes from different sensory modalities, so that the appearance of a bouncing ball, the sound it makes as it bounces, and the way it feels when grasped may not be perceived as related aspects of a single, intact object. Yet, recent research suggests that infants are born prepared to process a world full of three-dimensional objects and that their perception of these objects is amodal (i.e., knowledge that comes in from different sensory modalities is integrated in a common mental representation: Children perceive objects, rather than uncoordinated sights, sounds, and tactile sensations). The child’s mental representations of the world are interrelated from the very beginning; they are rich and complex and support all kinds of inferences and predictions about the appearance, motion, and qualities of objects.

Early findings along these lines, coupled with the invention of new technologies for studying cognition in preverbal children, have resulted in an explosion of research on the cognitive capacities of increasingly younger children and infants. Researchers have produced surprising new knowledge about infants’ capabilities that was previously unforeseen. For example, even infants in the first year of life seem to know that two objects cannot simultaneously occupy the same place (Baillargeon, 1987). They directly perceive causality in displays in which one object seems to bump into and propel another (Leslie, 1984). They know about the continued existence of an object even when it is hidden from view after being observed (Baillargeon & Graber, 1988). On the other hand, they do not apparently expect unsupported objects to fall (Baillargeon & Hanko-Summers, 1990; Hood, Carey, & Prasada, 2000). At this point, it is not settled whether (and if so, which types of) this infant knowledge is intact at birth, develops as a result of innate predispositions to attend to some things at the expense of others, or emerges as the result of general learning mechanisms, perhaps operating under constraints.

Knowledge about objects and motion supports predictions and expectations, delineates the kinds of events and evidence that will be salient to the perceiver, and provides constraints on the kinds of inferences that are made. Moreover, children’s knowledge about objects is not simply a list or collection of ideas; it appears to be organized in a tight network of interrelated concepts that are internally structured. Knowledge about objects also participates in wider knowledge structures, such as the coherent system of ontological classification that children develop (Gopnik & Meltzoff, 1997; Keil, 1992). Because the knowledge of objects (and certain other fundamental domains) appears to be structured in these ways, some researchers have argued that at least certain classes of infant knowledge can be appropriately described as early “theories,” which serve the function of organizing both past experience and the generation of new knowledge. The so-called theory theorists emphasize that even babies’ mental representations are structured, abstract, and complex. Therefore, although babies’ theories may differ in content from those of adult scientists, the theories of both groups nonetheless share important defining properties. Moreover, these theories may be revisable as experience strengthens them or requires their elaboration or adaptation (Gopnik & Meltzoff, 1997). Revisability, of course, is an attribute also characteristic of the theories of adult scientists.

Debate continues about how “theory like” these mental structures are and what forms of early knowledge can be presumed to share these theory-like properties. Frequently mentioned candidates include children’s “theories” of physical objects and their interactions, biology and living things, number/quantity, and the nature of human mental life.

Attempts to identify and characterize these “core theories” and to understand their character, their origins, and the mechanisms of their development currently account for considerable research activity in the field of cognitive development. The resulting domain-specific accounts of the ways that children’s theories emerge and develop over early years of life have now come to the awareness of science educators, who, for their part, have tended to pay close attention to the influence of naive theories, but only later in the life span. The “misconceptions” literature in science education has been conducted mainly with students at high school or university age. Hundreds of studies have now amply demonstrated that even after succeeding at high levels in school science instruction, students often continue to cling to naive preconceptions about the way the world works. In many cases, these preconceptions are at direct odds with the implications of the science that students have just “mastered.”

The growing research base about the origins of young children’s theories, considered against this context of older students’ failures to deeply understand the scientific theories they have been taught, suggests that it may be valuable to seek and develop potential links between children’s unschooled theories of the world and the concepts and theories introduced in school science.

Preschool Pathways to Science

This concern is reflected in Preschool Pathways to Science, a program for prekindergarten children (Gelman & Brenneman, 2004). In this program, instruction is organized around core concepts, such as *biological change*, that are central in children’s naive theories and also seem to hold the potential to serve as a firm foundation for acquiring important disciplinary understanding in science. The goal of instruction is the development of conceptual knowledge—not isolated definitions, but systems of concepts that are linked into the kind of rich, interconnected knowledge structures described in the research on core theories. The instruction also includes a focus on communication, including language and other forms of representation, such as writing, drawing, map-

ping, and charting. Students are encouraged to learn and use precise vocabulary, such as *observe*, *predict*, and *check*, that makes processes of their inquiry more visible to them and, hence, more open to inspection and self-evaluation.

Children’s science work in this program is designed to first capitalize on and then extend children’s initial theories about the world. One example described by Gelman and Brenneman (2004) involves a series of investigations about the distinction between what one knows and how one knows, a distinction that the “theory of mind” research identifies as difficult (and not only for young children). The teacher began with a discussion of the five senses, discussing what could be learned about an apple via each of the senses. Students were encouraged to record their observations and eventually to make predictions about things that could not be observed (such as the appearance of the inside of the apple, or the number of seeds). Children checked their predictions by opening the apple and making new observations. As a general principle, learning how to “talk science” (Lemke, 1990) and do science always occurs in the context of learning scientific concepts. Children develop their conceptual knowledge by doing science, and scientific processes and tools are regarded not as disembodied skills, but as a means to learn more about the domain at hand.

The emphasis throughout is on strengthening deep conceptual connections by revisiting the central concepts in a domain via a variety of activities and contexts. Because relevant prior knowledge enhances learning, the topics and concepts in the curriculum deliberately build on domains in which children already have relevant knowledge, such as the core theories about biology and physical properties of objects that have been identified by the theory theorists. Some of the concepts that teachers have developed from these starting points include change (biological, chemical, physical), insides and outsides of objects and organisms, relationships between form and function, and systems and interactions (Gelman & Brenneman, 2004), all topics in which children’s early intuitions provide potential starting points for instruction. In each case, the goal is to capitalize on a child’s-eye view of a topic, building on these early intuitions by providing additional illustrations, elaborations, and, in some instances, counterexamples that can challenge children’s initial mental schemas.

Strengths of this program include that the classroom work is innovative and well connected to a solid research

base. As in most of the educational interventions we have described to this point, an important principle is to build deep knowledge within a few content domains, rather than to sample broadly. Children's prior knowledge is to be identified and harnessed, not dismissed or overridden with correct conventional explanations. At the same time, capitalizing on children's intuitive ideas does not mean stopping there. In all cases, the point is to build on these ideas along what Gelman and Brenneman (2004) refer to as a "learning path." Particular emphasis is paid to explicitly marking for children the forms of thinking that are valued and helping underline distinctions between these and everyday kinds of thinking. Specialized vocabulary is cultivated to assist in achieving this goal.

In spite of the many strengths of this program, its long-term outcomes are as yet unknown. Perhaps because of the commitment to tying education tightly to existing research, the developmental trajectory of the program is somewhat restricted, in that it does not extend beyond first grade (although Gelman has been involved in science programs for high school students that share some similarities with this general approach; see, e.g., Gelman, Romo, & Francis, 2002). A critical next step is to first conceptualize and then test empirically the central thesis of the approach: how the extended elaboration of a few central ideas can pay off in the long term with a deeper understanding of scientific ideas that have traditionally been challenging for students to learn. In short, what does the learning pathway look like farther down the road? Conducting conceptual analyses of the links between early theories and later learning can provide first hints, but testing these ideas will require longitudinal study. At this point, little is known about how those relationships are ideally expected to develop or how consistently they can be supported across years of education. Understanding these important questions may require extending the learning research on this program into elementary school, possibly beyond.

Learning to Participate in Scientific Practice

As we mentioned earlier, all long-term investigations of development make commitments to initiating students in forms of practice. In this section, we review programs in which this orientation served as the overriding rationale, although each program clearly also draws from developmental studies conducted with images of theory

change or reasoning-skills/heuristics in mind. We contrast a founder program of work, *Fostering Communities of Learners* (Brown & Campione, 1994, 1996), which explicitly designed instruction to mimic the workings of a scientific community, with later programs that placed primary bets elsewhere, on supporting students' efforts to participate in practices of invention and revision of models of nature.

A Landmark in Developmental Science Education: Fostering Communities of Learners

One of the first attempts to implement and test a long-term developmental view of science education was the *Fostering Communities of Learners* (FCL) project, directed by Ann L. Brown and Joseph Campione over the course of a decade and a half in the 1980s and 1990s. This project was influential as an educational approach and as a way of conducting developmental research, although the influence on the field of development has been less pervasive than that on education. This work was pioneering in many ways, and all of the long-term projects described in this chapter have been influenced by it, in spite of some differences of opinion about goals and approaches.

In FCL, Brown and Campione (1994, 1996) sought to identify and test "developmental corridors," that is, pathways of the typical development of student knowledge from intuitive ideas to understanding of deep principles in the domains of investigation (like Gelman and Brenneman's, 2004, learning pathways). The shape and direction of these corridors was viewed as being determined by interactions among the capabilities and prior knowledge of students, the forms of teaching and support provided to learners, and the content and structure of the discipline being taught. These pathways were conceived both as conjectured trajectories for instruction (considered as continually revisable, based on emerging results) and as typical patterns of student change. The image of science was one of social community, where theories were developed and subjected to test according to criteria developed within that community. The vision of community was not insular: It included textual accounts and interactions with domain experts, including demonstration lessons. FCL was one of the first developmentally inspired projects in science learning that took seriously the importance of students' learning histories within the content domain of science.

Brown's earlier work in developmental psychology played an important role in the design of FCL. Indeed,

as early as 1978, Brown was foreshadowing a key assumption of FCL:

Our estimates of a child's competencies are sometimes dramatically changed if we consider them in naturally occurring situations. If, therefore, we are in the business of delineating the cognitive competencies of the 4-year-old, we will have a distorted picture if we see the 4-year-old only in a laboratory setting. (Brown & DeLoache, 1978, p. 27)

FCL was entirely consistent with Brown's early emphasis on studying cognitive functioning in the contexts where thinking is naturally put to work. Brown (1992) conceived of school as a place where learning and development could be studied in their interaction. As Vygotsky argued (see Brown & Reeves, 1987), development and learning are related in close and complex ways, a view that contrasts with the typical assumption that development precedes learning and acts as a constraint on it. Children are smarter in contexts where being smart has a function, is expected, and is supported; understanding development relies on opportunities to study it in contexts of that kind. These assumptions led Brown out of the psychological laboratory and into the business of engineering contexts that nurture development and, therefore, produce opportunities to observe and understand it. Although this was by no means the first design study, because of Brown's prominence in developmental psychology, it was the first to become widely known to scholars in that field.

Brown's investigations of memory development in the 1970s were also influential in the direction taken in FCL. Her specific interest in metacognition and self-regulation, a topic where her research was especially influential, foreshadowed the role of metacognition as a pervasive theme in FCL. In FCL classrooms, the overriding goal was to progressively turn over to students the responsibility for both the progress and the evaluation of their own learning and to help them construct the tools for managing this responsibility. This goal was pursued in a number of specific ways and was a prominent concern motivating everything from the activity structures in the classroom to the forms of discourse that were favored and supported. Much of the class's learning occurred in small research groups organized and directed by the students themselves. Students, rather than the teacher, were the ones to decide both who contributed to class discussions and the order of participation. Students learned to talk to, convince, and challenge each other rather than the teacher. The teacher, in turn, guided the

topic selection and student work in instructionally fruitful directions and worked to build a sense of accountability, both to one's fellow students and to other audiences of a variety of kinds (students were regularly responsible for making presentations, preparing teaching materials for younger children and reports directed to classmates, and communicating with scientists from outside the classroom). Standards for evaluation of classroom work were consensually developed, publicly shared, and, as far as possible, transparent.

A recurring activity structure in the FCL classrooms was reciprocal teaching, a reading comprehension program that Brown had developed in collaboration with Anne Marie Palincsar (Palincsar & Brown, 1984). Reciprocal teaching was another means of placing self-regulation front and center in students' learning, in this case, for understanding information presented in textual form. In reciprocal teaching, students acquired, practiced, and eventually mastered the kinds of comprehension strategies that more expert readers use spontaneously. Students first learned to imitate strategies modeled by the teacher and eventually, with assistance, began to take over key roles themselves. For example, readers might be asked to provide a summary, ask a clarifying question, or make an inference on the basis of the given information. As students became more expert, the teacher progressively ceded responsibility to student group leaders for these kinds of functions; eventually, students read together in small groups and group members negotiated meaning. The studies on reciprocal teaching documented impressive and lasting gains in the reading comprehension of even struggling readers.

FCL teachers relied heavily on reciprocal teaching to carry out the central activity in FCL classrooms, namely, the conduct and sharing of research in cycles that Brown and Campione (1996) referred to as "research-share-perform." The research conducted in these classrooms primarily involved reading, analyzing, and compiling texts of various kinds (written, electronic, or video). Products of the children's research were also typically in the form of text or talk; they might be posters, public presentations, written reports, or teaching materials intended for younger children. The heavy emphasis on reading, analyzing, integrating, and preparing written information was consistent with Brown's earlier work in reading comprehension with reciprocal teaching and also with the general emphasis on metacognition and self-regulation that permeated FCL.

Typically, a research cycle began with the teacher introducing an important disciplinary theme (e.g., biolog-

ical adaptation). These themes and topics were identified by the project team, which included domain experts, as being fruitful for supporting deep understanding of important disciplinary ideas and productive for focusing the research of student teams. Topics were introduced with an “initiating event,” such as a compelling story or a video, which provided a jumping-off point for students’ questions and interests. Students would next convene in a whole-class discussion to generate a list of questions that the story, video, or classroom visit raised for them. The teacher categorized and guided questioning with an eye to ensuring that the important themes identified by the project team were represented in the questions that were subsequently investigated. Small teams of students would adopt one of the questions to “research.” Commonly, an overarching theme like “food webs and chains” would be divided among the students, so that members of each research group became specialists in a single part of the problem. In the example explained in Brown and Campione (1996), the students studying food webs convened in specialty groups studying photosynthesis, energy exchange, competition, consumers, and decomposition. In another classroom, the same topic was subdivided in a different way, each group studying food webs in a different kind of ecosystem: the rain forest, grasslands, oceans, fresh water bodies, or deserts.

Over the course of these investigations, students were encouraged to develop expertise and knowledge in their own interest areas, to the point where some students became class experts whose knowledge exceeded that of most of the adults. For example, one student might become acknowledged for computer expertise, another for drawing and graphics, and a third for personal expertise in a related subject matter, for instance, a child who had sickle cell disease brought related personal biological knowledge to bear in the classroom investigations. This phenomenon, which Brown and Campione (1996) referred to as “majoring,” was explicitly encouraged. In contrast to typical classrooms, where the goal is for all students to know the same things at approximately the same time, teachers in FCL classrooms explicitly encouraged variability, both in what individual students knew and in the distribution of knowledge across groups.

For an extended period (typically weeks or even months), students worked in their research teams to identify and consult a variety of text and electronic resources to assist them in coming to an answer to their question. From time to time, the research teams would

form “jigsaw” groups composed of one “expert” from each of the subtopic specialty teams. Within the jigsaw groups, children taught each other about their own area of expertise and attempted to coordinate their disparate knowledge into a more integrated view of the problem. Often, a culminating “consequential event” (such as a performance, design task—e.g., “Design an animal of the future”—report, or parent visit) was planned to provide the motivation for this integrative work. Occasionally, outside experts (scientists, animal care professionals) would visit the classroom to conduct “benchmark lessons” in which they introduced new disciplinary concepts or modeled thinking from a disciplinary perspective. In “cross-talk” sessions, students convened in whole-class discussions to get preliminary feedback on their progress well before the consequential event, so that they might undertake corrective action or additional investigation, if it was considered warranted. In the class discussions, all assertions that students made were considered open to legitimate challenge from any group member. Students readily learned that they were expected to be able to produce evidence and refer to at least one identifiable source to back up a contested claim. Hence, the norms in the classroom included the idea that sources were to be recruited to support arguments whose purpose was to decide among alternative explanations.

For Brown and Campione (1996) and their colleagues, designing appropriate measures was a central challenge in conducting the research. Developmental researchers have considerable experience with interviews and pre- and posttests of conceptual knowledge, but these are not usually designed to track the development of deep forms of content knowledge that emerge over an extended period of time in ways that vary considerably from student to student. Moreover, in addition to the conceptual structures of science that were the targets of instruction, the FCL program had a broader set of learning goals. For example, researchers constructed ways to track changes in students’ ability to read, comprehend, and integrate textual information. They attempted to demonstrate increasing sophistication in classroom performances that are not typically assessed, such as children’s scientific reasoning in their groups and whole-class discussions. In this case, they classified the forms of classroom talk that students produced and sought to observe changes in frequency of use and levels of analogies, causal explanations, uses of evidence, argumentation, and predictions.

Beyond pioneering the FCL program and conducting research on students’ cognitive development, Brown and

Campione (1996) were also concerned with being able to capture the spirit of the program in a set of design principles that would serve to explain the mechanisms that sustained ongoing implementations and therefore to inform the spread of the program to new sites. This concern for principled explanation may partly have been motivated by Brown's experiences with reciprocal teaching. She noted that a weakness of reciprocal teaching and other strategy training programs is the danger that teachers and students may focus too literally on the processes of learning to the neglect of the underlying goal that motivated them. As Brown and Campione put it, "Without adherence to first principles, surface procedures tend to be adopted, adapted, and ritualized in such a way that they cease to serve the 'thinking' function they were originally designed to foster" (p. 291). In the case of reciprocal teaching, Brown and Campione observed that in its widespread dissemination, teachers sometimes focused too much on surface procedures, such as summarizing or questioning, that were not deployed for the original purpose of helping students learn to read for understanding. Sometimes these strategies were even practiced outside of the context of reading actual texts and were introduced as rituals rather than reflective strategies. It is as if the husk of the intervention had been communicated, but the germ had been left out.

Perhaps as a result of these earlier experiences, Brown and Campione struggled repeatedly through the 1990s to encapsulate and refine the design principles that motivated the FCL intervention in a way that would help the field understand both what FCL actually looked like in practice and how those systems of activity followed from their particular commitments to learning theory. For example, their 1996 chapter delineates 37 principles under six major headings: systems and cycles (a description of the recurrent activity structures utilized in FCL), metacognitive environment, discourse, deep content knowledge, distributed expertise, instruction and assessment, and community features. With some variation and adaptation, many of these features have been preserved in educational interventions that followed FCL.

With respect to science learning specifically, FCL was a sustained classroom project that attempted to identify "big ideas" in science that children might learn cumulatively, and to try to understand how those ideas might be developmentally constructed, given appropriate forms of instructional assistance. In spite of its stature and influence, two questions about FCL remain

open. The first concerns the utility of principles as a way to both describe and spread new educational programs. We do not doubt that principles may help readers understand the basis for the particulars of the intervention, but we do question their sufficiency for supporting the replication and adaptation of an intervention in a new site. As yet, little is known about the content and form of knowledge that are necessary and sufficient for catalyzing and sustaining changes in teaching practices. The Schools for Thought experiment, which attempted to capitalize on what was learned through FCL and two other successful classroom-based research projects, did not generate the results and sustainability that participants had hoped (Lamon et al., 1996). Participants in this work, including Brown and Campione, found that their principles were highly meaningful to those who had generated them, but were apparently open to all kinds of interpretations to outsiders who had not shared in the background experiences that motivated the principles in the first place. Principles seemed common sense after the fact, but as a means for prescribing what to do, they did not sufficiently constrain a designer's choices. For example, although one might agree in practice that it is a good idea to encourage shared discourse and common knowledge among students (one of the FCL principles), accepting the principle unfortunately provides no guidance about how to follow it or how one could know if the goal had been satisfactorily achieved.

A second major question about FCL is whether it is a good idea for school science to be so exclusively focused on the reading and integration of textual information. Certainly reading is an important way to build knowledge in science, but arguably, students should also experience direct forms of inquiry with the natural world. Ironically, the domain-general nature of FCL activity structures and goals—something that Brown and Campione probably considered a strength—may also entail a weakness from the perspective of a particular discipline. The activities and goals in the FCL classrooms would probably apply equally well to the learning of history or literature. However, one might legitimately wonder whether learning *about* science is sufficient for coming to appreciate its epistemology. One might legitimately take the position that students should also get some experience *doing* science. Indeed, Palincsar and Magnussun (2001) have subsequently developed an approach that blends textual instruction, which they call "secondhand investigations," with direct or firsthand investigations. In their educational approach, young stu-

dents read from carefully fabricated journals that explicitly display the thinking of a scientist, who explains in the text how she conceptualized a scientific problem, used graphs and other representational devices to interpret data, or otherwise made her thinking visible so that young children could model it in their own parallel investigations with physical materials.

The Development of Model-Based Reasoning

Philosophers of science have pointed out that the central activity of science is the generation and test of models (Giere, 1988; Hesse, 1974). In fact, Giere argues that all that distinguishes scientific explanation from everyday explanation is that the former is constructed with models that have been developed in the sciences: “Little can be learned . . . about science that could not be learned more directly by examining the nature of scientific models and how they are developed” (p. 105).

Until recently, modeling practices have taken a peripheral place, at best, in school science. Even in model-populated disciplines such as physics, students’ modeling activity is typically restricted to applying models developed previously by scientists, perhaps to solve textbook problems or to analyze a situation presented in a laboratory. In school, the word “model” usually denotes a noun, the product of the modeling enterprise, rather than a verb describing the practice of science. Students tend to be interpreters and users of models, but they do not generate and test them. Recently, however, scientists, mathematicians, and educators have been impressed with the potential of new computer tools to put modeling within the reach of school students. Although many investigations of modeling in mathematics and science education are focused relatively tightly on the acquisition of a specific body of disciplinary knowledge, they have also led to a more general interest in the early origins and subsequent development of model-based reasoning—a more general capability and propensity to play what Hestenes (1992) referred to as “the modeling game.” In the following section, we describe two classroom-based programs that seek to foster students’ capabilities to generate and test models of scientific phenomena, one at the middle school level and the second in elementary grades. The intent of these programs is to help students develop along two tracks simultaneously. First, students develop conceptual understanding of the specific scientific ideas in the domain of study. That is, students come to understand particular models and eventually to acquire a repertoire of models

usable across a variety of situations. Over a longer time span, the focus is on their understanding of modeling as a key epistemology of science.

Briefly, by modeling, we refer to the construction and test of representations that serve as analogues to systems in the real world. These representations can be of many forms, including physical models, computer programs, mathematical equations, or propositions. Objects and relations in the model are interpreted as representing theoretically important objects and relations in the represented world. A key hurdle for students is to understand that models are not copies; they are deliberate simplifications. Error is a component of all models, and the precision required of a model depends on the purpose for its current use. The two instructional programs that we describe take different approaches to the forms of models that they regard as central, so we will defer further discussion about the nature of models until the examples are introduced.

Causal Models: Understandings of Consequence.

Perhaps the most ubiquitous and general kind of structural relationship that can be captured in a model is the relationship of cause and effect. Causal models are ubiquitous in science, so the value of understanding the kinds of causal models that people can learn and the sources of learning difficulty seems straightforward (White, 1993). An extensive literature on the development of causal reasoning, conducted during the 1980s, suggests that even preschool children are adept at using a variety of cues from the environment to identify the cause of an event from a set of potential candidates. Among these cues are temporal contiguity, spatial contiguity, consistent covariation between the candidate cause and the effect, and mechanism, that is, whether there is a plausible mechanism that would account for A causing B (Leslie, 1984; Shultz, 1982).

Recently, Gopnik and her colleagues (Gopnik & Sobel, 2000; Gopnik, Sobel, Schulz, & Glymour, 2001) conducted a series of investigations with children as young as 2 years in an attempt to identify both *how* young children learn about new causal relations and whether these learning systems are domain specific or applied across different domains of knowledge, such as biological or physical systems. The strategy was to observe online as children went about learning a causal relation that they had not previously encountered or been taught. In one series of studies, children were introduced to the “blicket detector,” a machine that lights up

and plays music when (and only when) “blickets” are placed on it. Participants were shown several small blocks and told that one or more of them were blickets. Children were asked to identify which of the blocks were the blickets, either by observing patterns of placement and the resulting outcomes and then drawing a conclusion based on those observations or, in some studies, by taking direct action themselves to place blocks on the blicket detector. Across trials within a study and across studies, the patterns of evidence that children observed became increasingly complex, ultimately including multiple causes and probabilistic relationships. In most cases, even the 2-year-olds made correct conclusions about causality by observing patterns of contingency, although these young children did not perform as well as older preschoolers on tasks in which two additive causes were required to set off the blicket detector. Children demonstrated their reasoning in multiple forms, suggesting that they genuinely were reasoning about causes, not simply making judgments of association. These forms included causal conclusions and justifications made on the basis of observation, predictions about novel events on the basis of earlier learning, and direct production of requested outcomes. Moreover, children seemed to use similar kinds of causal learning principles across different content domains of knowledge.

Gopnik and her colleagues (2001) conjectured that data-driven formal learning procedures like these might be used in conjunction with innate, domain-specific causal schemas like those described in the prior section on the “theory theory.” She proposed that both kinds of causal reasoning are important and serve complementary and useful roles in children’s developing knowledge. The innate theories determine what features the child is likely to attend to and, therefore, what the data-driven procedures will operate on. In turn, the formal causal learning mechanisms provide a means by which initial theories can be modified or extended, as well as a way to learn new information not implicated in a core theory (Gopnik et al., 2001). Both kinds of knowledge are fundamentally important in determining the course of learning.

Research with young children (Bullock, Gelman, & Baillargeon, 1982; Gopnik et al., 2001; Shultz, 1982) emphasizes their competence at reasoning about causally complex situations. However, the developmental literature also tells another story that seems difficult to reconcile with these findings. As often occurs in

developmental psychology, findings of early competence stand side by side with studies that emphasize the reasoning flaws and biases shown by adults in situations that are described in similar ways. In this case, the developmental literature seems to conclude that very young children understand causality, whereas adults do not. For example, research conducted by D. Kuhn and her associates (D. Kuhn, 1989; Kuhn et al., 1988, 1992, 1995) demonstrates that adults frequently show characteristic flaws in reasoning about multivariable causal situations. Indeed, they make many of the same errors that children do: generating experiments that are not valid tests, interpreting evidence that is flawed or insufficient, avoiding evidence that challenges their prior theories, and failing to systematically search the space of possibilities, entertain alternative interpretations of data, or rely on evidence rather than mere examples.

Perkins and Grotzer (2000), who direct the Understandings of Consequence project, suggested that the difficulties many students have in learning science concepts stem from differences in the ways that students and scientists think about cause and effect. Nonscientists, they argue, hold a few simplistic causal structures into which all new information gets assimilated. (Similar arguments have been made by Chi, 1992.) Most of the time, these simple causal structures do a perfectly adequate job of supporting our actions and interpretations in the world, and these are the relationships that young children appear to master easily. However, when less familiar forms of cause are involved, as is often the case in science, these structures can be misleading. In contrast to novices, scientists entertain a wide array of causal structures, which vary in complexity. Perkins and Grotzer attempted to identify the features that account for this complexity and to summarize them in a taxonomy that permits estimating the difficulty of any particular causal model with respect to these features.

The taxonomy describes four aspects of causal structures: mechanism, interaction pattern, probability, and agency. Each of these varies across several levels of complexity (and, by implication, difficulty of learning). Perkins and Grotzer (2000) propose that any model or explanation can be identified on the taxonomy with respect to its hypothetical difficulty level by locating it within these four dimensions. For example, a model may vary with respect to sophistication in the level of *mechanism* that it ascribes to the phenomenon being modeled. Very simple models rely on surface generalizations or explanations at the same level of description as the

events being explained. At the more sophisticated end of the spectrum, a model may appeal to analogical mapping or underlying mechanisms, including properties, entities, and rules that account for the situation at an underlying level of description. Similarly, simple *interaction patterns* include those that appeal in a straightforward way to one thing acting on another, via pushes, pulls, supports, resistances, and so on. The entities on this level seem similar to the simple schemas that diSessa (1993) referred to as phenomenological primitives, that is, schemas at a midlevel of abstraction that are automatically activated to support interpretations of physical events. According to diSessa, these interpretations seem self-evident and do not require justification; instead, people simply “recognize” an event as belonging to one class or another. At more complex levels, students may entertain mediating causes, interactive causality, feedback loops, or constraint-based systems. The dimension of *probability* specifies whether a particular explanation is deterministic or appeals to chance, chaotic systems, or fundamental uncertainty. The final dimension concerns the perspective taken on *agency*: Does the model assume that a central agent is the causal actor, or are other, more complex possibilities considered, such as additive causes, long causal chains, self-organizing systems, or emergent properties? At this point in the research, the taxonomy should probably be considered hypothetical; the dimensions of complexity were derived via rational analysis rather than empirical test. Moreover, the taxonomy appears to capture only *order* of complexity, not *degree*; there is no claim that difficulty level increases in measurable quantitative steps from the least to the most complex level of each dimension. Also, it is not clear how to cumulate these dimensions to make a judgment about the overall complexity of a model. The best use of the taxonomy at this time seems to be heuristic, and the authors do not comment on whether they consider it to have scale properties.

Along with their analysis of models and model explanations, Perkins and Grotzer (2000) have also developed an analysis of what they call *epistemological moves* toward better models. These are the cognitive behaviors with respect to modeling that they find worthy of encouraging in students. They include seeking a model with no gaps or missing parts, putting the model at risk by actively seeking counterevidence or contrasting cases, detecting flawed evidence, and entertaining reasonable criteria for revising or replacing the model in the face of different forms of counterevidence. These

epistemological moves are similar to the criteria for changing theories that were delineated in the Conceptual Change model, described earlier. Presumably, acquiring and using these epistemological moves increases the likelihood that students will come to understand and, when appropriate, apply the most appropriate causal schema from their repertoire.

Initial research findings suggest that students who participated in activities that emphasized the underlying causal structure of a scientific topic and participated in direct discussions of these causal relationships performed better on measures of conceptual understanding of that topic than did students who worked on similar units that did not directly emphasize causal relationships (Grotzer, 2000; Perkins & Grotzer, 2000). However, the project had ambitions beyond simply boosting conceptual understanding domain by domain. In particular, the goal was that students who learned about causal structures in one topic (e.g., density) would transfer those structures to other topics (e.g., pressure) when it was appropriate to do so, and that importing the new causal structures would provide a firmer base for understanding the new material. Research to this point (Grotzer, 2003) suggests that there is some limited transfer of this kind from one topic to another when the causal structure in both tasks is isomorphic. However, the researchers found no evidence of spontaneous transfer when the causal structures between the two topics were not isomorphic. In other words, so far there is no evidence that students have acquired a general propensity to search among candidates for an appropriate causal model and then try to use it to understand novel cases. Grotzer (2003) observed that situation-specific default concepts like diSessa’s (1993) phenomenological primitives seemed to interfere with transfer of the appropriate causal relationships. The investigators are now seeking to enhance the metacognitive aspects of the instruction in an effort to learn whether more explicit reflection on the nature and uses of causal models might help improve the transfer of causal structures between science contexts.

An attractive feature of causal models is that they have both a domain-general aspect, derived from the general structure of the causal relationship that is expressed, and a domain-specific aspect, in that the relationship represents structure in a particular domain or situation (Gopnik et al., 2001). Because of this integrative quality, modeling approaches at least hold the potential of avoiding the process/content or syntax/

substance dichotomies that sometimes plague science education (and psychological accounts of scientific reasoning). The causal modeling approach being developed by Perkins and Grotzer (2000) may be described as a top-down modeling approach. Through rational analysis, the investigators first attempted to exhaustively describe the landscape of kinds of causal models, and content domains for study were apparently selected because they exemplified one or more of these target forms of causal reasoning. It is not clear whether considerations of conceptual development guided the selection of domain topics beyond a commitment to generating opportunities for the acquisition, transfer, or comparison of causal models. Therefore, in this program, development of scientific conceptual knowledge is probably a more important focus within units rather than across domains. Over years of a student's education, the acquisition of a repertoire of causal schemas takes priority as an educational objective over the development of any particular conceptual knowledge base.

Of course, when scientists construct, test, and revise models, they do so in the service of contributing to a base of knowledge within a coherent content domain. The final classroom research program we describe, our own, aims to open the activity of modeling to school students. It integrates Perkins and Grotzer's (2000) emphasis on refining a repertoire of structural analytical tools with the focus on conceptual development within a coherent domain that is favored by investigators like Gelman and Brenneman (2004) and Metz (2004).

Modeling Nature. The kinds of models that scientists construct vary widely, both within and across disciplines. Nevertheless, the rhetoric and practice of science are governed by efforts to invent, revise, and contest models. We (Lehrer & Schauble, 2005) have been investigating the implications of this view of science for the education of students in elementary and middle school grades. Our primary interest was not just on students' understanding of models per se, but, more specifically, on their understanding of modeling. To provide a context where the development of model-based reasoning could be studied, participating teachers worked collaboratively and systematically to build on young children's interests and abilities in representing aspects of the world in all kinds of ways—via language, drawings, physical models, maps and globes, rules that capture regularities and patterns—and to provide effective forms of instructional support, building on chil-

dren's initial modeling attempts to help them achieve a progressively more sophisticated grasp of science. Early emphasis on representational form, especially on purposes and uses, was derived from developmental studies that suggested a rich repertoire of such resources (e.g., Karmiloff-Smith, 1992) and from social studies of science, which indicated their critical role in model building (e.g., Latour, 1999). We were especially interested in those forms of representation that would help children "mathematize" (Kline, 1980) natural phenomena, such as growth or relations between structure and function. By mathematizing, we mean the common scientific practice of quantifying or visualizing phenomena geometrically (or both). Privileging mathematics meant introducing mathematics to elementary children that went beyond arithmetic to include space and geometry, measurement, and data/uncertainty (e.g., Lehrer & Chazan, 1998; Lehrer & Schauble, 2002). The focus of the research that was coordinated with this instructional agenda was on the early emergence and subsequent development of model-based reasoning. A secondary agenda concerned students' conceptual development in target forms of mathematics and science.

The developmental literature illustrates that there are myriad ways in which even preschool children come to regard one thing as representing another. This representational capacity provides roots for the development of a modeling epistemology. For example, long before they arrive at school, children have some appreciation of the representational qualities of pictures, scale models, and video representations (DeLoache, 2004; DeLoache, Pierroutsakos, & Uttal, 2003; Troseth, 2003; Troseth & DeLoache, 1998; Troseth, Pierroutsakos, & DeLoache, 2004). In pretend play, children treat objects as stand-ins for others (a block stands in for a teacup, a banana for a telephone), yet they still understand that the object has not really changed its original identity, character, or function (Leslie, 1987). Later in school, they will capitalize on very similar understandings to use counters for "direct modeling" to solve simple early arithmetic problems that involve grouping and separating.

However important, these early symbolic capacities do not yet capture all the key aspects of a scientific modeling epistemology. Although they certainly know the difference between a model and its referent, children do not usually self-consciously think about the separation of the model and the modeled world. Consequently, they often show a preference for copies over true models, because they tend to resist symbolic depic-

tions that leave out information, even if the information is not important to the current theoretical purposes (Grosslight, Unger, Jay, & Smith, 1991; Lehrer & Schauble, 2000b). For example, children using paper strips to represent the height of plants may insist on the strips being colored green (like the plant stems) and demand that each strip be adorned with a flower (Lehrer & Schauble, 2002). Students are unlikely to spontaneously consider issues of precision and error of a representation or the implications of deviations between the model and the modeled world in light of current goals (although they certainly have intuitions that are helpful as starting points; see Masnick & Klahr, 2003; Petrosino, Lehrer, & Schauble, 2003). Having identified a way to represent one or more aspects of the world, they may be unable to entertain the possibility of alternatives. Indeed, the search for and evaluation of rival models in evaluating alternative hypotheses is a form of argument that does not typically emerge spontaneously (Driver, Leach, Millar, & Scott, 1996; Grosslight et al., 1991).

In addition to these general symbolic capacities, the development of specific representational forms and notations is also a critical part of being able to enter what Hestenes (1992) referred to as the “modeling game.” Representational tools such as graphs, tables, computer programs, and mathematical expressions do not simply communicate thought; they also shape it (Olson, 1994), so acquiring a vocabulary of inscriptions and notations and a critical understanding of their design qualities was considered essential. Accordingly, helping students develop their metarepresentational competence (diSessa, Hammer, Sherin, & Kolpakowski, 1991) was a central target of both instruction and the related research.

Particular emphasis was placed on mathematics as a tool that both describes the world and serves as a resource for meaning making (Lehrer, Schauble, Strom, & Pligge, 2001; E. Penner & Lehrer, 2000). Often, science educators delay the mathematization of scientific ideas, believing that students should first develop a qualitative analysis of the science underlying the phenomenon, and that too early attention to mathematical description may encourage an emphasis on computation rather than understanding. This assumes, however, that students have no history of learning mathematics as a sense-making enterprise. Experience and research suggest that this need not be the case. With good instruction even young students can meaningfully consider the epistemic grounds of generalization and even proof (Lampert, 2001; Lehrer et al., 1998; Lehrer & Lesh, 2003).

These epistemic considerations often arise when children investigate the mathematics of shape and form, measurement, and data. Therefore, developing and testing appropriate inroads to these new mathematical ideas was an important part of the program (e.g., Lehrer & Chazan, 1998; Lehrer, Jacobson, Kemeny, & Strom, 1999; Lehrer & Romberg, 1996; Lehrer & Schauble, 2000c, 2005). If they are lacking these mathematical resources, it is unlikely that students’ conjectures can be held accountable in any meaningful way to data, which has mathematical qualities that need to be appreciated if their interpretations are to be disciplined. The aim was to develop students’ mathematical understanding to the point where it would be sufficient to support description and systematization of the natural world—the heart of modeling.

In the science class, we attempted to orient instruction around a cumulative focus on important core themes, such as growth and diversity, behavior, and structure and function, as described in national science standards (National Research Council, 1996). Themes were selected in part for their centrality to science disciplines, but also for their potential for engaging students in the progressive mathematization of nature (e.g., Kline, 1980). Central concepts such as diversity and structure derive their power from the models that instantiate them, so to fulfill the promise of the “big ideas” outlined in national standards, students must realize these ideals as models. Moreover, models are not simply constructed; equally important, they must be mobilized—that is, put to work—to support socially grounded arguments about the nature of physical reality (Bazerman, 1988; Latour & Woolgar, 1979; Pickering, 1995). Achieving these goals with school students meant identifying forms of modeling that are well aligned with children’s development.

We concluded that in children’s instruction, it is advisable to begin with models that resemble their target systems (i.e., the phenomena being described or explained) in ways that can be easily detected, because resemblance helps children make and preserve the mappings between models and their referents (Brown, 1990; Lehrer & Schauble, 2000c). For example, when first graders were given a variety of materials from a hardware store and asked to construct a device that “works like your elbow,” initial models were guided by a concern for copying perceptually salient features (Grosslight et al., 1991). Most of the children insisted on using round foam balls to simulate the “bumps” in their

elbow joints and Popsicle sticks to simulate fingers (D. E. Penner, Giles, Lehrer, & Schauble, 1997). However, this beginning concern with “looks like” lost importance over multiple revisions of the models, which eventually began to focus on “works like”: relations among and functions of components in the target system, in this case, ways of constraining the motion of the elbow. Consistent with the emphasis on mathematics in children’s modeling activity, third graders went on to mathematically explore relationships between the position of a load and the point of attachment of the tendon in a more complex elbow model (D. E. Penner, Lehrer, & Schauble, 1998).

Modeling is a form of disciplinary argument, one that students learn to participate in over a long and extended period of practice and only with good teaching assistance. Lehrer and Schauble (2005) argued that acquiring disciplinary forms of argument requires emphasizing students’ long-term development of central conceptual and epistemic structures, not the acquisition of nuggets of instruction that are delivered within brief periods. Decisions about what is taught should be informed by a long-term view, one that regards learning as a historical activity in which current learning builds from and on learning achieved in earlier weeks, months, and years. Therefore, the research focused on identifying and empirically testing science themes that provide easy entry for young children, while supporting plenty of conceptual challenge for students in the upper grades. Identifying mathematical and scientific models and concepts that could potentially serve as a core and then working with teachers to investigate the potential of these ideas across grades of schooling constituted an important part of the design research agenda.

An example is the theme of growth and change. Students in primary grades represented the growth of flowering bulbs planted under different conditions (in soil or water), using paper strips to depict the heights of plant stems at different points in the growth cycle (Lehrer, Carpenter, et al., 2000). Depiction of height required a transformation in children’s thinking from considering the plant as an intact whole to thinking of it as a set of attributes, height being the most salient. Representing and comparing heights required working out standard ways of measuring and a firm understanding of the mathematics of measure, which was developed systematically during this investigation. Indeed, it is worth noting that understanding an attribute and understanding how to measure it are related ideas, regardless of the grade of the “scientist.” When children raised the ques-

tion *how much faster* one plant grew than another, their attention turned from comparing final heights to noting successive differences in the lengths of the strips from day to day. These questions relied on the arithmetic of comparative difference, a form of mathematics within their grasp. They noted that the amaryllis grew faster at the beginning of the life cycle and then slowed, whereas the paperwhite narcissus grew very slowly at the beginning and then “caught up.”

In the third grade, students investigated change of Wisconsin Fast Plants™ in a variety of ways (Lehrer, Schauble, Carpenter, & Penner, 2000). (Wisconsin Fast Plants, or *brassica rapta*, complete an entire life cycle in about 40 days, making it feasible to use them in population studies or other classroom investigations that require comparisons of groups of plants that can be readily grown within one school semester.) They developed pressed plant silhouette graphs that recorded changes in the plants over time, coordinate graphs that showed relations between plant height and time, rectangles that represented relationships between plant height and canopy “width,” and three-dimensional prisms and cylinders to capture changes in plant volume. These diverse representations raised new questions about the plants. Students wondered whether the growth of roots and shoots were the “same” or “different.” They concluded that the rates of growth were different at similar points in the life cycle, but that the general shape of growth (S-shaped logistic curves) was similar. Why, students wondered, might the growth of different plant parts have the same form? When was growth the fastest, and when the slowest, and what features in the plants were changing in ways that might account for this? Teachers played a central role in helping students compare and evaluate their questions, produce and contrast different kinds of representational displays, and generate evidence-based claims. Although it is not possible to include detailed information here about the data on teachers’ professional development and changing teaching practices, these were necessary conditions for the student learning that was observed (more information on this aspect of the program is provided in Lehrer & Schauble, 2000c, 2005).

In the fifth grade, students compared populations of plants and reasoned about features of distributions of the plant measurements to decide whether growth factors such as fertilizer and amount of light were affecting variables such as height and reproductive capacity (i.e., number of seeds and seed pods) of the plants (Lehrer & Schauble, 2004). Features of distributions such as typicality and spread were investigated thoroughly, and dif-

ferent representations of these statistics were invented and explored. Sampling experiments based on the students' measurements of plant height at a particular day of growth supported discussions about typical plant height and its variability under different numbers of samples and samples of different sizes. Children learned to read the shape of different distributions as signatures of growth processes. For example, a distribution with a left wall was interpreted as representing the plants early in their life cycle because, as one child explained, "You can't get any shorter than zero mm."

As these examples illustrate, at each grade children's representational repertoires were systematically stretched, making it possible to expand their knowledge about growth and change in new ways. In turn, as their knowledge grew, there was change in children's considerations about what might next be worthy of investigation.

Lehrer and Schauble (2000c, 2003, 2005) reported observing characteristic shifts in understanding of modeling over the span of the elementary school grades, from an early emphasis on literal depictional forms to representations that were progressively more symbolic and mathematically powerful. Diversity in representational and mathematical resources both accompanied and produced conceptual change. As children developed and used new mathematical means for characterizing growth, they understood biological change in increasingly dynamic ways. For example, once students understood the mathematics of ratio and changing ratios, they began to conceive of growth not as simple linear increase, but as a patterned rate of change. These transitions in conception and inscription appeared to support each other, and they opened up new lines of inquiry. Children wondered whether plant growth was like animal growth, and whether the growth of yeast and bacteria on a petri dish would show a pattern like the growth of a single plant. These forms of conceptual development required a context in which teachers systematically supported a restricted set of central ideas, building successively on earlier concepts over grades of schooling.

Learning research was conducted to investigate the development and use of a variety of mathematical and scientific models. One strategy was to conduct detailed studies of student thinking in the context of, or immediately following, particular units of study. The purpose of these investigations was to learn whether and how students developed new models, to identify the variability in student understanding of the mathematical and scientific concepts at hand, and to document how students appropriately applied mathematical concepts learned in

one context to novel situations. For example, in one study, students explored the mathematics of ratio via geometry by investigating the properties of families of similar rectangles (Lehrer & Schauble, 2001). Subsequently, while investigating properties of materials, they spontaneously wondered whether materials might also come in families, a reference to whether there might be constant ratios between volume and weight for objects made of Styrofoam, wood, Teflon, and brass. Pursuing this question led to an extended investigation of the properties of coordinate graphs and linear relationships as models (the plots of weight by volume seemed nearly linear, but many of the points did not lie directly on the line). Lehrer and Schauble conducted numerous classroom investigations of student model-based reasoning in the context of instruction in mathematics (e.g., data modeling, classification, distribution, similarity) and science (e.g., growth, diversity, motion, density). Details of this work are reported in a variety of publications (Horvath & Lehrer, 1998; Lehrer, Carpenter, et al., 2000; Lehrer & Schauble, 2005; Lehrer, Schauble, & Petrosino, 2001; Lehrer, Schauble, Strom, et al., 2001; D. E. Penner et al., 1997, 1998). Most of these investigations were cross-sectional; they either focused on students within a classroom or classrooms at the same grade or drew comparisons of the performance of students in different grades at the same time point.

In addition to these within-grades and between-grades studies, longitudinal investigations were conducted to confirm whether and, if so, how students' understanding of mathematics was growing systematically over years of instruction, because mathematics was the primary tool employed for modeling. Because students were learning forms of mathematics that are not typically taught in elementary grades or measured by current standardized assessments, the project team created a series of standardized measures to assess student achievement, organized into a 3-hour test that could be administered to groups of students. There were two forms for this instrument, one for the primary grades and the other for upper elementary grades. Each form was revised every year, although a core pool of items was administered each year to all students. Several released items from the National Assessment of Educational Progress were included to benchmark student achievement to national performance. The results, reported in detail in Lehrer and Schauble (2005), found gains in student learning that were reliable at each grade from grades 1 through 5 (effect sizes ranged from 0.43 to 0.72). The average gain scores indicated substantial

growth in student understanding, and the gains were widespread (i.e., not confined to selected strata of students). Moreover, on the nationally benchmarked items, students in the early grades outperformed those from much higher grades in the national sample.

Of course, there is much yet to be learned. One issue is the relationship between mathematics and science. We generally first introduce students to mathematics, so that they have opportunities to explore and understand mathematical structure before these structures are employed to model nature. We are concerned that if we introduce only the mathematics that students need to model a particular system, then much else about the mathematics will be lost (e.g., its more general, systematic quality). However, this approach clearly contrasts with curricular approaches that emphasize integrating mathematics and science. A related issue is how students view epistemologies within each discipline. For example, in some of our classroom studies, we have noted children drawing clear distinctions between mathematical (e.g., general by definition) and scientific (e.g., general by model) senses of generalization (Lehrer & Schauble, 2000a). How these epistemologies unfold over time is not yet understood.

Summary: Classroom Design Studies

In this section, we reviewed seven extended programs of classroom research in which researchers studied the development of student thinking in contexts that were engineered to support it. Although these are by no means the only developmentally informed investigations of scientific thinking in classrooms, they do represent a range of visions about what scientific literacy should entail. Each vision was either consistent with or directly informed by related research in cognitive development. Many, although not all, of the scholars who conducted this work also articulated an explicit perspective on the relationship between learning and development.

In the chapter's introduction, we claimed that new answers to the questions "What develops?" and "What is development?" were being raised within this niche of classroom-based developmental research. We next briefly summarize what these investigations, taken as a group, suggest about potential answers to these two questions.

With respect to their views of science and science literacy, all of the investigators reviewed in this section acknowledge the complexity and variability of science. The focus on what develops is necessarily much broader

than in typical studies of learning and thinking, which appropriately tend instead to focus tightly on particular skills or concepts. This broader focus is necessary, of course, for seeking to characterize and understand development that occurs only over years of education. The wider perspectives taken here may also be useful for considering the implications of more traditional research on scientific thinking with respect to the goals of education. For example, consider Chen and Klahr's (1999) research on the control of variables strategy in juxtaposition to Metz's (2004) broader agenda of helping students conduct self-initiated and self-regulated inquiry. Both studies share a focus on helping children understand the logic and methods of research, yet they do not come to the same conclusion about what should happen in classrooms. Indeed, one of the unresolved issues in science education is this disagreement about whether children should first explicitly be taught strategies and procedures for conducting inquiry and then later learn to apply them, or whether they should learn these strategies and methods in contexts of their use, so that they are situated within a larger, coherent process of inquiry. This question takes on special poignancy when the children are struggling students or come from cultures where they have had less exposure to forms of thinking valued in school. Lee and Fradd (1996) have argued that in these situations, it is important to directly instruct children first on processes and strategies of inquiry, so that they do not come to science instruction with a disadvantage. In contrast, Warren and Rosebery (1996) have emphasized the many points of contact between everyday thinking and scientific thinking, which seem to hold for all children, even those whose first language may not be English and whose first culture may not be Anglo-European. In their view, with sensitive instruction children are quite capable of sophisticated forms of inquiry, and the evidence seems to bear out these claims. It may be, however, that the dispute is more apparent than real. The need to be explicit and clear about the forms of argument and evidence valued in science is widely accepted, and there is plenty of evidence that this need is not restricted to students who are struggling. The reason for contrasting Chen and Klahr's position with Metz's is not to suggest that one conclusion necessarily is associated with psychological research and the other with classroom research. It is to make the more general point that in many cases, taking the wider view that an educational perspective demands, leads to a realignment of what is valued, so that design researchers are not simply involved in bringing together

in one site interventions that have individually been more thoroughly studied in psychology laboratories.

Whether one thinks it is more useful for purposes of instruction to highlight science as building knowledge or theories, conducting investigations, or generating and testing models, these are probably best regarded as partially overlapping rather than mutually exclusive views of science and science literacy. They may lead to somewhat different commitments with respect to choices of topics of study or classroom activities. Regardless, theory change, inquiry, and modeling are mutually reinforcing. Therefore, any well-formulated program may focus on all of these goals, even though the relative emphasis or proportions of time spent on each may differ. Similarly, there may be differences in what teachers are oriented toward in professional development, perhaps leading to discernibly different results in teachers' practices and student learning. At this point, we do not know.

There is both a normative (What *should* students be learning?) and empirical (How *does* development typically unfold?) aspect to these guiding perspectives. Taking a longer-term developmental view raises questions about what educators should be trying to achieve in the long term and also about the instructional pathways that can best lead students toward these goals from their current conceptual resources. Ideas about instructional pathways should be conceived as rational analyses that require empirical testing. It is impossible to know in advance how students' cognition is likely to develop given the right kinds of instructional support, partly because we cannot know in advance which kinds of instruction are optimal and partly because our initial views of students' capabilities almost always are distorted by knowing the way they usually perform under typical (or lacking) instructional conditions (Brown & Campione, 1996).

For the most part, the research reviewed in this chapter reflects a preference for students doing science over simply learning final-form science concepts. This preference is due not to a naive belief that knowledge is somehow better if it is reinvented by students, but to a commitment to providing opportunities for students to experience one of civilization's most powerful forms of epistemology. We would probably agree that all students should learn to write to some level of fluency, even though few will eventually become employed as professional authors. Similarly, all students should get a taste of doing science, and those opportunities should not be restricted to those bound for careers in science or technology.

The emphasis on doing science, however, does not imply that nobody cares if students learn any scientific knowledge. Without exception, the emphasis in the programs we have reviewed is on doing science for the purpose of building rich, elaborated bases of knowledge. That is why the programs reviewed in this section value extended study within a bounded content domain over broad sampling of science topics. Focusing deeply in a domain provides a base from which students can develop criteria for evaluating their changing theories about the domain and also provides the foundation of knowledge necessary for inquiry to be both fruitful and meaningful. Not all of these researchers, however, have a clear vision of how science content knowledge is expected to cumulate over a student's education, or even whether having such a vision is considered important. Some investigators (e.g., Metz and Gelman) expect that students will sequentially investigate domains of study in depth, one at a time, but they do not say much about what space of domains needs to be visited by the time a student leaves elementary education. Lehrer and Schauble seek scientific and mathematical themes, such as growth, structure and function, and behavior that can connect inquiry across years of schooling. These themes serve as the criteria for selecting specific topics of study. However, Lehrer and Schauble (2005) argue that it is necessary to empirically test conjectures about the themes that best permit easy entry to younger or less sophisticated students and, at the same time, provide abundant curricular challenge for those who are more knowledgeable. Hennessey and Grotzer and Perkins appear to be focused primarily at a more domain-general level on causal schemas and criteria for conceptual change. Presumably, domain knowledge is selected for its exemplification of the variety of causal schemas that students need to learn about or its potential to highlight criteria for theory change.

To varying degrees, all of these investigators place instructional emphasis on one or another form of metacognition. That said, what is meant by metacognition varies somewhat from program to program, and the actual cognitive processes involved may have little or nothing in common. Brown and Campione generally encouraged students to assume responsibility for their own learning, a goal that Metz also adopted but applied in a more focused way to student planning and conduct of empirical investigations. As we have seen, Hennessey wanted students to understand and apply specific evaluative criteria to their own theories and the theories of classmates. This is a view of metacognition that seems more closely related to the one articulated by Grotzer

and Perkins, who expected students to notice and describe the causal structure underlying content domains whose surface features varied. Lehrer and Schauble regarded metacognition somewhat differently, as learning to use varying forms of representation that allow one to literally grasp thought, and as putting these representations to use in the service of arguments about qualities of natural systems.

There was widespread agreement on the importance of data representation and other forms of symbolization. Many of these researchers endorsed the value of capitalizing on the variability in students' invented representations. Repeatedly producing, critiquing, and revising representations helps students appreciate the uses and purposes for inscriptions, what they communicate, and the design trade-offs entailed in their construction. In traditional classrooms, students are taught conventional forms for graphing, making tables, drawing maps, and the like, as context-free tools. They may be given a variety of problems to practice on, but these are regarded merely as contexts to serve the primary goal of learning how to construct and use the inscription in its conventional form. In contrast, a theme common to the programs we reviewed is tying education about forms and uses of representation and inscription to contexts of their use. Other tools as well, from scientific instruments to rulers, are introduced when students have encountered a problem that the tool would be helpful in addressing.

Views on the nature of development emphasize continuity from children's early intuitions and theories to their instruction in conventional theories of science disciplines. In distinction to the misconceptions literature in science education, which tends to draw sharp contrasts between students' conceptions and those of experts, these investigators see early theory building as a resource for rather than a barrier to instruction. Attention to the features of learning contexts that optimize development is considered an essential part of an account of development for these researchers, although the extent to which they focus on cataloguing these features varies somewhat. Brown and Campione, with their 39 principles, are probably most exhaustive in their attempt to specify the features that account for developmental change in a classroom context. Across the six projects, a range of features was proposed that varied from the kinds of tasks presented to students (all of the researchers in this section) to the forms of activity repeatedly engaged, the classroom norms, and the kinds of evidence and argument that characterize classroom discourse.

We have briefly described seven classroom design studies organized around investigation of the development of some aspect of scientific thinking. Each was grounded in a particular vision of what develops in scientific thinking and literacy, and each provides at least initial data about the learning potential of the program. However, at this point in time, none of these projects has secured a base of longitudinal research that is extensive enough or has been sustained for a long enough period to permit clear comparisons about the long-term educational consequences of pursuing one design rather than another. We still know little about what we might expect of a student who participates in one of these programs for an extended period. What capabilities or propensities would this student develop, and what forms of practice would he or she master that graduates from the other programs might not? From a design perspective, the point of having longitudinal comparative data would be not to find out which approach is best, in the simple sense of winning a horse race, but to better understand the characteristic profile of strengths and weaknesses of each, so that choices about educational directions can be informed by their fit to more clearly articulated values. Do some of these programs provide a smoother transition to becoming a generally literate citizen, whereas others provide a better pathway to the professional practice of science? Do some do a better job than others of providing foundational tools that will pay off consistently over the scope of a child's education? What does each approach emphasize, and what does it tend to move to the background?

We now know something about how education starts off under these approaches and a little about how it proceeds, but we know little or nothing about how it ends up many years down the road. In the final section of the chapter, we seek to understand what it takes to build and sustain conditions that permit the acquisition of comparative data of this sort. This question is pursued in the context of discussing the implementation challenges of conducting classroom design research.

IMPLEMENTATION ISSUES IN DESIGN STUDIES: WHY AREN'T WE MAKING FASTER PROGRESS?

Why is it so difficult to conduct the kind of longitudinal, comparative work that can inform educational decisions

about science literacy in a systematic, scientific way? There are both conceptual and logistical challenges to developing and refining educational programs that are informed by developmental theory and research, sustaining those programs in ways that preserve and extend their educational integrity, and assessing learning in organizational systems that are both highly changeable and politically sensitive. Rather than discussing these implementation issues in general, we will view them through the lens of our own work. As explained earlier, information about these matters is seldom openly discussed. Therefore, we resort here to our own experience, trusting that it is more common than uncommon.

Challenge 1: Developing and Refining the Design

Although previous and concurrent research can be of help in identifying likely starting points for children's learning, learning research insufficiently constrains educational design. A significant amount of conceptual and empirical work is required to develop and refine an educational design that can foster long-term development. The more extensive the target of educational concern, the more conceptual and empirical work is required to cash in, test, and revise the elements of the educational design. Careful consideration of what is to be done, day by day, does not follow obviously and smoothly from a few key principles or even from hypothetical prospective trajectories of student learning. For instance, deciding that we intend to support the development of model-based reasoning in children, that we will seek to build on early origins of this form of thinking, and that we will systematically provide mathematical resources, representational tools, and appropriate classroom norms still leaves us with the need to make day-to-day decisions about how to accomplish these goals. If the means are wrong, it will not matter if the principles are right.

The instantiation of an educational design routinely requires the revision of initial plans and assumptions. Students have a way of getting stuck on forms of learning that seem relatively straightforward until one tries to help children achieve them, or to the contrary, of readily producing forms of thinking that seemed unlikely on first consideration. At key points during instruction, it is necessary to be able to predict the near landscape of educational possibilities most likely to unfold and to foretell the consequences of following one or another path through this landscape (Lehrer &

Schauble, 2001). Developing this kind of knowledge requires replicating the "same" lesson sequences—while exploring key variants—on multiple occasions and often at different grades. Cross-grade study helps us better understand both what is developing and the likely pathways of development.

For example, we deliberately adopted a developmental focus with the previously described study of data classification (Lehrer & Schauble, 2000b), in which children developed models to predict the age of the artists of a series of self-portraits. This investigation was conducted in grades 1, 4, and 5. The first graders readily classified the portraits by the presumed grade of the artist and identified the features that they felt differentiated the pictures drawn by kindergarteners ("dinosaur" hair, no feet) from those drawn by fifth graders ("lots of detail," all five fingers). However, their classification systems were merely post hoc descriptions applied to decisions they had already made via casual inspection. Tellingly, they did not use their feature lists to make predictions about a set of novel portraits. Therefore, to the first graders, the lists did not really serve as models at all. In contrast, the fourth graders did develop models and apply them to support predictions, but it took many attempts to use the models and rounds of subsequent revision before students came to prefer models that did not include extraneous detail. These fourth graders struggled with the idea that a model that did not include all discernible information about a portrait might be preferable to one that did. Fifth graders not only eliminated features that were not predictive from their models; they even developed quantitative estimates of the predictive power of their features ("A portrait drawn by a fifth grader is twice as likely to have eyelashes as it is to have shoes with shoelaces"; "Two thirds of the time, a fourth-grade portrait will include eyelashes").

To the extent feasible, we replicate instructional sequences to understand more about what is repeatable, what varies, and what routes development typically takes. Our purpose is to achieve a clearer understanding of what constitutes the intervention. That is, what is essential to produce desired outcomes and what is peripheral? What variations in features still produce similar results, and what forms of variation fundamentally change the character of the outcomes? What is the permissible window of variability of each key feature within which we would judge that the intervention maintains its integrity? Failing to understand these issues,

we believe, accounts for much of the difficulty experienced in attempting to “scale up” educational interventions—much of the time, what is being “scaled” is only dimly understood. For this reason, we seek to understand the generalization (and generativity) of a pathway of learning by investigating how lesson sequences play out with a variety of different student and teacher populations. We attempt to replicate within and across grades in a participating school, across schools in a district, and across sites. Portions of our work have been replicated in both suburban and urban school districts in the upper Midwest, in Phoenix, Arizona, and currently in Nashville, Tennessee. Yet replicating educational interventions that extend over several years is a very slow process, one that should be pursued before comparative trials are undertaken. At a minimum, they involve considerable challenges in assisting teachers’ professional development to a level where the intervention can be reliably produced. Treating a program as if it were transparent to teachers is an invitation to the kinds of lethal mutations discussed earlier.

Challenge 2: Implementing and Sustaining the Program and Its Integrity

So far, we have been discussing the conceptual challenges involved in identifying the defining features of an educational program. There are equally daunting logistical challenges, which require solutions that are every bit as intellectually demanding. These solutions are costly in terms of both researcher time and resources, and our training typically does not equip us to address problems of this kind. First among the implementation challenges is the difficulty of marshaling and maintaining capacity to do this kind of work within our own organizational setting, in this case, the university.

The education of graduate students poses challenges. Rather than introducing students in a gentle way to well-understood and routine procedures, we must help graduate students learn within and make productive contributions to an enterprise that is under continual evolution. One is always updating newcomers of all kinds (staff as well as students) to an ongoing effort that existed before they came and will extend beyond their tenure. Participants at all levels need to continually recalculate the relationships between the part of the project in which their contributions are made and the larger enterprise in which it resides. These features of the research sometimes generate dif-

ficulties for the indoctrination and socialization of new students into this form of research.

Classroom design research requires interdisciplinary teams and multiple forms of talent that are unlikely to reside within one individual. We have found it helpful to form collaborations with individuals from other disciplines: in-service teachers and school administrators, of course, but also biologists, mathematicians, and psychometricians. Identifying and coordinating multiple participants and forms of expertise over extended time periods is a goal that does not always align well with the expectations of university promotion and tenure committees, resources and cycles of funding agencies, or colleagues’ existing disciplinary allegiances. We have needed to play multiple roles ourselves, including educator, professional development provider, and community politician, in addition to education researcher.

Sometimes these roles involve managing contingencies as they emerge and cannot be identified in principle beforehand. For example, our decade-long program of work in a school district was preceded by a decade of work that one of us conducted in classrooms in that district. This earlier work involved coming to be seen as a member of the school district by teachers, administrators, and parents. It entailed countless conversations “in the cracks” that gradually built trust, so that stakeholders, especially teachers, did not perceive research as something done to them and their children. Some of these events might be viewed as extraordinary, even bizarre, from some perspectives. For example, one parent was concerned that the screen image of the Logo programming language might be a form of idolatry prohibited by her religion. Concerns like this were not anticipated by the researcher but, nonetheless, had to be addressed in ways that preserved the integrity of all concerned. An outcome of this previous work was increased capacity for teacher leadership, so that teachers were prepared to build on the changes they had already begun. This preparation served as an essential foundation to the research we described; without it, it is highly unlikely that we would have been able to achieve significant levels of student learning within a 3-year period. Hence, this history proved relevant to the conduct of the research program, but it also raised the problem of identifying which aspects of history should be judged relevant when reporting current design research.

Schools, of course, are daunting organizations in which to pursue research, especially if they are organized around an educational change agenda. This is par-

ticularly the case in today's climate of politicized education. The leadership in most districts is unstable, schools are vulnerable to all sorts of competing political pressures, and their goals and activities are publicly contested. In our work, we have struggled with an array of havoc-producing events, including the resignation of a supportive superintendent, a shift in the school board's political affiliation, the serious illness of a teacher-leader's young child, internal disagreements among the faculty (e.g., over whether to pursue *looping*, in which teachers graduate with their students across one or more grades, or multiage classes). We are confident that other classroom researchers have similar tales to tell. The legitimate agendas of schools often inadvertently put them at cross-purposes to the goals of the research. At one site, we were making good progress at consolidating a cross-grade team of like-minded teachers who had worked for several years together on professional development oriented around the study of student learning. Over the years, the group had achieved strong community affiliation and had amassed impressive technical knowledge about the development of student thinking, achievements that were central to our shared goal of supporting a systematic and consistent approach to mathematics and science education. However, this district was one of the fastest growing in the state. As the district expanded, it became necessary to build a new elementary school. To our dismay and that of the teachers, administrators moved several of the participating teachers to the new school to colonize the reform in this new site. Although the intentions were noble—administrators hoped to see these new forms of teaching spread more widely—the result was the disruption of the cross-grade community and our capability to follow students longitudinally across grades in which the experimental instruction was being implemented. Even when radical changes of this kind are not occurring, the degree of teacher and student mobility that is typical of American schools makes longitudinal research difficult to sustain.

Within the past several years, we have found the politics of education to be especially disruptive to any agenda that includes systematic capacity building. Lack of consensus over the role and form of education leaves teachers highly vulnerable to disagreements about standards, testing, curriculum, grading, student grouping, and almost every other aspect of education. It is not uncommon for the major focus of a district's educational effort to shift suddenly in response to a biannual school board election or the arrival of a new member of the ad-

ministrative staff. Mandatory testing is now highly consequential for both students and teachers, yet national and state tests lag behind curricular innovation. Hence, research and development aimed at upping the ante for what is taught and learned may not show up on widely accepted measures. Under these circumstances, it is difficult to maintain the sustained focus required to effect educational improvement.

Sometimes logistical and conceptual difficulties become intertwined, for example, the problem of deciding whether the educational program has, in fact, been implemented. All change in schools is uneven, and at any point in time it is far from complete, even if the change has been supported or even mandated by district leadership. Some teachers are early adopters who become essential to the maintenance of the program; others hang on the periphery. Some are enthusiastic about the program but never achieve more than a superficial understanding of it; some resist in active or passive ways. This unevenness of implementation poses problems for the research, especially if the design includes comparison between schools or classrooms that are and are not considered participants. How much and what kinds of participation make a teacher a participant?

In sum, design researchers do not just need to address the conceptual and measurement problems involved in changing and studying the long-term development of learning. In addition, they must cultivate and maintain relationships with the research site, a role that usually includes providing the forms of professional development that support desired forms of teaching and learning. (Professional development that produces generative change in teachers' practice is a difficult and important goal to which an entire base of literature is devoted. See, e.g., Grossman, 1990; Palincsar, Magnussun, Marano, Ford, & Brown, 1998.) Researchers must assist the participating site in managing change, a process that is not always comfortable and that may perturb roles and identities for some individuals. Developing a test bed for extended research is a full-time job in itself. The effort invested in this enterprise means that it is not feasible to step away from site activity to spend a year in uninterrupted analysis of data. One cannot wave goodbye to a school that has come to depend on your support, leaving teachers and students with a promise that you will return when the sabbatical is completed or the book written. Although change may become self-sustaining over time, it is impossible to predict in advance when this will occur, as the organization and constraints of

schooling are powerful forces that operate continually to push teaching and learning back into their more conventional forms. As Spillane (2000) and others have demonstrated, educational reforms usually get assimilated into the patterns of knowledge and practice that preexist in a school, with the result that they are often distorted and rendered sterile.

Challenge 3: Assessing Learning

In these classroom investigations, it is necessary to coordinate fine-grained studies of change in individual students (to identify typical strategies and typical forms of change over time) with coarser-grained measures of achievement in groups of students. The finer-grained studies are required to learn more about the development of scientific thinking that is taken by researchers to be the desirable core of scientific literacy, whether the focus is on change in theories, in students' capabilities to conduct self-regulated investigations, or to engage in modeling practices. As suggested earlier, studies of development that span multiple years pose significant measurement problems because at the outset, little solid evidence exists about how thinking develops when it is systematically supported in an educational context. Therefore, it is unclear when one should look for expected benchmark changes. Coarser-grained studies of student achievement must simultaneously address educators' and parents' concerns about performance on assessments that are consequential with respect to progress, graduation, and college, and at the same time must be sensitive to the goals that are specific to the design.

In our work, we found that developing, revising, and retuning the achievement measures constituted a psychometric project of considerable scope. First, there were no measures of long-term development for the forms of thinking we wished to study (e.g., students' representational competence, spatial visualization, data interpretation, statistical reasoning). Therefore, we developed and/or borrowed items based on our own and others' previous research and initial conjectures about likely forms and rates of student learning. In advance, we were not always able to accurately foretell when it would be reasonable to expect particular benchmark changes. As the educational design unfolded, it was frequently necessary to recalibrate the measures, leading to some undesirable shift from year to year in the data we could collect. Other data collection problems followed from student mobility, the bane of longitudinal designs.

Students who studied in collaborating classrooms for 2 contiguous years constituted a reasonably large proportion of our sample, but the proportions of those in project classrooms for 3 years in a row or longer dropped considerably.

There were design issues that followed from the problem of how to identify a fair comparison. The difficulties of accounting for teacher effects and differences in student populations are well established in education research, and these are certainly contributors to the complications of understanding variation in the design, as described earlier. But these difficulties are not just logistical; they are also conceptual. We do not favor control groups that do not control for anything in particular, and moreover, we felt it unlikely that we could persuade teachers in comparison classrooms to spend 3 hours per year testing students on difficult forms of mathematics that they had never studied. Rather than setting up straw-person comparisons of experimental classrooms with those that pursue business as usual, we feel that much more could be learned if the field would pursue a collaborative assessment strategy. Specifically, we hope that in the near future it will be possible to compare the development of student thinking across a few key design studies that vary in interesting ways. The overall strategy would be to develop and use a negotiated common bank of items to assess the learning of students enrolled in different research programs. Because each lead researcher could identify the features theoretically considered central to his or her intervention, the results of such a comparison would be more informative than a typical experimental versus traditional instruction comparison. Presumably, the results would show characteristically different patterns of strengths and weaknesses associated with identifiable instructional approaches. In our opinion, this kind of comparison is a potentially powerful strategy for better understanding the developmental affordances of different designs. We might find, for example, that some approaches produce impressive results in the short term, but others do a far better job over the long haul of producing and sustaining valued outcomes.

Challenge 4: Explaining Contingency

Although design studies offer new opportunities for educational inquiry, they differ from more traditional kinds of study in their purpose, scope, and form of explanation. Like evolutionary biologists and practitioners in some other disciplines (see, e.g., Rudolph & Stewart,

1998), researchers engaged in explaining extended inter-relationships between instruction and learning need to account for phenomena that are contingent and historical. Because classroom learning has this character, an important goal for research is to identify and explain the contingencies that the design accounts for—in other words, the patterns of learning and change that, broadly speaking, can reliably be expected to emerge if the design is instantiated. These contingencies need to be teased out from the broad array of features that are not accounted for in the explanatory structure (Lehrer & Schauble, 2001).

One way that researchers address this problem is to generate a set of conjectures that, collectively, take the form of a learning trajectory or pathway. Collectively, these conjectures form a hypothesized sequence or route, one that describes our best-informed guesses of how students typically progress along the path from less expert to more expert forms of thinking. The sequence is conjectural because design studies are typically employed to investigate the teaching and learning of unexplored or underexplored content. For that reason, one cannot be confident that the trajectory will play out as foreseen. Although less detailed and broader in scope, a learning trajectory is a little like an instructional task analysis in cognitive psychology. Its purpose is to guide the overall direction of instruction in domains in which little research currently exists to inform teaching and learning. Accordingly, a learning trajectory embodies one's best bets (informed by research, general knowledge of children's thinking, and reconceptualization of central ideas in the relevant domain) about how development is likely to occur. Of course, as instruction based on a hypothetical learning trajectory is instantiated, the trajectory needs to be revised in real time, in response to what one is learning in the classroom.

Although this brief description captures the general purposes and processes of design studies, there is some danger to taking the analogy too literally. The metaphors of "developmental corridors" and "learning trajectories" do not foreground contingency and variability, which we have argued are very important to understand. What comes to mind when one thinks of "corridor" is an invariant and circumscribed path from a particular beginning place to a known goal. Thinking of development as a path supports the sense of going from somewhere to somewhere else but does not capture the kind of variability in student thinking and performance that often serves as a fundamental mechanism of change.

For this reason, it may be more accurate to conceive of development as an ecology that emerges in interactions determined (in part) by the learning opportunities and constraints of tasks, semiotic means (e.g., tools, systems of inscription), recurrent activity structures, and the ways teachers or other members of the community recruit, select, and enhance the contributions of participants (see Lehrer, Strom, & Confrey, 2002).

From this perspective, corridors or trajectories are retrospective accounts of particular realizations of this prospective space of interaction. Designing for education must encourage emergence and variability or else risk pruning the potential for development to sanctioned pathways. Faced with such complexity, educators can choose the path for students and use teaching assistance primarily to minimize straying from the predetermined route. Or instead, one can foster and encourage variability in student thinking and then capitalize on the local opportunities that emerge from it. In that case, the design problem is to craft situations and tasks that are most likely to produce forms of variability that are rich with instructional potential. Of course, one needs an overall vision of where instruction is headed, but that vision can be an elastic one, modifiable at all points by an ongoing assessment of what next move best capitalizes on the contingencies that emerge in the classroom. We argue that this approach is best for capitalizing on students' cognitive resources and performances, but it admittedly makes it more difficult to explain conceptual change. If one reconceives of variability not as error or noise but as grist for development (Siegler, 1996), then documenting and accounting for contingency become an essential part of the research enterprise.

For purposes of tractability, we often ignore these contingencies; indeed, much research is designed so that we can safely do so. But explaining learning entails explaining a phenomenon that is fundamentally historical. Students come to classrooms with learning histories, and moreover, teachers seek to build on those histories. If they succeed, those histories coalesce into enduring propensities and capabilities of the kind that we sometimes call "development." Effective learning does not simply cumulate; instead, later learning transforms what we knew earlier on. Understanding development means understanding those histories, not just their shape, but also their causes. Indeed, the internal psychological characteristics of the learner are important mechanisms, but to understand how scientific thinking and scientific literacy take shape, instruction and other

forms of assistance must also be accounted for. One cannot understand these forms of development without understanding the means by which they are supported. In that sense, an account of development is an account of its history. As Gopnik and Metzliff (1997) explain:

Like Darwinian biology, the view presented here suggests that explanations in cognitive science will often be historical and contingent. If we want to say why we have a conceptual structure of a particular kind, we will typically not be able to reduce that structure to some set of first principles. Rather, we will need to trace the historical route that led from our innate theories to the theory we currently hold. On this view, all of cognitive science would be developmental. (p. 218)

Recognizing contingency is an important first step. Developing sound models of history is an enduring challenge.

One of the limitations of verbal language—the medium of this *Handbook* and hence of this chapter—is its linear nature. This linearity permits only a single opening paragraph, and the problem is that I would like to write three. Each would be designed to seduce a different audience to read the chapter that follows. The first would be a paragraph aimed at attracting scholars who are interested in cognitive development in general and in the development of spatial thinking and spatial representation in particular. The second would be aimed at attracting developmental scholars who, although not

necessarily interested in spatial thinking per se, have an interest in the interplay between theory and practice and are themselves perhaps in the throes of designing applied research or intervention programs related to some substantive domain. Learning about experiences in linking theory and practice in one domain may be useful for identifying opportunities and challenges in another. Finally, the third would be a paragraph aimed at attracting individuals who have responsibility for children's educational lives, including anyone who has (or will some day have) responsibility for planning, selecting, or implementing educational experiences or who is in a position to teach those who will eventually assume these positions. This is a broad group that includes personnel in both formal education (e.g., teachers, school administrators) and informal education (e.g., museum professionals, youth group leaders),

Much of the research reported here was funded by the National Institute of Education (G-83-0025) and by the National Science Foundation (ESI 01-01758, RED-9554504, REC-0411686), although the opinions expressed are those of the author and not necessarily those of either agency.

those who develop and distribute educational materials (e.g., curriculum writers, textbook publishers, television programmers, software designers), faculty in institutions of higher education (e.g., professors of curriculum and instruction), those who set educational policy (e.g., school board members, political leaders), and those who affect even one or two individual children's experiences directly (e.g., parents).

I have written this chapter for all three audiences. Following this introduction, in the section "Conceptualizing Spatial Thinking," I offer examples of spatial thinking intended to demonstrate its pervasiveness and importance. I then provide more formal definitions of the constructs of space and spatial thinking and illustrate the relevance of spatial thinking for a wide range of disciplines, concepts, tasks, and settings.

To the degree that my examples are convincing, readers may conclude that spatial thinking is, indeed, important and pervasive, but perhaps so much so that education for spatial thinking appears to be unnecessary. I would offer here an analogy to Molière's *Bourgeois Gentleman*, in which Monsieur Jourdain is shocked to discover that he has been speaking prose all his life. The point is that it is easy to take for granted that which one is accustomed to using freely. Prose is indeed pervasive and important, and even preschoolers are adept at using it. Yet, none of these facts leads us to ignore language in our educational curriculum. Instead, our schools provide instruction in all aspects of English—skills needed for comprehension and production of the written word, lessons in the beauty and traditions of great literature, and exercises in designing and delivering spoken arguments. Our informal educational systems are also designed to foster language skills, as in teaching young children the basics of reading through television programs, computer software, or games, or as in public service campaigns encouraging parents to read to their children. At all educational levels, the performance of individual students and institutions is assessed by measuring verbal functioning.

Monsieur Jourdain would probably have been equally shocked if he had stopped to consider how pervasively spatial thinking is used in our mental, physical, and social worlds. However, as with language, the fact that spatial thinking is pervasive should not be taken to imply that it is mastered automatically and effortlessly, nor to obviate the need for spatial education. In the section "Individual and Group Differences in Spatial Thinking

and Spatial Development," I draw from scholarship in developmental psychology to show that masterful levels of spatial thinking are not universally achieved by all individuals and groups, and to review briefly some of the explanations that have been given to account for these differences.

Having established the existence of individual and group differences in spatial thinking, in "The Case for Spatial Interventions: When Differences Are Deficits," I address the question of whether these differences matter for educational goals. After enumerating several reasons why spatial performance does, indeed, matter, I present illustrations from laboratory and classroom contexts to suggest that spatial skills can be facilitated through interventions.

In "The Place of Geography and Map Education in Developing Spatial Thinkers," I consider the means by which one might address the goal of enhancing spatial thinking in the real world of education. I first review reasons for rejecting one possible approach: adding spatial education as a stand-alone curriculum. I then turn to discussing an alternative approach: infusing spatial education within existing school subjects. Ideally, an infusion approach would involve enhancing spatial thinking in a diverse set of school subjects. In this chapter, I focus on a single school subject—geography—as an illustrative case. I argue that geography is an excellent vehicle for spatial education because at its core, the discipline involves explaining spatial patterns and processes. Further, I argue that—within geography—map education is a particularly useful focus for developing spatial thinking. To explain the power of maps as tools for spatial thinking, I provide a mini tutorial on the principles, challenges, functions, and diversity of maps.

There are several motivations for my focus on maps. First, the skills involved in producing, understanding, and using maps are like the spatial skills that have been identified as important for a wide range of observational and representational tasks in many sciences (e.g., distinguishing figure from ground; using distal frames of reference even in the face of proximal, embedding frames of reference; mentally rotating objects or diagrams; determining cross sections). Second, maps are pervasive. They are central tools not only in geography, but also in many other school subjects, occupations, and daily life activities. Third, there is extensive evidence that, without instruction, neither

children nor adults exploit the full representational and spatial meaning maps offer.

A fourth and more personal reason is that map education has been at the center of much of my own applied developmental research. Particularly relevant are two ongoing collaborations. The first involves roughly 2 decades of collaborative work with Roger Downs, a geographer. Our projects have included designing and teaching a curriculum unit on geography and mapping for elementary school children (Liben & Downs, 1986), advising Children's Television Workshop on their design of a geography curriculum for *Sesame Street* (Liben & Downs, 1994, 2001), and partnering with the National Geographic Society in a study of boys' and girls' dramatically differential success on the National Geographic Bee (Liben, 2002a). The second collaboration is with Kim Kastens, a marine geologist. Our interactions began when she was funded by the National Science Foundation to develop materials for teaching elementary school children to read and use maps (*Where Are We? [WAW?]*; Kastens, 2000) and I was an advisor to the project. Our interactions evolved into a number of collaborative research projects aimed at investigating children's spatial thinking in map use, evaluating the effectiveness of the *WAW?* curriculum, and exploring college students' three-dimensional spatial thinking while learning geological skills in the field (Kastens, Ishikawa, & Liben, 2004; Kastens & Liben, 2004; Liben, Kastens, & Stevenson, 2002).

I draw from these collaborative projects to address various developmental and educational issues related to map understanding. Specifically, in "The Developmental Pathway to Map Understanding," I characterize the developmental course of map understanding, and in "Map Education: Illustrative Materials and Activities," I discuss educational interventions. In the final section of the chapter, "Educating Spatial Thinkers: Conclusions and Questions," I summarize key lessons and highlight remaining questions relevant for each of the three audiences identified in the opening paragraph of this chapter.

CONCEPTUALIZING SPATIAL THINKING

Because space literally surrounds us, and because we so often use spatial metaphors and spatial representations automatically, we often fail to notice or analyze these

concepts, or to define terminology explicitly. In this section, I thus highlight the many ways in which spatial thinking enters human life, offer definitions of key terms, and provide a developmental perspective with which to approach spatial thinking.

The Pervasiveness of Spatial Thinking

Our daily lives are filled with space-related action, perception, and representation. When we awaken in the dark, we know where to reach to hit the snooze button; our stored representation of the bedroom allows us to avoid stubbing our toes as we move to the bathroom; we know which cabinet door to open to find our toothpaste or hairbrush; where to look for our clothes; where to find the orange juice. When we read the morning paper, we see aerial photographs of the East Coast during a blackout, a map of a battlefield, a bar graph reporting the results of a recent political poll, a satellite image of a storm system. We drive to work and draw upon a cognitive map of the city to detour around a traffic jam. When we arrive at the office, we examine graphs showing the relative costs, income, and profits for the new digital cameras we have been involved in developing; we examine maps showing the spatial distributions of the factories that manufacture them; we compare the resolutions of the images they create. Our elementary school children wait at the right corner for the school bus; they notice that the driver took a different route to avoid a construction site; once they get to school, they learn to color within the lines and the direction in which to write their letters to form their words; they learn to produce graphs and maps. Our high school children examine the positions of various organs from a frog dissection in biology class and draw and label pictures of each in their lab notebooks; they learn about how hydrogen and oxygen atoms combine by using three-dimensional models in chemistry class. In earth science, they search the Web to find information about the latest earthquakes, clicking the mouse at the right locations on their screen, and negotiating the hierarchically organized and modeled site map; in social studies they use a Geographic Information System (GIS) to explore the links between income level and voting patterns. After school, they get and follow directions to bike to their friend's house; they play a video game when they get there, and then infer the villain's location from a series of discrete elevation views of the castle's rooms. In short, human lives

are filled with spatial thinking at home, at work, at school, and at play.

Definitions

Although there would probably be general agreement that the examples just given draw on various aspects of spatial thought, there would probably be far less agreement about how to define or parse the constituent constructs of *space* and *spatial thinking*. That is, unlike the more commonly studied symbolic domain of language, for which there is a well-established taxonomy of components (phonology, syntax, and semantics) and formalization of the domain (grammars), the constructs of space and spatial thinking have no commonly agreed upon set of components or universally shared formalisms, at least as they are studied in human development. As a consequence, answers to the foundational questions *What is space?* and *What is spatial thinking?* are complex and controversial and would require far more pages than the current chapter allows. Thus, the brief answers offered here can provide only the foundations for the topics developed in later sections of this chapter. More fully articulated answers may be found in earlier reviews and collections on space, spatial cognition, and spatial representation (Cassirer, 1950; R. Cohen, 1985; Eliot, 1987; Gattis, 2001; Jammer, 1954; Liben, 1981, 2002b; Liben, Patterson, & Newcombe, 1981; Newcombe & Huttenlocher, 2000; O’Keefe & Nadel, 1978; Olson & Bialystok, 1983; Piaget & Inhelder, 1956).

Space

Space—like many words and ideas we use casually and frequently in daily language—is a surprisingly difficult concept to define. In earlier days, one might have used a dictionary definition or an encyclopedia to demonstrate the range and perhaps even the elusiveness of a concept; today one is more likely to turn to an Internet search. A search with the words “space definition” in *Google*© returns as the first entry a page titled “Definitions of space on the Web” that includes definitions from (and links to) mathematics (“the infinite extension of the three-dimensional field in which all matter exists”), astronomy (“the expanse in which the Solar System, stars, and galaxies exist”), film (“story space, the locale of the totality of the action . . . and plot space, the locales visibly and audibly represented in the scenes”), music (“areas between or below or above the lines of a musical

staff”), time (“the interval between two times . . . [as] in the space of 10 minutes”), typography (“a blank character used to separate successive words in writing or printing”), and kinesthetics (“where the body is moving”), to sample only some.

Embedded within these and other definitions of space is the ancient tension between conceptualizing space as absolute versus relative. In the former, space is defined as a framework that remains unchanged irrespective of whether anything is contained within it, where its contents are located, or from what perspective the space and its contents are viewed. For example, a Cartesian coordinate grid offers such a framework. In the latter, space is conceptualized as an expression of relationships among objects. The space between words, for example, emerges only in relation to characters that come before and after it. In this relative conceptualization of space, the space changes as objects within it change or move. The conception of space as absolute is associated with Plato and Clarke in philosophy and with Newton in physics; the conception of space as relative is associated with Leibniz and Kant in philosophy and with Einstein in physics.

Fortunately, just as physics can progress by modeling light as waves and as particles even though the two models are physically incompatible, developmental science can progress by asking how individuals acquire, refine, use, and consciously reflect on both absolute and relative space. Illustrative of a developmental question within the former is asking how children come to establish and use abstract, homogeneous coordinate systems that, even when empty, provide frameworks for *potential* locations or distances (Piaget, Inhelder, & Szeminska, 1960; Somerville & Bryant, 1985). Illustrative of a developmental question within the latter is asking when and how individuals come to appreciate relational topological spatial concepts such as “above” and “between” (Piaget & Inhelder, 1956; Quinn, 2003).

Also embedded within the illustrative definitions are a number of different views on the metaphysical nature of space. Some definitions imply that space is a physical reality (as in planetary outer space or as in the environment through which individuals move or dance), a cognitive construct (as in a formal spatial model created to represent some spatial or nonspatial content), a metaphorical construction (as in time as space), or an emergent reality (as in the spaces created by drawing lines of a music staff). One parsing of space relevant to these alternatives is that proposed by

O'Keefe and Nadel (1978, pp. 6–7), who distinguished between *psychological* and *physical* space. The former was said to be “any space which is attributed to the mind . . . and which would not exist if minds did not exist,” and the latter, “any space attributed to the external world independent of the existence of minds.” As behavioral scientists (rather than, say, physicists or geologists), we are presumably interested in the former rather than the latter. And indeed, this is the position taken by O'Keefe and Nadel.

However, to say that our focus is on psychological space in no way denies the relevance of physical space. First, the qualities of the physical world set conditions for human action and cognition, although, as well articulated in embodiment theories (see Liben, 2005, in press; Overton & Müller, 2002), the reverse holds as well. That is, qualities of the human actor (both physical and mental) likewise set conditions for human action and cognition. Second, insofar as important aspects of psychological space are concerned with the physical world, physical space is a critical substantive domain for much of human cognition. For example, much of psychological space is devoted to knowledge about or cognitive representations of the world that allow people to solve inferential problems (see Stevens & Coupe, 1978) or to navigate within it (Allen, 2004; Downs & Stea, 1973, 1977; Garling & Evans, 1991; Golledge, 1999; Kitchin & Blades, 2002). Third, at least some scholars take the position that characteristics of physical space determine (in whole or in part) characteristics of psychological space. For example, Lynch (1960) observed that the Aleuts (who depend on waterways for travel) attend to and label water features of their environment in detail, but differentiate little among landforms. In short, focusing on psychological space does not make physical space irrelevant. Its relevance is, however, mediated through human thought, which is, of course, necessarily the central focus of a chapter entitled “Education for Spatial Thinking.” Thus, I turn from definitions of space to definitions of spatial thinking.

Spatial Thinking

Although authors of books and articles concerned with spatial cognition often write very briefly (if at all) about the meaning of the “space” to which the cognition refers, they are usually very deliberate in defining what they mean by spatial cognition or spatial thinking. However, as noted earlier, there is no single definition to which all or even most scholars subscribe. The one I

have chosen to provide here is that offered in the recent report issued by the National Research Council (NRC; 2005) on thinking spatially. I have selected it for several reasons. First, it is one of the broadest definitions of spatial thinking in the literature. Its breadth is probably explained, at least in part, by the fact that the definition was generated by a committee of scientists representing not only the behavioral sciences (psychology, education, human development) but also the physical sciences, for which spatial thinking is central (geology, physics, geology, astronomy, geography). Second, because it is recent, and because NRC reports are consensus reports written by committee, it builds from, and is viewed as compatible with, a range of earlier and alternative conceptualizations and definitions. Finally, because the charge to this particular NRC committee was focused on educational issues (as evident in its title, *Learning to Think Spatially: GIS as a Support System in the K–12 Curriculum*), the definition is well-suited to educational topics that are also the focus of this chapter.

Specifically, the report identifies three components of spatial thinking as follows:

To think spatially entails knowing about (1) *space*, for example, the relationships among units of measurement (e.g., kilometers versus miles), different ways of calculating distance (e.g., miles, travel time, travel cost), the basis of coordinate systems (e.g., Cartesian versus polar coordinates), the nature of spaces (e.g., number of dimensions [two- versus three-dimensional]); (2) *representation*—for example, the relationships among views (e.g., plans versus elevations of buildings or orthogonal versus perspective maps), the effect of projections (e.g., Mercator versus equal-area map projections), the principles of graphic design (e.g., the roles of legibility, visual contrast, and figure-ground organization in the readability of graphs and maps); and (3) *reasoning*—for example, the different ways of thinking about shortest distances (e.g., as the crow flies versus route distance in a rectangular street grid), the ability to extrapolate and interpolate (e.g., projecting a functional relationship on a graph into the future or estimating the slope of a hillside from a map of contour lines), and making decisions (e.g., given traffic reports on a radio, selecting an alternative detour). (pp. 12–13)

In essence, the first and third components fit fairly readily into the common distinction in cognitive psychology between, respectively, declarative knowledge (“knowing what,” as in knowing various systems or models of space) and procedural knowledge (“knowing how,” as in knowing how to manipulate or transform

spatial information). The second is more closely identified with the spatial domain in particular and highlights the centrality that spatial-graphic representations play in spatial thinking (see Liben, 1999, 2001, 2005; Tversky, 2001).

Spatial Thinking across the Life Span

Developmental psychologists have been interested in the way that understanding spatial concepts, interpreting or creating external spatial representations, and establishing, manipulating, and remembering spatial images evolve over the life course, beginning with infancy (see Kellman & Arterberry, 1998), continuing through childhood (see Liben, 2002b), and extending through adulthood and old age (see Kirasic, Allen, Dobson, & Binder, 1996). Although there can be little debate that spatial behaviors look very different during infancy, childhood, and adulthood, there is relatively little agreement about whether the age-linked differences in observed behaviors signify qualitative differences in the way that space is represented and thought about, or instead signify only quantitative changes in other cognitive skills or structures (e.g., changes in speed of processing; see Kail, 1991).

Undoubtedly, the theoretical position arguing most emphatically for qualitative change in spatial development is that proposed by Piaget and Inhelder in *The Child's Conception of Space*, first published in French as *La Représentation de l'Espace chez l'Enfant* in 1948 and appearing in English in 1956 (referenced in this chapter as Piaget & Inhelder, 1956). In this view, children were said to come to construct spatial constructs gradually through their interactions with the physical and social worlds. The notion of the self-regulatory construction of spatial concepts was thus an instantiation in a particular domain—space—of the more general developmental processes described by Piaget (1970). In Piaget's description of this general process, neonates are thought to be biologically endowed with a very small repertoire of behaviors (e.g., the sucking reflex) and a few key processes (assimilation and accommodation) aimed at general states or end points (equilibrium). Environments are understood as important for presenting certain opportunities and challenges that support individuals in exercising and extending their repertoires. In applying these general processes to spatial development, Piaget (1954) argued that infants gradually come to interact

with and understand the spatial world in a physical or sensorimotor sense (e.g., coming to appreciate that objects have a permanent existence even when out of the child's own view; learning to adjust grasping movements in relation to an object's location in space) and later, at the end of the sensorimotor period, in a representational manner (e.g., solving problems about relations between two objects by mental imagery).

Once having developed representational thought, children were said to develop, first, topological spatial concepts and later, in tandem, projective and Euclidean spatial concepts (Piaget & Inhelder, 1956). Topological spatial concepts discussed by Piaget may be described as “rubber sheet” spatial concepts, that is, those that are conserved even as a rubber sheet is stretched. Illustrative are concepts such as *next to*, *on*, *on the border of*, and *between*, which are relationships that are conserved even as metric qualities are distorted through stretching. A preschool child who has constructed only topological concepts can, for example, differentiate between open and closed figures (e.g., a circular versus a U-shaped figure) but not between two figures that differ only with respect to metrics (e.g., four-sided figures with equal versus unequal sides or equal versus unequal angles).

Projective spatial concepts are “point of view” spatial concepts, that is, those that are affected by vantage point. Probably the best known measure of the child's understanding of the effect of viewing position on the appearance of an object or group of objects is the classic *three mountains task*. Children are shown a table-top model of three (papier-mâché) mountains and asked to indicate (e.g., by selecting one of several pictures) how the mountains would look to someone seated in a different location (e.g., directly across the table). Of interest is whether children can appreciate that the other person's view is different from their own (i.e., can overcome egocentrism), and if so, whether they can identify the spatial characteristics of that view. For example, questions may address whether a young boy understands that a small mountain that is visible to him (because from his vantage point, it is in front of the large mountain) would be entirely invisible to an adult seated directly across the table, or that a blue mountain that appears to him to be to the left of the yellow mountain would appear to be to the right of the yellow mountain to the adult facing him. Understanding the relevance of point of view is also critical for using principles of pro-

jective geometry in drawing (as in Renaissance art, for example; see Hagen, 1986) or in predicting the shape of the shadows cast by light falling on objects as they are rotated toward or away from a screen (Merriwether & Liben, 1997; Piaget & Inhelder, 1956).

Finally, Euclidean concepts are what might be called “abstract spatial system” concepts because they provide the structures by which locations and objects are represented in reference to an abstract, stable, general system. The classic illustration of such a system, and the one that plays a central role in Piaget’s own empirical work on space (Piaget & Inhelder, 1956; Piaget et al., 1960), is a Cartesian coordinate system, which establishes a point of origin and a grid of horizontal and vertical axes. Such systems allow for stable measurement and hence conservation of distance and angles. Although mature spatial systems are typically conceptualized as Euclidean, it might be more useful to characterize maturity as the ability to understand and use abstract spatial systems in general (Liben, 2003). First, a more pluralistic approach appears to be more consistent with the notion of hypothetico-deductive reasoning that Piaget ascribed to formal operational thought. Second, a more flexible characterization would offer closer links to a broader range of phenomena that include those better conceptualized with non-Euclidean spatial models. For example, when modeling outer space, the hyperbolic geometry of Lobachevskian space might be more useful; when modeling Earth space, the spherical geometry of Riemannian space might be more useful.

Indeed, Piaget himself revised his own position on spatial development and substituted a sequence of intra-, inter-, and transfigural relations in the place of topological, projective, and Euclidean concepts (Piaget & Garcia, 1989). Others have offered sequences that concern a particular aspect of spatial development rather than spatial development in general. For example, those who have studied infants or toddlers (Acredolo, 1981) observed a developmental shift in which spatial behaviors are based on *egocentric* coding (in which the infant’s own bodily experiences provide the referent by which locations in space are organized) to *allocentric* (in which external objects or external frameworks are used to code location). Conceptually, this shift parallels Piaget’s description of the developing understanding of vantage point (projective spatial concepts), although it suggests a dramatically earlier developmental shift than proposed in the original Piagetian work.

Another model of spatial development is the sequence proposed by Siegel and White (1975; see also Siegel, Kirasic, & Kail, 1978) with respect to environmental knowledge. They suggested that children first master landmarks, then routes, and finally develop integrated configurational or survey knowledge of the environment. These three stages are similar to the developmental sequence initially suggested by Piaget and Inhelder (1956) insofar as the use of landmarks is akin to the use of topological concepts (e.g., knowing that the school is *next to* the supermarket); the use of routes is akin to the use of projective concepts (e.g., knowing that when traveling from home to school, one turns right at the traffic light, but on the return trip, one turns left at the light); and the use of survey knowledge is akin to the use of Euclidean concepts (e.g., conceptualizing locations of places and pathways by using metric distances and angles).

Although these various alternatives thus differ in the way that the developmental sequences are characterized or in the chronological ages associated with transitions, they retain the fundamental notion of qualitative developmental change that was posited by Piaget. More radical alternatives have also been proposed in which qualitative developmental change is explicitly said to be minimal or even absent entirely. One of the most explicit positions rejecting the notion of qualitative developmental change was proposed by Hagen (1986), whose focus was on the geometries used by various cultures in the drawings and paintings of representational art. As noted earlier, Piaget and Inhelder (1956) saw an individual’s ability to use projective geometry in drawing as reflective of having constructed projective spatial concepts. Thus, in the Piagetian view, young children—those who had constructed only topological concepts—should be unable to understand the consequences of viewing position, and thus be unable to create or appreciate graphic representations that employ projective geometry (as in the vanishing points of Renaissance art). In contrast, Hagen argued that it was different cultures—rather than different levels of ontogenetic maturity—that affected the way space was conceptualized and represented. Under this view, the reason that mature individuals in the Western cultures studied by Piaget favor projective geometry in their spatial-graphic representations is that they have been exposed to such representations in their daily lives. Individuals exposed to spatial-graphic representations that use alternative geometries would thus be expected to follow a different representational path.

Consistent with this view, Hagen (1985) offered evidence that those living in cultures that use other geometries in their representational art (e.g., affine geometry in Asian art; orthogonal projections or metric geometry in Northwest Indian art) do not evidence the developmental increases in projective geometry reported for Swiss children.

In contemporary work, Newcombe and Huttenlocher (2000) explicitly offer their own position as falling between the nativist position that attributes high levels of spatial competency to the neonate and the Piagetian position that posits significant qualitative change from infancy through late childhood. In particular, they cite their empirical finding that infants are able to identify specific locations in space as challenging both views. That is, they argue that their data support neither the nativist position that infants under a year are sensitive to metrics, nor the Piagetian proposition that it is not until middle childhood that children evidence metric understanding. Elsewhere, I have suggested that their position is actually more consistent with that of Piaget than they themselves have painted it (Liben, 2003), but irrespective of precisely where on the continuum their theoretical stance may be said to fall, it is evident from the approaches mentioned here as well as from others not discussed here (see R. Cohen, 1985; Kitchin & Blades, 2002; Liben, 2002b) that various theories of spatial development fall along a continuum defined by the degree to which development is presumed to involve qualitative shifts in underlying competence in spatial thinking.

However, despite the presence of scholarly disagreements about whether there are qualitative changes in *competencies* of spatial thinking, there is little disagreement that there are age-linked differences in *performance* on a wide range of spatial tasks. From an educational perspective, then, it may or may not be necessary to intervene to help children establish basic competencies; however, it is surely necessary to intervene to facilitate children's propensity for activating existing spatial competencies and using them effectively. In this light, it is interesting to return to the recent NRC report on *Learning to Think Spatially*, which identifies as its overriding goal fostering "a generation of students (1) who have the habit of mind of thinking spatially, (2) who can practice spatial thinking in an informed way, and (3) who adopt a critical stance to spatial thinking" (2005, pp. 3–4). These goals imply that the challenge is to find ways to facilitate students' application of spatial

thinking rather than to find ways to establish students' facility in spatial thinking in the first place.

INDIVIDUAL AND GROUP DIFFERENCES IN SPATIAL THINKING AND DEVELOPMENT

As illustrated in the preceding discussions, there is a tendency for developmental psychologists to discuss change as if it occurred for children in general. Although some programs of developmental research concentrate on describing age-linked differences at the group level, others are more concerned with identifying and explaining differences among children in developmental rates or end points. In this section, I consider the way that both perspectives are relevant for the study of spatial thinking.

In Theory: The Universality of Spatial Thinking and Spatial Development

The "grand theories" of child development describe age-linked progressions as if they were universal. This is most obviously true of those theories that are unabashedly addressed to universal human development such as Piaget's (1970) or evolutionary psychology (Geary & Bjorklund, 2000), but it is arguably also true even for most theories that are specifically concerned with development in social contexts (Vygotsky, 1978). That is, even as culturally sensitive theorists identify the way specific social traditions and environments vary over time and place, they typically do so in the context of identifying the similar developmental functions that are being served. For example, ecological or contextual theorists may examine the varying ways adults transmit the knowledge and skills of their culture to the next generation. The function is thus viewed as similar across settings, even though the instantiation of that function is said to differ in form (e.g., whether it occurs in situ, as in teaching children to weave via an apprentice, or in a formal educational setting that draws on abstract representations such as words and diagrams; Bruner, 1964; Gauvain, 1993; Rogoff, 1993).

Descriptions of the more focused topic of spatial development likewise tend to imply that developmental mechanisms and outcomes are universal. Given a shared

biological heritage that provides humans with certain kinds of sensorimotor capacities (e.g., the ability to see visible but not infrared light; the ability to walk but not fly), and given a shared environmental heritage that surrounds humans with a certain kind of physical world (e.g., a world that has a gravitational field that defines an axis for up and down even if the specifics of the landscape vary), it might be reasonable to anticipate that humans will develop spatially along similar paths and with similar outcomes. Indeed, consistent with this view, the two major monographs on spatial development that have been written during the past 50 years (Newcombe & Huttenlocher, 2000; Piaget & Inhelder, 1956) are completely silent about variability within any given age group or developmental achievement being discussed. This is not meant to imply that these scholars are ignorant of or inattentive to variability. Indeed, much Piagetian and neo-Piagetian work is specifically addressed to identifying mechanisms that promote development in both natural and educational settings (Inhelder, Sinclair, & Bovet, 1974). Similarly, Newcombe (1982), in other aspects of her research, has explicitly studied gender-related variation in spatial behavior. Nevertheless, in these monographs as in much of developmental psychology, the focus is on the development of “the” child, just as in much of cognitive psychology the focus is on characterizing “the” human (most often instantiated by the college student in an English-speaking culture).

As with most generalizations, there are exceptions. In the field of human development in general, probably the most sustained exceptions to characterizing development as if it follows a single trajectory and reaches a single outcome are found in the scholarship in developmental psychology that is labeled “life span.” In part, the term is used to underscore the notion that development does not end at adolescence (as might be erroneously inferred from theories such as Piaget’s or from the content of many developmental psychology textbooks). Consistent with this thrust of the life span approach, a number of investigators have studied spatial development in the years beyond childhood and adolescence (Willis & Schaie, 1986). But even more important for the question of universality is the observation that researchers associated with the life span approach investigate not only interindividual commonalities or regularities of development, but also interindividual differences (Baltes, Staudinger, & Lindenberger, 1999). In practice, however, few if any investigators immersed in the theo-

ries and methods of life span developmental psychology have focused their research on spatial development during the portions of the life course that are of greatest interest to educators (i.e., prekindergarten through grade 12). This lacuna is presumably the result of the assumption that during infancy and childhood, the major sources of influence are biological maturation processes and age-graded socialization experiences that are common across contexts (Baltes, 1987). Thus, life span investigators who are interested in studying the effects of history-graded and nonnormative influences have tended to concentrate their efforts on later rather than earlier portions of the life course. In principle, however, a life span approach might be used to study early spatial development in relation to contextual factors; in fact, it is possible to interpret extant research from other empirical traditions in this light (see Liben, 1991a). It is not only a life span approach, however, that has led to an interest in factors other than chronological age that are associated with different levels of spatial performance, a point developed in the section that follows.

In Reality: The Diversity of Spatial Thinking and Spatial Development

At the same time that most theories of spatial development seem to assume, posit, or imply universality across historical time, individuals, demographic subgroups, and national cultures, there are forces that challenge the characterization of spatial development as a universal. In this section, I consider work leading to the conclusion that spatial development is not, in reality, as universal as our overarching theories might appear to imply. I begin with a discussion of work that stems from the research tradition addressed to individual differences, and then turn to work addressed to group differences.

Individual Differences

As argued earlier, developmental theories tend to focus on the universals of cognitive functioning, even if they vary with respect to whether they posit qualitative age-linked differences or context-linked differences in the details of that functioning. A second tradition in psychology, the psychometric approach, instead focuses on the *differences* among individuals. Psychometricians, or differential psychologists, begin from the premise that individuals differ among themselves on virtually all

physical and behavioral human characteristics (e.g., height, weight, muscle mass, memory span, inferential reasoning). Given this starting point, one would anticipate differences among individuals in the domain of spatial thinking as well.

In a review of the psychometric approach to the study of spatial functioning, Eliot (1987) proposed that work in this tradition could be divided into three major phases. The first, which Eliot dated as occupying roughly the first third of the twentieth century, was focused largely on establishing the existence of a specific spatial factor as distinct from general intelligence. The precursors of this first phase lay in the mental testing movement that was driven by practical concerns stemming largely from the social Darwinism and eugenics movements. These movements were concerned with optimizing the quality of the genetic pool of the population or maximizing the way the raw genetic material was used. Thus, for example, early testing efforts were employed to make decisions about matters such as who should be allowed to enter the United States, which young students should be assigned to vocational versus college-bound educational paths, who should be institutionalized, and which applicants should be accepted into the armed forces and for what positions.

Early measures of intellectual functioning typically produced some index of general intelligence, with measures relying on the verbal modality. However, there were conditions under which verbal testing was impossible (e.g., immigrants who did not know English; deaf children), and thus nonlanguage “performance” intelligence tests were developed. Such tests required respondents to solve various kinds of sensorimotor or graphic challenges, for example, completing construction tasks or paper-and-pencil mazes. Whether skills in these domains should appropriately be considered “intelligence” was controversial. Some, such as Terman (1921, as quoted in Eliot, 1987, p. 43), argued in the negative because “an individual is intelligent in proportion as he is able to carry out abstract thinking.” Others, such as Wechsler (1950, as quoted in Eliot, 1987, p. 43), argued in the affirmative, suggesting that there are “several kinds of intelligences, namely abstract (an ability to work with symbols), social (an ability to deal with people) and practical (an ability to manipulate objects).” The latter interpretation took on increasing weight in the psychometric movement as intellectual assessments included a diverse range of tasks, and as analyses of response patterns in samples of those tested

revealed coherent factors, including a spatial factor (Thurstone, 1938).

With the work in phase 1 having provided evidence for a spatial factor as a separate domain of intelligence, the work in phase 2, covering roughly the next quarter-century, was focused on trying to identify component subskills within the broader spatial domain and to understand how they related to one another. Different investigators have identified different factors over the years (e.g., the ability to encode and store spatial patterns), but no single set of factors has been endorsed by all investigators. Indeed, Eliot (1987, p. 55) suggested that various “descriptions of spatial factors were frustrating to other researchers because they appeared at best vague and at worst self-contradictory.” Despite this relatively discouraging conclusion that there is no single, universally accepted way to characterize spatial subskills, this work has generated a number of internally coherent alternative models for conceptualizing the structure of spatial ability (see Eliot, 1987, for detailed presentation of these models).

Eliot (1987) distinguished a third phase beginning in the early 1960s, during which the focus turned to identifying the sources of variance affecting performance on spatial tasks. Work since the publication of Eliot’s review in 1987 has generally continued along the same lines, although with an increasing emphasis on neuroscience foundations and consequences of spatial thinking (Shelton & Gabrieli, 2004).

In summary, work in the psychometric tradition has identified the spatial domain as a component of intellectual functioning that shows variability among individuals. Before leaving the topic of individual differences, however, it is important to note that one need not be working within the psychometric tradition to focus on differences among people rather than central tendencies. Many developmental investigators have noted that within a given age (even within a demographically homogeneous sample), there are dramatic differences among children in their performance on spatial tasks. Some investigators have studied whether the observed variations in performance are linked to variations in theoretically prerequisite concepts (Liben & Downs, 1993). Others have attempted to identify subgroups of individuals (latent classes) that underlie the observed distributions and thereby generate hypotheses about different strategies that people may be using to solve the tasks at hand (Thomas & Lohaus, 1993; Thomas & Turner, 1991). When the latent groups so identified dif-

fer on some salient group membership (e.g., different proportions of males and females that fall into the identified classes; Thomas & Lohaus, 1993), the individual difference approach blends into the group difference approach discussed next.

Group Differences

Variations among individuals at any given moment in time could represent differences among them with respect to the degree to which they are endowed with the quality of interest (here, spatial skills). Alternatively, they could represent differences among individuals with respect to how far along the developmental pathway they have traveled at the point at which they are tested. In either case, once one has documented that there *are* differences among individuals, a key question becomes how to account for those differences. One means of formulating hypotheses about what factors may account for within-group variation is to explore between-group differences. If groups that differ systematically in spatial performance also differ on some biological or experiential factor, that factor becomes a good candidate to examine for its possible relevance to spatial performance. Ideally, in addition to testing whether variations in the identified factor are also systematically related to variations in spatial performance *within* a given group, investigators study whether experimental manipulation of that factor (assuming such manipulation is both possible and ethical) affects spatial performance. Although a finding that the manipulated factor significantly affects some spatial outcome cannot prove that it accounts for differential outcomes in the course of natural development, it shows that it *can* affect outcomes, and thus that it has potential educational utility.

One category of group comparisons that may be informative about spatial outcomes are those that are in some way related to culture, that is, the qualities of the ecology in which individuals develop and live. Any number of cultural variables are potentially relevant. Language is one obvious way cultures vary, and the way that languages mark and use space may affect spatial thinking. For example, different spoken languages differentially privilege absolute versus relative frames of references (Levinson, 2003) and differentially mark spatial features such as whether there is a distinction between something contained within a loose-fitting versus a tightly fitting container (see Choi & Bowerman, 1991). Languages in visual-gestural modes (such as American Sign Language; see Emmorey, Kosslyn, &

Bellugi, 1993) use space explicitly, unlike languages in oral-aural modes (such as spoken English). These different linguistic environments may well effect differences in spatial thinking. Another ecological contrast concerns terrain and navigation through that terrain. Thus, for example, whether one is surrounded by a “carpentered” or “uncarpentered” environment, travels roads that are laid out in a regular grid or a spaghetti-like arrangement, navigates by land or by sea, are factors that may affect one’s spatial representational systems (see Berry, 1966, 1971; Cole & Scribner, 1974; Liben, 1981; Norman, 1980). Another cultural variable that may be important concerns the geometric traditions of representational art mentioned earlier. Exposure to different geometries in art may in turn affect the kinds of geometric concepts and mental representations about space that individuals develop (see Hagen, 1986).

A second kind of group comparison that may be informative about spatial outcomes concerns special populations. That is, individuals who are atypical in some way provide “experiments of nature” in which some kind of potentially important experience is absent, reduced, or modified in ways that could not otherwise be manipulated in humans. For example, comparisons of spatial outcomes in blind and sighted children may illuminate the role of vision for spatial thinking (Landau, Spelke, & Gleitman, 1984; Millar, 1994; Morrongiello, Timney, Humphrey, Anderson, & Skory, 1995), investigations of children with Williams syndrome may help to disentangle the role of executive versus attentional processes in completing spatial tasks (Hoffman, Landau, & Pagani, 2003), investigations of children with early brain injury may illuminate neurological bases of spatial development (Stiles, Bates, Thal, Trauner, & Reilly, 2002), and investigations of children with motor impairments such as cerebral palsy or childhood arthritis may reveal the role of autonomous self-exploration (Foreman, Orenkas, Nicholas, Morton, & Gell, 1989).

It is a third set of group comparisons that has attracted the most attention in the developmental literature—those related to participant sex. One reason for the popularity of this focus is probably that sex differences had not been predicted *a priori*. The unexpected nature of the difference has led many to see these differences as an intellectual puzzle to be solved (Vasta & Liben, 1996). A second reason is practical. It is far easier to identify well-matched samples of males and females (e.g., drawn from the same elementary school or university) and to obtain them in adequate numbers than

it is to identify adequate and well-matched samples drawn from other potentially interesting comparison groups (e.g., across cultures or special populations). A third reason is that so much is already known about factors that differentiate males and females, factors that thus supply ready-made candidate explanations for differential spatial outcomes.

Studies of children and adults in Western cultures have demonstrated robust sex-related differences on spatial tasks, with the observed advantage for males often falling between what have been labeled by J. Cohen (1977) as medium and large effect sizes (Linn & Petersen, 1985; McGee, 1979; Voyer, Voyer, & Bryden, 1995). Although some of the earliest reports of sex-related differences in spatial skills suggested that they did not emerge until adolescence (Maccoby & Jacklin, 1974), more recent work suggests that at least some differences emerge earlier. For example, Johnson and Meade (1987) reported a male advantage on a range of spatial tasks by 10 years, and S. C. Levine, Huttenlocher, Taylor, and Langrock (1999) reported a substantial male advantage by 4½ years on both spatial translation and rotation tasks.

In what has become a classic paper on sex-related differences in spatial skills, Linn and Petersen (1985) used meta-analyses to identify three components of spatial skills. The first, *spatial perception*, refers to the ability to recognize one's own position (e.g., gravitational upright) in relation to the surrounding environment, even when that environment presents conflicting or embedding cues. The second, *mental rotation*, refers to skill in manipulating, in imagination, figures or objects as they move through two- or three-dimensional space. The third, *spatial visualization*, refers to the use of some combination of verbal or visual strategies to perform multistep spatial tasks. The largest and most robust sex differences have been found in the first two subcomponents. There has been a less consistent pattern of sex differences in the third.

In addition to programs of research that have attempted to identify which categories of spatial skills show sex differences, there have also been programs of research on sex differences on particular tasks. One task that has attracted considerable attention is the water-level task, originally designed by Piaget and Inhelder (1956) to study the child's developing ability to conceptualize space with a Cartesian coordinate system. Specifically, Piaget and Inhelder argued that the

ability to represent invariant horizontals and verticals in the physical world (e.g., the horizontal position of water; the vertical position of a plumb line) would depend on the child's having constructed a conceptual grid of horizontals and verticals. To test this notion, they asked children to indicate the position of water and plumb lines under stimulus conditions that provided conflicting (nonparallel or nonorthogonal) alternative frames of reference, as when the water line needed to be drawn in a tilted bottle. The original description of the task and data seemed to imply that children would master this understanding by the age of 9 or 10, and thus investigators were surprised when reports began appearing showing that many adults had serious difficulty on the task and that women were disproportionately evidencing difficulty (Liben, 1978; Rebelsky, 1964; Thomas, Jamison, & Hummel, 1973).

Explaining Individual and Group Differences in Spatial Thinking

The take-home message from the material presented thus far in this section of the chapter is that people vary with respect to performance on spatial tasks. These variations might reflect different rates of progress through developmental spatial achievements, different developmental end points, differential access to nonspatial component skills that are needed for spatial processing (e.g., working memory), or differential success in activating competencies in a given test environment (e.g., as a consequence of test anxiety). In trying to understand the observed differences, investigators have studied a range of factors drawn from both biological and social domains.

Within the domain of biology, a number of mechanisms have been studied to illuminate both individual differences and sex differences (see review in Liben, Susman, et al., 2002). Genetic influences on spatial skills have been one area of focus. From the perspective of individual differences, investigators have reported significant heritability for spatial visualization and spatial orientation abilities in both children and adolescents (Bratko, 1996; Plomin & Vandenberg, 1980). From the perspective of group (sex) differences, investigators have proposed an X-linked recessive gene for good spatial skills as one explanation for males' higher performance (Bock & Kolakowski, 1973; Thomas, 1983; Thomas & Kail, 1991; Vandenberg & Kuse, 1979). Hor-

monal effects have also been considered as an explanation of both individual and sex differences in spatial skills. For example, investigators have explored links between fluctuating levels of circulating hormones (e.g., as a consequence of pubertal, cyclical, or exogenously administered hormones) and spatial performance with mixed results (see reviews in Kimura, 1999; Liben, Susman, et al., 2002). There is more consistent evidence for effects of prenatal hormones on spatial outcomes. Experimental research with animals has shown direct effects of manipulating prenatal hormones (see Kimura, 1999; Liben, Susman, et al., 2002), and correlational research with humans has linked prenatal exposure to androgens to later spatial abilities. For example, girls with congenital adrenal hyperplasia who are exposed to atypically high levels of prenatal androgen later show elevated spatial skills in comparison to their unaffected sisters (Hampson, Rovet, & Altmann, 1998; Resnick, Berenbaum, Gottesman, & Bouchard, 1986).

Given that biological interventions are unlikely, it is the other major category of explanations, those in the social or environmental domain, that holds more interest for educators. Most of the research linking experience to spatial outcomes has been framed within the study of sex differences. There are plentiful data showing that boys and girls are socialized for different kinds of play, leisure activities, and educational experiences that are thought to be relevant for developing spatial skills (Etaugh, 1983; Serbin & Connor, 1979; Sherman, 1967). Correlational data show significant links between selected kinds of experience and spatial skills both within as well as between sexes (Newcombe, Bandura, & Taylor, 1983; Signorella, Jamison, & Krupa, 1989; Voyer, Nolan, & Voyer, 2000). However, it may be that children who begin with higher spatial skills choose to participate in these kinds of activities, and it may be that children with better initial skills benefit more from similar opportunities (see Casey, 1996; Casey, Brabeck, & Nuttall, 1995).

Only a few studies to date have attempted to examine the role that experiences unrelated to sex typing may play in accounting for differences in spatial outcomes. Illustrative is research showing that the frequency with which parents direct their 5-year-old children's attention to spatial-graphic features of a picture book relates to their children's success on spatial-graphic tasks (Szechter & Liben, 2004). Thus, research to date suggests that certain kinds of experiences do appear to fos-

ter spatial development, although considerably more research is needed to separate what effects are linked to experience separately from biological sex or socialized gender. From an educational perspective, what is most interesting is whether the experiences (e.g., different levels of play with spatial toys) that have been linked to higher spatial performance in correlational research can be exploited as educational interventions to enhance spatial skills.

THE CASE FOR SPATIAL INTERVENTION: WHEN DIFFERENCES ARE DEFICITS

In this section, I turn to interventions, first considering whether interventions are justified and then considering whether there is reason to think that interventions can be effective.

Why Might Spatial Performance Matter?

The research reviewed in the preceding section has established that there is a wide range of performance on any given spatial task at any given chronological age. From an educational perspective, the critical question is whether these performance differences matter. Consider, for example, the water-level task. Should anyone be concerned that some children perform poorly on it at an age at which the majority of children perform well? Should anyone be concerned that, on average, the task elicits significantly worse performance in groups of girls or women than in groups of boys or men? Should anyone be concerned that even by adulthood, a sizable portion of the population fails, even though the task was designed for young children and even though the initial Piagetian description of responses to the task implied that it would be universally mastered by middle or late childhood?

There are at least three potential reasons that these kinds of differences in performance might be of concern. The first is when performance on a given task directly affects the educational or occupational opportunities open to the individual student. It is easiest to appreciate the direct impact of test-specific performance by example. Consider elementary children's scores on an intelligence test such as the Stanford-Binet Test of Intelligence that may be used to decide on admission to a gifted program or a magnet school, or consider high school students' scores on national tests such as the

Scholastic Aptitude Test (SAT) that may be used to decide on admission to a selective college or eligibility for a scholarship. Unquestionably, performance on specific tests can play a critical role in opening or closing educational doors to individual students. If the water-level task (or some other spatial test) were used for educational decisions of this kind, performance would indeed matter to the individual student.

Second, performance on a given task, amalgamated at the level of an educational institution, can play a powerful role in how the institution is evaluated, and thus ultimately on how that institution operates. Again, the point is made most dramatically by considering the way teachers, schools, and school districts are being evaluated by their students' performance on national, standardized tests of reading and mathematics. Units whose students are judged to demonstrate inadequate levels of performance may be subject to various kinds of administrative sanctions. If students' performance on spatial tests were added to performance on English and math tests in evaluating institutions, then performance on the specified spatial tasks would be educationally critical.

Third, and conceptually most important, performance on a given spatial task may be educationally important because it reveals something about the child's mastery of cognitive tools that are truly needed for myriad educational challenges in their current and future educational, occupational, and daily lives. Again, by way of analogy, consider the arguments made for concern about students' performance on English tests. Performance on, say, a reading comprehension test is considered important not because it shows that the individual has understood the particular passages used in that test, but because it is taken as indicative of verbal literacy. Educational institutions and society as a whole view verbal literacy as critical for individuals' roles as students (e.g., learning from textbooks), workers (e.g., reading equipment manuals, reading and writing memos), and competent and informed citizens (e.g., reading newspapers to acquire knowledge relevant to political choices). A similar argument holds for tests of quantitative skills and mathematical literacy, which are likewise understood as necessary for school subjects (e.g., chemistry and social studies), occupations (e.g., sales and engineering), and daily life (e.g., adjusting a recipe, calculating how many gallons of paint are needed for one's house). If spatial literacy were judged to be similarly important for educational, occupational, and life tasks, performance on tests that assessed rele-

vant components of that literacy would also be judged to be educationally important.

Does Spatial Performance Matter?

In the preceding section, I argued that under certain conditions, performance on particular assessment tasks would matter educationally. Do any of these conditions hold for spatial assessments?

The first condition concerns whether an individual's performance on particular spatial tasks directly affects the educational or occupational opportunities afforded that individual. In general, performance on spatial tasks is not used as a criterion for selection into academic programs. That is, most admissions or selection committees use performance on verbal and quantitative assessments in their decisions, and typically do not even ask applicants to submit data from explicit spatial assessments. This may well explain why research samples drawn from a given school population (e.g., a highly selective university) typically have a wide distribution of scores on spatial assessments such as the water-level task (Sholl & Liben, 1995). There are, however, some specialized programs in which performance on spatial tasks is explicitly used as part of selection criteria. For example, dental schools require applicants to take the American Dental Association's admission test that includes a Perceptual Ability Test designed to assess visual spatial skills. Many schools of architecture employ institutionally designed tests with spatial skill components. For younger students, it is unusual although not impossible to find selection through spatial testing. One example is the Johns Hopkins University Center for Talented Youth (CTY), which includes performance on a spatial test battery as one route for admission into its special programs. Interestingly, and consistent with the general assertion that spatial testing is not common, the spatial test battery is one that was developed and is administered through CTY. This home-grown approach contrasts markedly to the way CTY handles verbal and mathematical assessments. For these, applicants are simply asked to submit test results from any of a large set of national and state tests (e.g., the SATs, California Achievement Tests, Differential Aptitude Test, Independent School Entrance Examination, Iowa Test of Basic Skills). Thus, to summarize, there is some evidence that performance on spatial tests does open or close doors to some kinds of educational and occupational opportunities, although performance on tests de-

signed to test verbal and mathematical skills or achievement is generally used far more pervasively.

With respect to the second potential reason that scores on spatial measures might be of educational importance, I am aware of no case in which students' spatial performance is used to evaluate the efficacy of educators or educational institutions. In the closing section of this chapter, I return to this issue from the perspective of educational policy.

Finally, as noted in the prior section, the third and most important reason that one might be concerned if an individual performed poorly on a particular spatial task is that this performance indicates inadequacy in a cognitive tool that is needed (or useful) for achieving valuable educational goals. The empirical work on which one can draw to answer this question is somewhat spotty, in large part as a consequence of the relatively sparse use of spatial testing (noted in discussing the first of the three conditions). There are data showing a relationship between performance on spatial tests and success in specialties that are—on their face—highly spatial in nature. As summarized by Shea, Lubinski, and Benbow (2001):

Proficiency in spatial ability has long been associated with success in cognitively demanding educational tracks and occupations such as engineering, architecture, physics, chemistry, and medical surgery, as well as trades such as artisan, certain industrial positions (e.g., die checker, detailer, and pattern checker), surveyor, draftsman, and cartographer. (p. 604)

This is, of course, the rationale behind using spatial testing for admissions decisions for entry into some of these fields.

What is less well established is the relationship between performance on spatial tests and success in more universal components of education. The most commonly examined link between spatial ability and standard educational curriculum is in mathematics, again with much of this work being driven by an interest in accounting for sex-related differences. For example, in one program of research addressed to the role of spatial abilities in mathematics (Casey, 1996), mental rotation scores predicted to math ability as measured by the mathematics portion of the SAT. Combining these data with those from other research paradigms, Casey suggested that what accounts for the relation is not merely that some mathematical thinking is explicitly spatial (e.g., geometry), but also that effective mental rotation skills may

mark a general predisposition to using spatial strategies to process information. Such strategies may be generally helpful for mathematical reasoning that is not explicitly spatial (e.g., as in using spatial representations to solve algebra problems or transitive reasoning tasks). This interpretation has been supported by findings from research with middle school children as well (see Casey, Nuttall, & Pezaris, 2001), and by various studies examining strategies for solving different kinds of math problems (e.g., Johnson, 1985; Pattison & Grieve, 1984).

The other major educational domain that has been linked to spatial skills is science. The most dramatic links come not from research correlating spatial test performance to science outcomes, but from autobiographical accounts of scientific discoveries. Among the best known is Kekule's (1965) attribution of his discovery of the benzene ring to a dream in which he saw a serpent of atoms seizing its own tail, Einstein's claim that "he rarely thought in words at all" and that his visual and "muscular" images had to be translated "laboriously" into conventional verbal and mathematical terms, and Feynman's use of "Feynman diagrams" rather than lists of equations to work on quantum mechanics (Ferguson, 1992, p. 45). Working at an entirely different size and time scale, Wegener (1915/1966) noticed the "fit" between the coastlines of Africa and South America, leading him to develop the theory that continents were once one encompassing continent (Pangaea).

These descriptions from the history of science suggest that spatial thinking may well be important for dramatic scientific discoveries, but they do not necessarily bear on the question of whether spatial skills facilitate mastery of existing science curriculum among students in general. A number of scholars interested in science education have hypothesized that there should be such a connection (Mathewson, 1999), and investigators have tested this relation empirically in particular disciplines. In chemistry, for example, Bodner and colleagues (Bodner & McMillen, 1986; Carter, LaRussa, & Bodner, 1987) have reported significant correlations between performance on a variety of spatial assessments and success in solving various chemistry problems. Interestingly, however, the associations between variables have been found not only for chemistry problems that are analyzed as being "spatial" but also for chemistry problems that do not, at least on their face, appear to require spatial reasoning. One possible reason for finding an association between higher spatial skills and better performance on chemistry problems in general might be

that the spatial assessment taps students' general intellectual levels. It is also possible that students with better spatial skills are more likely to create spatial-graphic representations (diagrams) to stand for nonspatial problems and hence organize the relevant information more effectively (Wu & Shah, 2004). Additional research is needed to test increasingly specific hypotheses about what spatial skill or skills are required for solving particular scientific problems, and then focus directly on these more specific relations.

In the research just described, the strategy has been to identify, analytically, spatial skills that underlie learning science concepts, and then to test for a correlation between that spatial skill and learning. A second research strategy is to provide instruction in the spatial skill so identified, and then study whether there is concomitant improvement in science learning. Finding a positive effect of the intervention would not only provide converging evidence for the hypothesis that the identified spatial skill is relevant to the math or science outcome, but, in addition, would support the utility of using interventions aimed at enhancing spatial skills. In the next section, I turn to work in this tradition.

Can Spatial Thinking Be Improved?

Before promulgating greater attention to spatial education in our educational system and before identifying routes through which it might be offered, it is important to ask whether there is any evidence that spatial skills can be affected by intentional interventions. Two major strands of work are encouraging in this regard. The first is found in the psychological research literature. This work has focused largely on the degree to which abilities are subject to intervention in general, with particular interest in whether it is possible to overcome the well-documented sex-related difference in spatial performance through training. The second is found largely in the professional or disciplinary education literatures, where the work has focused on developing and evaluating curricula designed to improve students' educational success.

Illustrative of work in the psychological tradition is laboratory research showing that performance on traditional spatial tests can be improved with training. For example, Kail and Park (1990) gave children and adults (11- and 20-year-olds) extensive practice and feedback on mental rotation tasks and found that speed of rotation improved significantly. The improvement, however, was confined to the same kinds of stimuli that were used in

training. Similar findings were reported by Sims and Mayer (2002) using the computer game Tetris in which the user must rotate shapes as they fall downward so that they fit neatly into openings as they reach the bottom of the screen. Students who were already skilled with Tetris performed better on a mental rotation task than did non-Tetris-players, but only when the shapes to be rotated were similar to those familiar from Tetris itself. Parallel findings have been reported for training on the water-level task: Participants given experience with feedback on the water-level task improved relative to controls. However, the advantage was found largely on items that were highly similar to those used in training (i.e., same-shaped containers at the same angles). These findings suggest that it may be specific angular relations between the water line and the bottle side that are learned rather than a generalized representation of invariant horizontality (Liben, 1991b). On the other hand, some training studies have shown positive effects of practice from mental rotation games or water-level stimuli to later performance on paper-and-pencil tests with different stimuli (De Lisi & Wolford, 2002; Okagaki & Frensch, 1994; Vasta, Knott, & Gaze, 1996). More generally, Baenninger and Newcombe (1989) summarized spatial training effects by a meta-analysis of training studies that were aimed at examining whether the sex differences in spatial performance are amenable to instruction. From the perspective of gender, what is particularly interesting about their findings is the conclusion that sex differences remained comparable even after training. From the perspective of spatial education, however, what is particularly interesting about their findings is the conclusion that training affected spatial performance significantly and often with considerable generality in both males and females.

Illustrative of work in the professional education tradition is work in engineering. For example, engineering students who performed at relatively low levels on a mental rotation test were given a curriculum to teach 3-D visualization skills prior to entering the required course in engineering graphics (Sorby & Baartmans, 1996, 2000). Participation in this curriculum increased performance on later standardized tests (e.g., the Spatial Relations test of the Differential Aptitude Test), and improved student retention. There have also been various spatial training programs as part of science education. For example, Pallrand and Seeber (1984) provided college students taking a college physics course with practice in drawing outdoor scenes, instruction in geom-

etry and geometric transformations, and other curricula that focused students' attention on how views differ from different positions. Instructional sessions were over an hour long and were given weekly for roughly 2½ months. The intervention was successful: Visual skills and physics grades were higher in the intervention group than in a control group. In chemistry, interventions have also been shown to have a positive effect. For example, giving students training on visualization skills later elicited higher performance on test questions requiring the use of 3-D models (Small & Martin, 1983), and practice on several kinds of visual thinking relevant to chemistry improved students' test performance (Tuckey, Selvaratnam, & Bradley, 1991). Educational interventions of these kinds have not, however, been uniformly successful in improving outcomes or in generalizing to new settings. For example, engineering students whose performance on spatial tasks had improved from software used in an engineering graphics course were no more likely to remain in the program (Devon, Engel, & Turner, 1998). Chemistry students who showed gains from spatial training did not transfer those gains to new settings (Tuckey & Selvaratnam, 1993). The pattern of both positive and negative results establishes that educational interventions *can* be effective, although we are far from knowing precisely the detailed conditions required to make them so.

Should Spatial Performance Be Improved?

A strong case for spatial education may be built from the kinds of evidence described earlier indicating that spatial thinking is important not only for generating scientific discoveries but also for mastering routine educational curricula in math and science. Furthermore, it is likely to become increasingly important as technology offers increasingly sophisticated and complex spatial-graphic displays of voluminous quantities of information relevant to our occupational, educational, and everyday lives. Even apart from facilitating cognitive outcomes, research suggests that enhancing spatial skills may offer motivational benefits. Relevant is work by Casey and her colleagues (Casey, Nuttall, & Pezaris, 1997, 2001), who examined the role that spatial abilities may have in girls' attitudes toward math. Casey et al. (1997) found that 10th-grade girls' (but not boys') attitudes toward math were affected by their scores on a mental rotation task. Given that attitudes have a powerful effect on whether students decide to take more advanced mathe-

matics classes and whether they are motivated to apply themselves to master the material (Jacobs & Eccles, 1992), enhancing spatial skills may have a positive impact even apart from their direct facilitation of mastering mathematical or scientific material.

Taken together, these issues lead to the conclusion that there is great value in incorporating education for spatial thinking into the school curriculum. Indeed, given the wide range of educational, occupational, and daily activities that draw on spatial thinking, it is puzzling that spatial education does not already occupy central stage. One might hypothesize that the omission is simply a reflection of the pervasiveness of spatial thought discussed in the introductory section of this chapter. But it is relevant to recall that Molière's Monsieur Jourdain was shocked to discover he had been speaking prose all his life, not shocked to discover that he had been thinking spatially all his life. Yet, so much of our educational curriculum explicitly focuses on verbal, not spatial, skills. One might hypothesize that the balance is linked to the differential need for verbal versus spatial education in boys versus girls. It is interesting to observe that the educational community provides extensive education and remedial programs in the verbal arena that traditionally presents more problems for boys, but not in the spatial arena that traditionally presents more problems for girls. There are many potential attributions for this difference, ranging from chance, to political beliefs about the differential importance of having the full range of occupational opportunities open to males versus females, to beliefs about the role of biological foundations of verbal versus spatial abilities, to beliefs about their differential susceptibility to environmental input. But regardless of which (if any) of these factors has played a role in creating an educational environment that emphasizes verbal but not spatial education, it is time to begin to redress the balance. In the remainder of this chapter, I turn to one avenue by which spatial thinking might be fostered in the school context.

THE PLACE OF GEOGRAPHY AND MAP EDUCATION IN DEVELOPING SPATIAL THINKERS

Thus far in this chapter, I have argued for the pervasive nature of spatial thinking and its importance for a range of educational goals and have reviewed various kinds of evidence leading to the conclusion that it is risky to

leave children entirely to their own devices to develop spatial concepts and to become fluent in developing and applying spatial skills. That is, psychometric studies and research by cognitive and cognitive-developmental psychologists show that not all individuals excel in the declarative, procedural, and representational skills that constitute spatial thinking, nor in the metacognitive skills that allow students to identify and implement potentially useful spatial strategies. At the same time, data from intervention studies show that certain kinds of experiences can be effective in enhancing spatial performance. This does not imply that interventions will necessarily bring all children to the same skill level (any more than instruction in English or in mathematics brings all children to the same level of sophistication in reading, writing, calculating, or mathematical reasoning). But it does imply that it is possible to enhance spatial thinking, and that there is a role for spatial education in our schools.

Spatial Education in the School Context

Even if one accepts the conceptual arguments about the importance of spatial thinking and the empirical conclusion that spatial thinking can be facilitated through interventions, there remains the practical question of how spatial thinking might be taught in the school environment. There are two potential avenues to implement spatial education.

One approach is to target spatial skills for education much the way verbal and mathematical skills are targeted for education, that is, as domains in their own right that are taught through specific courses and evaluated through specific achievement assessments. This approach may be rejected on two grounds, one conceptual and the other practical. The conceptual argument against it is that we do not currently have the kind of analysis of concepts and skills to support a developmentally sequenced abstract curriculum of this kind (see, e.g., the discussion in the introductory section on definitions concerning formalisms in language versus space). The practical argument against a stand-alone spatial curriculum is compelling. Quite simply, the pressures on instructional time already overwhelm teachers, and adding an entirely new core curriculum would be unworkable.

The second and more realistic approach is to infuse spatial education into disciplinary instruction that is already in the curriculum. Ideally, the infusion process

would involve making spatial education explicit in a broad range of school subjects. Courses in science and mathematics provide obvious examples. One might, for example, explicitly contrast two- versus three-dimensional models of chemical molecules, provide practice in linking rotations of concrete models to mental rotations of internally stored images, and perhaps explore what might be understood or communicated differently with alternative models of the same molecule. But even school subjects that are not as obviously spatial in nature can offer relevant opportunities. For example, in discussing literature, spatial representations might be used to model the flow and interconnections among plot lines of the story or among characters.

Even this second approach is subject to practical constraints, however, because teachers, like most of us who have been educated in the United States during the past century, are unlikely to have experienced explicit spatial education themselves. It is thus likely that they would find it difficult to identify opportunities for explicit instruction in spatial thinking and representations. A more realistic approach is to identify one or more existing school subjects that are transparently relevant for studying and facilitating spatial thinking and to use that subject as a vehicle for providing instruction aimed at developing spatial thinking. There are a number of desiderata for selecting a school subject: It should be viewed as an important component of any child's education; it should be taught across a range of grades; and it should be a subject that explicitly places all three aspects of spatial thinking identified earlier (i.e., declarative, procedural, and representational) at its core. I would argue that one school subject that satisfies these desiderata well is geography. In the remainder of this section of the chapter, I develop the argument that geography education is an important and viable route for educating spatial thinkers, and that a core component of geography education—map education—is a particularly valuable vehicle through which to develop spatial thinkers.

Geography and Geography Education

In the period following the founding of the United States as a nation, geography was viewed as an essential part of education. A citizen would have been considered educated only if educated in geography. This point was argued by John Adams in a letter to Abigail Adams in 1776 when he wrote:

Geography is a Branch of Knowledge, not only very useful, but absolutely necessary, to every Person of public

Character whether in civil or military life. Nay it is equally necessary for Merchants. . . . America is our country, and therefore a minute Knowledge of its Geography, is most important to Us and our Children. (as quoted in Downs, 2004, p. 184)

The centrality of geography as a school discipline has since declined. Indeed, there was a long period in the United States in which geography was not taught systematically in the classroom. Following one such era in the 1980s, the media began carrying articles about shocking levels of geographic ignorance among U.S. citizens. Illustrative was a report that 20% of 12-year-olds in North Dallas misidentified Brazil as the United States on a map of the world, and that only about a third of students tested in a North Carolina college knew that the Seine was in France (*U.S. News & World Report*, March 25, 1985). Stories like these led to the proclamation of Geography Awareness Week by the U.S. Congress and to the establishment of an annual National Geography Bee by the National Geographic Society (see Liben, 2002a). From the perspective of formal education, however, probably the most significant sign of the reemergence of geography as a school discipline was its inclusion in federal legislation that established goals for K–12 educators. Specifically, the third goal of *Goals 2000: Educate America Act* (Public Law 103-227, March 31, 1994) included geography among the list of subjects that students should master.

As was the case for other school subjects named in *Goals 2000*, leaders in the discipline worked together with consultation from other stakeholders to develop national standards. Standards were designed to specify the knowledge and skills that children should acquire in the course of their education in each of the *Goals 2000* disciplines. Assuming that many readers would approach the geography standards with the regrettable assumption that geography is merely the compilation of endless place location and product production facts (e.g., that Paris is the capital of France, or that cheese is a major product of Wisconsin), the writers of *Geography for Life: National Geography Standards 1994* (Geography Education Standards Project, 1994) began their definition of geography by saying what it is *not*: “Geography is not a collection of arcane information.” Rejecting the notion of geography as “the rote memorization of isolated facts,” the authors went on to define geography as

the study of spatial aspects of human existence . . . an integrative discipline that brings together the physical and

human dimensions of the world in the study of people, places, and environments. Its subject matter is Earth’s surface and the processes that shape it, the relationships between people and environments, and the connections between people and places. (p. 18)

Myriad examples of what geography is and why it matters may be found in the *National Geography Standards*.

Once one appreciates that geography is more than place locations, it becomes apparent that geographic ignorance is more than a failure to know endless strings of location facts. And just as there is ample evidence that children (and even many adults) are ignorant about location facts, so, too, there is ample indication that many individuals are ignorant about deeper geographic thinking, and make geographically uninformed decisions as a result. Illustrative are the industrial decisions that lead to venting manufacturing pollutants into the air or water without considering possible global effects, building new residential developments without adequate thought to infrastructure demands, and making military or political decisions without knowledge of the terrain or the way the terrain is used by local inhabitants. Recognizing the costs of geographic ignorance has in part motivated more attention to geography education in our public schools (although the commitment contributes to ebb and flow even in contemporary times; Downs, 2005).

In the context of the current chapter, what is particularly important about geography education is that it provides an entrée into spatial thinking: “At its core, geographic thinking is *spatial* thinking. Geography is concerned with the explanation of spatial patterns and processes, and therefore the discipline is by its nature one that requires and fosters spatial thought” (Liben & Downs, 2001, p. 223). Geographic spatial thought takes place not only in abstract ideas and concepts, and is recorded and communicated not only in words and numbers, but also with maps.

Maps and Map Education

In this section, I turn more explicitly to the importance of maps and map education, not only as a support for geographic understanding, but also as an important kind of representation for a variety of other disciplines, intellectual processes, and educational goals. Given my expectation that most readers will be products of an educational era in which geography has held a relatively small role, I also include a brief tutorial on the principles and functions of maps. Only if one appreciates the richness of map forms and functions can one appreciate

the role that map education may play in educating spatial thinkers.

Maps as Tools within and beyond Geography. Maps are arguably the single most important tool for geographical thinking and hence for geographic education. Their centrality is made readily apparent by the role they play in the *National Geography Standards* (Geography Education Standards Project, 1994). It is telling that the very first standard explicitly states that students should know “how to use maps and other geographic representations, tools, and technologies to acquire, process, and report information from a spatial perspective” (p. 61). This general standard, like all standards, is then translated into recommendations for the knowledge and skills that children of different ages should master. For example, the standards prescribe: “By the end of the fourth grade, the student knows and understands . . . characteristics and purposes of geographic representations—such as maps, globes, graphs, diagrams, aerial and other photographs, and satellite-produced images” (p. 106). The standards identify the kinds of observable behaviors that may be used to indicate that the child has, in fact, acquired the prescribed knowledge and skills. To continue with the illustration of the first standard, by the end of fourth grade, the student should be able to “interpret aerial photographs or satellite-produced images to locate and identify physical and human features. Examine a variety of maps to identify and describe their basic elements. . . . Design a map that displays information selected by the student” (p. 106). But the role of maps is not limited to the first standard. Of the 18 standards listed in *Geography for Life*, 13 of them refer explicitly to maps or other kinds of representations of spatial distributions. Of the remaining five, maps are strongly implicated in three and implicitly relevant to the other two (Liben & Downs, 2001).

Even in the absence of geography lessons, most people are familiar with maps. In the United States, maps appear at information booths of shopping malls, in newspapers, in travel brochures, in parks, and in cars, to name only a few of the many venues. In light of this pervasiveness, it is perhaps not surprising that both children and adults are highly familiar with some kinds of maps and map functions. For example, when preschool children were asked “Do you know what a map is? What’s a map?” (Liben & Yekel, 1996, p. 2786), over half were able to explain maps as archives of location information (e.g., “Where things are” and “Things with different countries”), as navigation tools (e.g., “Something to get around places” and

“Something if you get lost, it helps you to get somewhere . . . maybe home”), or as both (e.g., “Something you see around the world. You can know where to go. If you get lost, you can look at a map and know where to go”). When college students were asked similar questions (Liben & Downs, 2001), responses likewise revealed familiarity with maps, although again, with an almost exclusive focus on archiving and wayfinding functions (rather than on other map functions discussed later). Similarly, both children and adults readily recognize that certain kinds of graphic representations are maps. However, for children, the map category tends to be relatively restricted to a small set of prototypical maps (e.g., state road maps and political maps like those hanging on classroom walls). Adults have a broader category, but even many adults reject graphic representations of place that expert geographers categorize as maps (Downs, Liben, & Dagg, 1988). It is thus important to review the broad range of maps and the functions that they serve.

Map Definitions and Map Principles. Just as the writers of the *National Geography Standards* began their definition of geography by saying what it is not, it is helpful to begin defining *map* by saying what it is not. Maps are not simply miniaturizations of some singular reality: “A map is a generalized, reduced, symbolic spatial representation of reality that has been transformed from the spherical surface of the Earth (or any celestial body) in some dimensionally systematic way” (Liben & Downs, 1989, p. 180). All maps instantiate three general principles (Liben, 2001):

1. The *duality principle*: A map has a dual existence: It *is* something and it *stands* for something.
2. The *spatialization principle*: A map has a spatial essence: It not only represents something, it represents something *in relation to space*.
3. The *purpose principle*: A map has purpose: It is not only *of* something, it is *for* something.

The Duality Principle. The duality principle is one that applies to any concrete, physical, spatial representation (or *spatial product*; see Liben, 1981, 2005). Anything used to stand for something else simultaneously has an existence in its own right as well as an existence as a representation or symbol that stands for its referent, a fact long recognized about representations and symbols (Goodman, 1976; Potter, 1979). The duality principle means that some but not all map qualities carry representational meaning about the referent. As an illustration,

consider a road map of Pennsylvania such as one that might be stored in the glove compartment of a car. Many qualities of the map carry representational meaning about the environmental referent for which it stands. The lines stand for roads, the bends in the lines stand for the bends in the roads, and different colored lines represent different categories of roads. The first two qualities of the road symbols—that they are linear symbols and that they bend in certain directions—are motivated by the properties of the referent. That is, both the representation and the referent are linear and bend. The third quality of the road symbols—their color—is arbitrary. The different line colors do not imply different pavement colors; instead, they are used to symbolize different kinds of roads (e.g., toll roads, two-lane roads). The cartographer's choice of colors might be entirely arbitrary, based on convention, motivated by an aesthetic judgment, driven by metaphor, or chosen because they are perceptually easy to discriminate (see Brewer, 1997; Brewer, MacEachren, Pickle, & Herrmann, 1997). Users must refer to a map key to interpret the referential meaning of each colored line.

Not all qualities of the representation, however, carry referential meaning. For example, the fact that the map is a flat piece of paper is not meant to suggest that the state itself is flat, nor are the layers of the folded map meant to represent the geological folds of the mountains of central Pennsylvania; the width of the road lines is not informative about the road width, but is instead selected for legibility. For example, if one were to apply the scale given in the National Geographic Society (1998) *Road Atlas of the United States* to the road symbols, the roads would be calculated to be over five miles wide. In these examples, the flatness, folds, and line width are incidental features of the map. Interpreting the relationship between the referent and the representation, or what have been called the *representational correspondences* between the symbol and map (see Liben & Downs, 1989), is a necessary component of map understanding. In the absence of understanding representational correspondences, map users will draw incomplete or incorrect meanings from representations, a point discussed at greater length later in this chapter.

The Spatialization Principle. Implicit in the examples used to discuss the duality principle have been allusions to spatial qualities of maps. For example, the road symbols were referred to as linear, with the placements and bends in the lines following an analogous path to locations and bends in the road. Linear symbols may be contrasted to “point” symbols, appropriately used for

specific locations (e.g., highway exits), and to “areal” symbols, appropriately used for regions (e.g., areas of national forests). The type of symbol is not determined solely by the type of referent, however; it also reflects the scale of the map. Thus, for example, Chicago would be represented by a point symbol on a small-scale map of the entire world, but would be represented by an areal symbol on a large scale map of Illinois. These spatial qualities of symbols and referents (see Muehrcke & Muehrcke, 1998) thus segue to the spatialization principle, which highlights the central place of space in all maps. The centrality of space is evident in an introductory statement about maps taken from a classic cartography textbook, “All maps have the same basic objective of serving as a means of communicating spatial relationships and forms” (Robinson, Sale, Morrison, & Muehrcke, 1984, p. 4), and in a dictionary definition of maps that begins: “a representation, usually on a flat surface, as of the features of an area of the earth or a portion of the heavens, showing them in their respective forms, sizes, and relationships according to some convention of representation” (Flexner & Hauck, 1997, p. 1173).

The spatial qualities of any given map may be described by reference to the three dimensions of the “cartographic eye” (Downs, 1981) or the “mapmaker's vantage point” (Muehrcke & Muehrcke, 1998), illustrated in Figure 6.1. These include viewing distance,

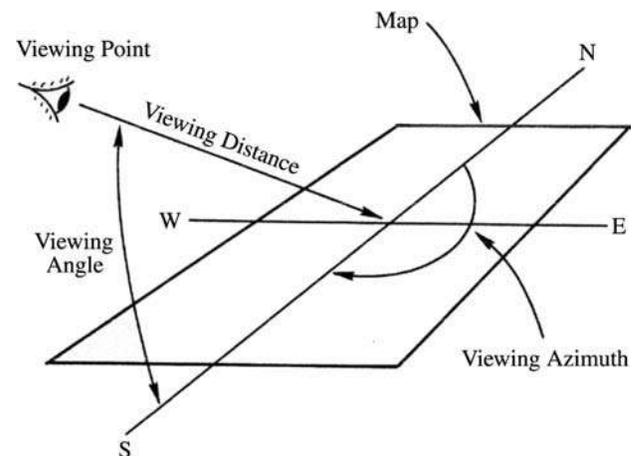

Figure 6.1 The cartographic eye showing the three dimensions of viewing distance, viewing angle, and viewing azimuth. *Source:* From “Maps and Mappings as Metaphors for Spatial Representation” (pp. 143–166), by R. M. Downs, in *Spatial Representation and Behavior across the Life Span: Theory and Application*, L. S. Liben, A. H. Patterson, and N. Newcombe (Eds.), 1981, New York: Academic Press. Reprinted with permission.

viewing angle, and viewing azimuth. Thus, just as there are representational correspondences that refer to which aspects of the referent are depicted on the map and the symbolic forms that are used to depict them, so, too, there are *geometric correspondences* that refer to the way the spatial qualities of the referent are represented by the spatial qualities of the map. Interpreting these geometric correspondences, like interpreting representational correspondences, is critical for map understanding.

The first dimension of the cartographic eye, viewing distance, refers to the distance from which the referent space is depicted. Viewing distance translates into the scale of the map. A map of any given referent space (i.e., the area being depicted) shown on any given representational space (i.e., the size of the particular piece of paper on which it is drawn) fixes the map scale (in cartographic terms, the “representative fraction”). For example, a piece of paper that measures $8\frac{1}{2}'' \times 11''$ might be used to represent all of Chicago, in which case the scale would be roughly 1:12,000. Alternatively, it might be used to represent a room, in which case the scale would be roughly 1:20. The second dimension of the cartographic eye, viewing angle, refers to the direction along the vertical dimension from which the referent space is depicted. The most common viewing angle is 90° (straight down), producing what are known as orthogonal, overhead, nadir, or vertical views, resulting in plan view maps like those commonly posted on hotel doors to show the locations of fire escapes. Shallower or oblique views (e.g., of 30° or 45°) depict the referent space from a slanted angle; these are often seen in historical maps of cities and are sometimes used in contemporary times for tourist maps. Oblique maps make landmarks (such as buildings) more recognizable and depict important topography (e.g., the steep hills of San Francisco). Illustrations of plan and oblique maps are shown in Figure 6.2. Finally, the third dimension of the cartographic eye, viewing azimuth, refers to the direction from which the referent space is depicted, conventionally expressed as angular disparity from north. Figure 6.3 shows an oblique map of the same region from two different viewing azimuths.

When small or even medium-size areas are being mapped (e.g., rooms, buildings, neighborhoods, cities), the relationship between referent space and paper space remains constant because over these distances, one can generally disregard the Earth’s curvature (at least with maps that use parallel rather than central perspective; see

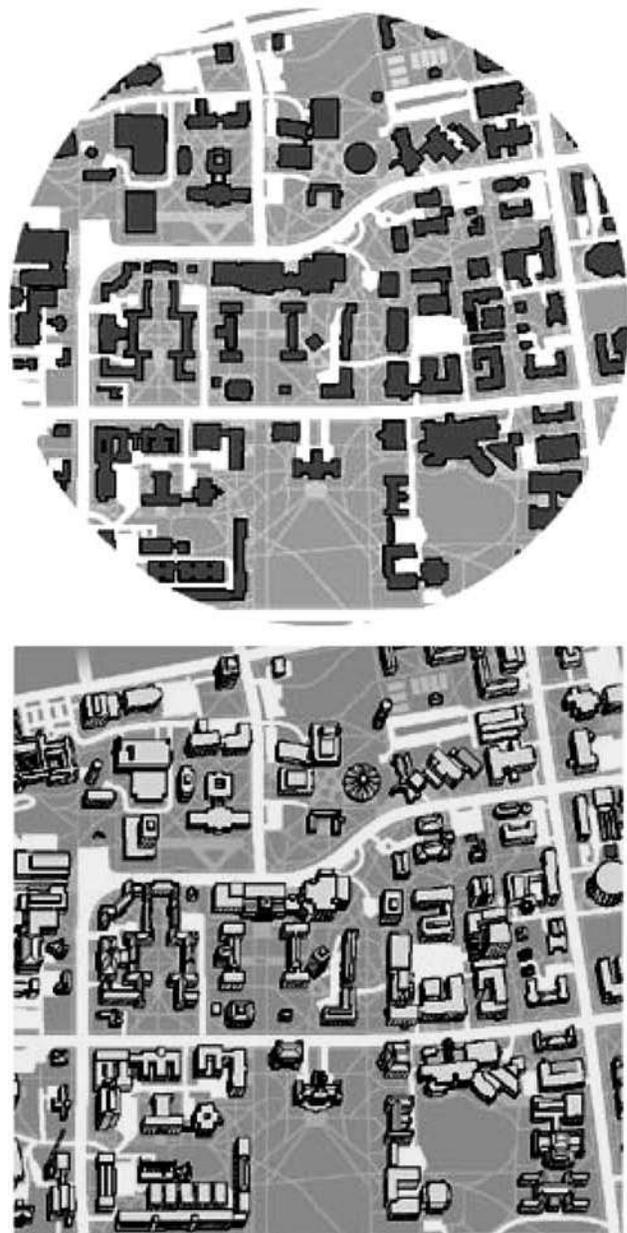

Figure 6.2 A circular plan map (top) and a square oblique map (bottom) of the Penn State campus.

Muehrcke & Muehrcke, 1998). However, when larger areas are mapped (e.g., states, countries, or continents), the Earth’s curvature becomes relevant, and geometric solutions are needed to project the curved surface of the spherical Earth onto the flat surface of the map. The kind of surface on which the three-dimensional sphere is projected before being “unfolded” (e.g., a cone, a cylinder) and the location at which it is centered (e.g., centering the representation on the equator versus the North Pole)

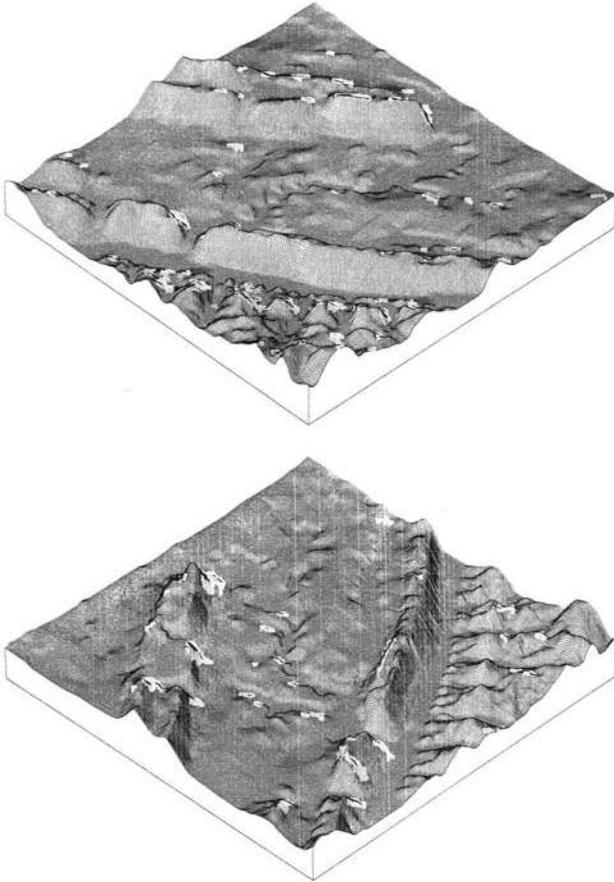

Figure 6.3 Two oblique perspective representations. In both images, the viewing angle is 30° . The viewing azimuth of the top representation is 315° clockwise from north (0°), and the viewing azimuth of the bottom representation is 45° clockwise from north.

also play powerful roles in determining the appearance of the representation. It is important to appreciate that whenever a three-dimensional space is projected on to a two-dimensional surface, at least one spatial property of the referent space (area, direction, distance, or shape) *must* be distorted. Thus, there is no single “correct” solution to this projection problem. A solution used for a particular map should be driven by the purpose the map serves, thus leading to the third map principle.

The Purpose Principle. As might be inferred from the examples given in the course of discussing the duality and spatialization principles, there are virtually limitless choices with respect to the “what” for any given map (i.e., the referential content that is depicted) as well as with respect to the “how” of any given map (i.e., the

representational and geometric qualities used to represent the chosen content). This diversity of content and form is another way of reinforcing the general point made earlier that maps are not simply some externally determined and singular miniaturization of some fixed reality. The purpose of a map affects the form that a map takes. Thus, for example, a map intended to show major political divisions and perhaps the role of physical geography in those divisions (e.g., the locations of rivers, ports, and mountain ranges that might be used for determining political boundaries) would sensibly be created in a smaller scale (i.e., depict a larger space) than would a map intended to allow someone to plan a car trip across the same areas. The former would omit roads; the latter would show them in detail. Although decisions to omit or include particular kinds of information (e.g., roads) may reflect practical matters (e.g., the room for the symbols given a particular map size), more important, they reflect the cartographer’s intentions to highlight certain ideas and relationships.

Consider the two examples of world maps shown in Figure 6.4. The first is the highly familiar Mercator projection; the second is an equal area projection. Both distort spatial features of the real world, as they must,

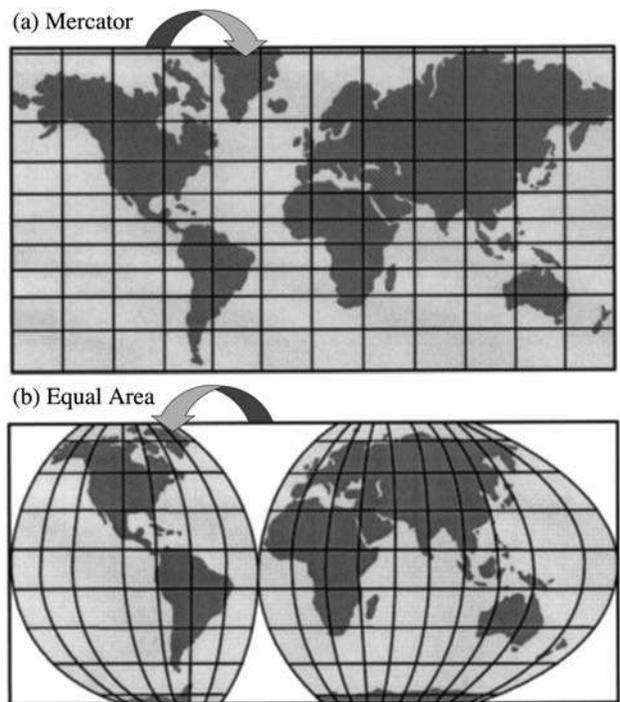

Figure 6.4 World maps in (a) a Mercator projection and (b) an interrupted flat polar quartic equal-area projection. Arrows point to Greenland.

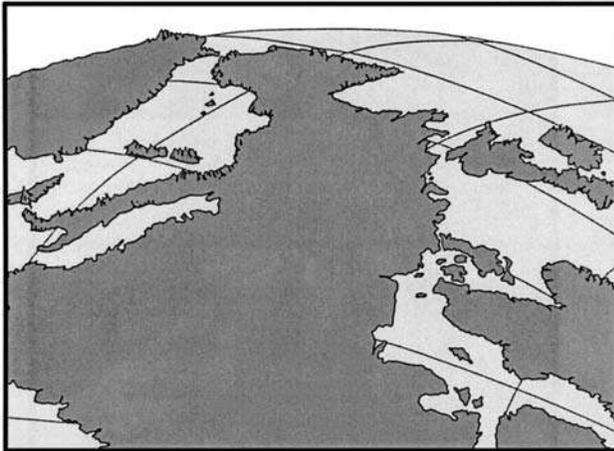

Figure 6.5 An oblique perspective map of Europe as viewed from the east. *Source:* From “Thinking through Maps” (p. 53), by L. S. Liben, in *Spatial Schemas and Abstract Thought*, M. Gattis (Ed.), 2001, Cambridge, MA: MIT Press. Reprinted with permission.

given the need to project the three-dimensional oblate spheroid of Earth onto two-dimensional paper. But the choice of distortions is linked to the purpose of the map. The Mercator projection distorts area but preserves direction; the equal area projection distorts direction but preserves area. The former is no less accurate than the latter, and it serves the purpose for which it was intended, namely, sea navigation. As another example, consider the map of Europe shown in Figure 6.5. It suggests the vulnerability of Western Europe to military action from the east. It thereby offers a vision of “reality” that is different—but no less “accurate”—from the one most of us will have developed from repeated exposure to the more common north-at-the-top, vertical view maps of Europe.

Map Functions. From the perspective of using map education as a means of the more general goal of spatial education, it is useful to summarize map functions from the perspective of geography, and in the course of doing so, provide a few additional illustrative maps that fall outside the prototypical maps commonly found in cars, psychology journals, and teacher-preparation classes. A useful list of map functions is the following one, taken from a basic cartography text by Muehrcke (1986, p. 14):

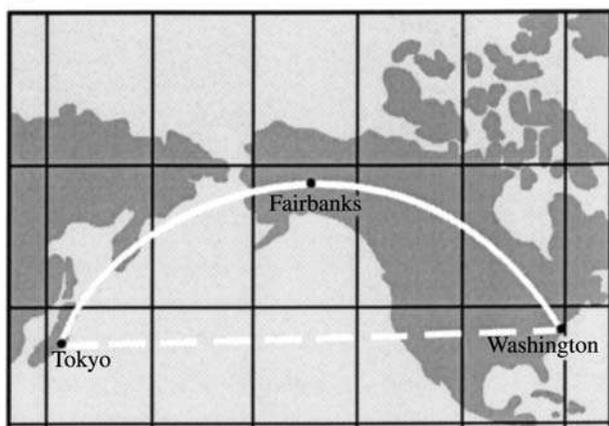

1. Record and store information.
2. Serve as computational aids.

3. Serve as aids to mobility.
4. Summarize complex, voluminous data.
5. Help us to explore data (analyze, forecast, spot trends).
6. Help us to visualize what would otherwise be closed to us.
7. Serve as trigger devices to stimulate thought.

As noted earlier, both children and adults tend to be most familiar with archival (1) and wayfinding (3) functions, and, by implication, computational functions (2). It is important to recognize that using maps even for just these first three functions depends on understanding the representational and geometric correspondences discussed earlier. For example, if users do not understand the relationships between referent space and paper (or computer screen) space that hold for different projections, they may make faulty inferences about the referent space or computing distances in that space. There is evidence that just such faulty inferences occur. For example, many adults hold the belief that Greenland is larger than Brazil (Nelson, 1994), presumably a consequence of failing to understand the distortions of area that occur on a Mercator projection but are avoided on an equal-area projection (see Figure 6.4). As another example, President Ford was criticized for stopping in Alaska to give a campaign speech as he traveled (at taxpayer expense) to Japan. However, when the route is shown as a great circle route, the justification for giving the speech as part of an efficient refueling stop becomes evident (see Figure 6.6).

The other map functions (4 through 7) listed by Muehrcke (1986) are rarely represented in children’s or adults’ responses to questions about map functions, or in psychologists’ investigations of map understanding. However, these are key map functions in geography as well as in the many other disciplines for which maps are central tools (e.g., anthropology, ecology, urban planning, military science, agriculture, meteorology, demography, criminal justice, epidemiology, history, geology, astronomy, environmental science, oceanography, and political science). An example is provided by the thematic maps shown in Figure 6.7 (p. 222), which show cancer rates for men and for women, by county, over a 20-year period. Patterns emerge from representations like these that would be virtually impossible to detect in tabular lists of cancer rates. Such patterns raise a host of questions, some of which may be answered by overlaying other data on the same base map. For exam-

(a) Mercator

(b) Orthographic

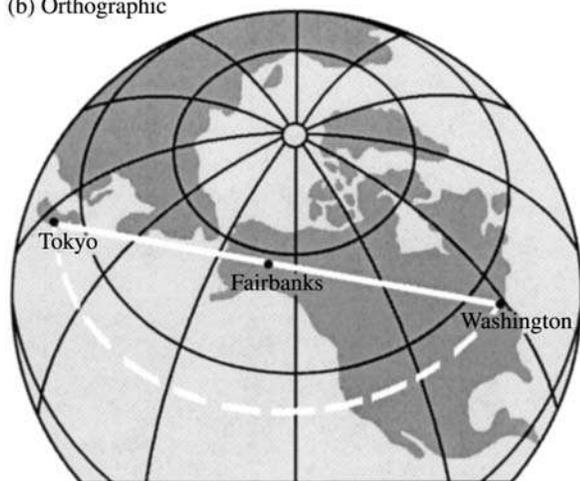

Figure 6.6 Depictions of the route taken by President Ford from Washington, DC, to Tokyo, Japan, with a stop in Fairbanks, Alaska, using a Mercator projection (a) and an orthographic projection (b). ple, are there lifestyles, employment patterns, features of physical geography, sources of water or food supplies that covary with these incidence patterns? What characterizes the living patterns of men versus women residing in the northwest corner of Nevada that may help to pinpoint disease etiology? Maps may also be used to reveal patterns of change or events over time, which, in turn, may suggest mechanisms of change. Plotting the locations of earthquakes over time has been used to generate hypotheses about the existence of tectonic plate bound-

aries; plotting the changing distributions of disease has been used to generate hypotheses about routes of contamination (see MacEachren, 1995).

In short, maps are important not only because they can archive place information per se, but also because they can reveal patterns and help to generate and test hypotheses. They provide excellent models of spatial thinking that can be applied across a wide range of educational and occupational tasks, as well as useful for the real-world tasks encountered in daily living (see Liben, Kastens, et al., 2002).

Summary

The title of this section of the chapter, “The Place of Geography and Map Education in Developing Spatial Thinkers,” is meant to carry two meanings. First, it is meant to imply that geography and map education have a place (i.e., a role) in helping to develop (i.e., to create) spatial thinkers. The subject matter of geography, which describes and explains the spatial distribution of phenomena, necessarily involves and promotes spatial thinking. Furthermore, the key tool of geography—the map—is inherently spatial. Maps challenge users to understand a wide range of declarative spatial knowledge (e.g., measurement), spatial representations (e.g., the symbolic meaning of a particular map), and procedural spatial skills (e.g., using mental rotation to compensate for a map that is unaligned with the space it represents). Many other school subjects (e.g., chemistry, history, mathematics) also draw on and challenge students’ spatial thinking, and make plentiful use of both concrete and mental spatial representations, but they generally do so only implicitly. Thus, geography education in general, and map education in particular, can have an important place in developing spatial thinkers.

Second, the title it is meant to imply that geography and map education take place in the context of developing spatial thinkers (i.e., children who are themselves developing *as* spatial thinkers). In other words, just as the process of becoming educated in geography and maps enhances spatial thinking in the students who learn these topics, so, too, students come to this material with certain qualities as spatial thinkers. Children’s own cognitive qualities influence the way the material can be taught and processed, and, particularly important, these qualities evolve as part of normal cognitive developmental processes more generally. In the next section, I turn to considering how these two meanings are entwined in children’s developing understanding of maps.

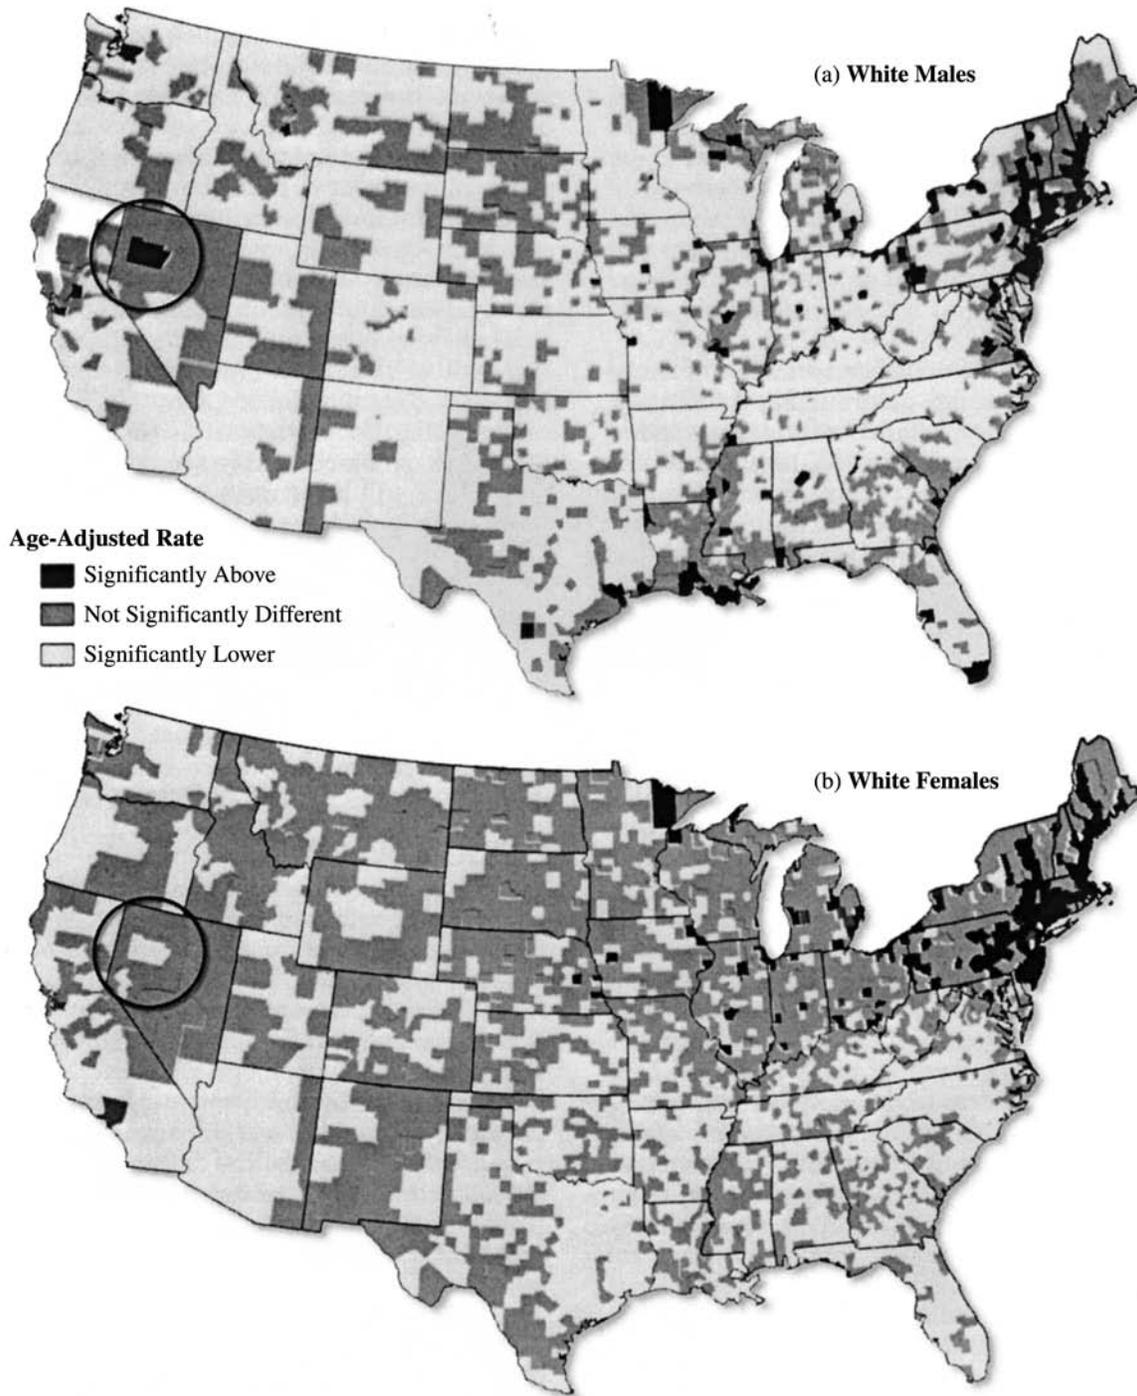

Figure 6.7 An illustrative thematic map showing cancer mortality rates for males and females, by county, from 1950 to 1969. Adapted from *Map Use: Reading, Analysis, and Interpretation* (4th ed., p. 10), by P. Muehrcke and J. O. Muehrcke, 1998, Madison, WI: JP Publications. Reprinted with permission from "Thinking through Maps" (p. 73), by L. S. Liben, in *Spatial Schemas and Abstract Thought*, M. Gattis (Ed.), 2001, Cambridge, MA: MIT Press.

THE DEVELOPMENTAL PATHWAY TO MAP UNDERSTANDING

Thus far, I have defined spatial thinking and provided an argument for its importance, reviewed empirical work showing that individuals and groups vary with respect to their spatial thinking skills when left to develop in their natural ecologies, and provided data demonstrating that spatial performance can be facilitated through educational interventions. In addition, I presented arguments for why geography education in general and map education in particular offer good vehicles for educating spatial thinkers. In recognition that most readers will not have had extensive training in geography or cartography, and with the knowledge that even adults without such training typically have restricted views of maps and map functions, I provided a brief tutorial aimed at expanding readers' appreciation for the diversity in appearance and function of maps. In this section of the chapter, I focus in more detail on what map understanding entails, and highlight findings from our research on children's developing understanding of maps.

Figure 6.8 illustrates one way of organizing the components of map understanding and, hence, map education. There are two critical links in the enterprise, depicted by the arrows shown in the figure. The left arrow links the referent and the map. Map education involves teaching the connections between the referent and the representation, connections that involve representational correspondences (what is mapped) and geometric correspondences (the spatial content), discussed earlier. These two are intimately entwined. For example, a map that depicts the topography of a region has certain

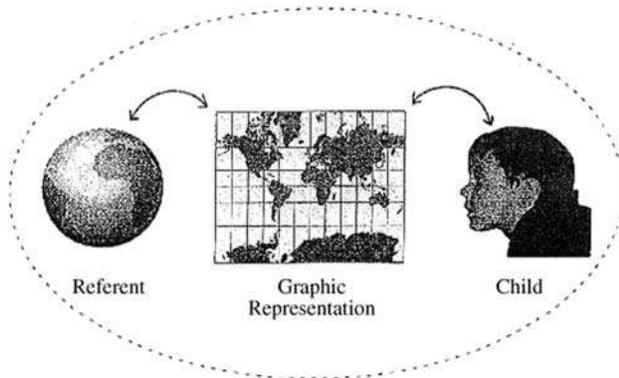

Figure 6.8 Components of map understanding and map education.

referential content (e.g., information about elevations of land, size and locations of lakes) that is itself spatial (e.g., height above sea level, how much area is covered by the lake). In some sense, the symbols are nonspatial (e.g., different elevations might be shown by different colors, or by hachure lines, or by relief shading, or by contour lines labeled with elevation data; lakes may be shown in blue), but the symbols also have spatial qualities that are driven both by the spatial qualities of the referent space (e.g., the placement of the colors to indicate elevation depends on the way the land is contoured; the area of blue depends in part on how large the lake is) as well as by various cartographic decisions (e.g., the area of colors used for various elevations or the lake also depends on scale and the kind of projection that is used). Students (and the educators teaching them) need to understand these links.

The right arrow links the map user and the map. Two kinds of map user connections are relevant. First, qualities of the user affect the way the map is processed. This statement is an instantiation of the more general constructivist view of knowledge that holds that meaning emerges through interactions shaped by qualities of the stimulus (here, the map) and qualities of the person (here, the child's spatial concepts). When applied to the domain of spatial-graphic representations such as maps, the details of this constructive process may be conceptualized by the embedded model (Liben, 1999), shown in Figure 6.9.

Three aspects of the embedded model are central. First, various perceptual and cognitive processes (such as projective spatial concepts) are used by the child for learning from referents themselves (e.g., acquiring knowledge about the locations of buildings from moving around a campus), for learning from representations (e.g., extracting meaning from a map or photograph of the campus), and for learning about the strategies used to create representations (e.g., learning about photographic or cartographic techniques). Second, as a result of interacting with each of these three types of stimuli (referents, representations, and representational strategies), the child acquires specific declarative and procedural knowledge (e.g., information about the campus itself; understanding of distance between two landmarks shown on the map; skill in making maps). These interactions may also facilitate more general development (e.g., helping the child to appreciate that vistas look different from different vantage points, thus fostering projective spatial concepts).

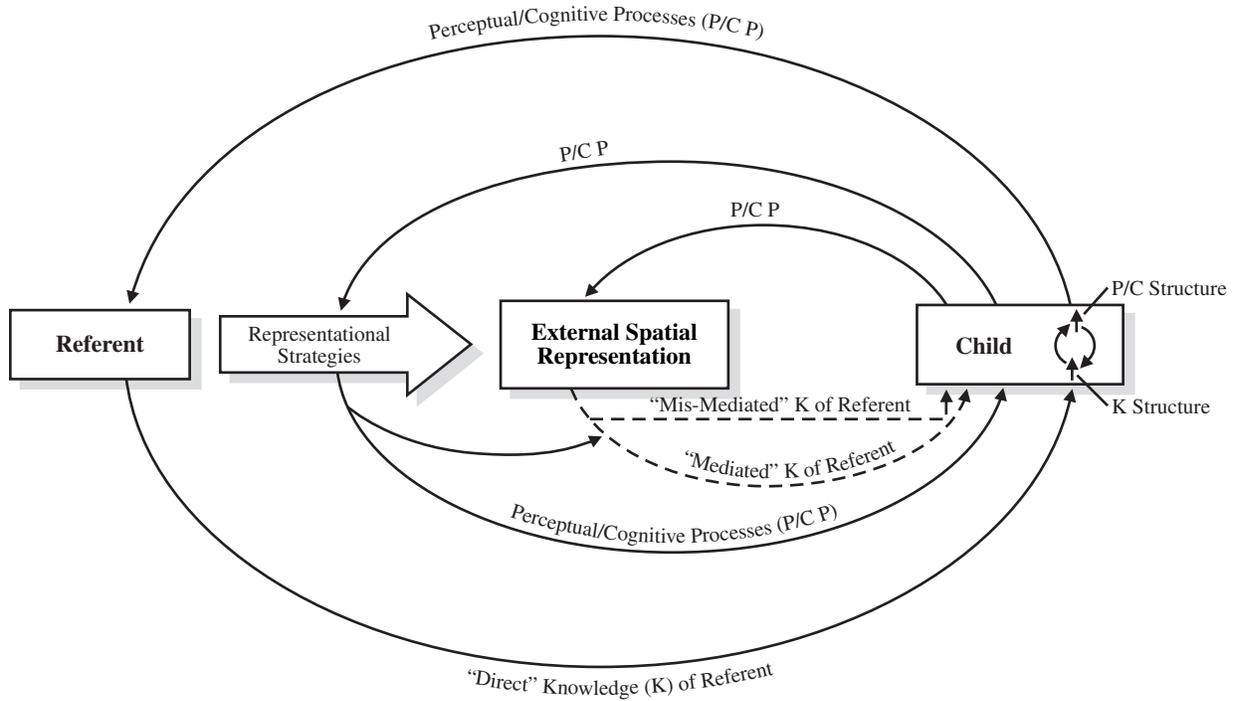

Figure 6.9 The embedded model of understanding external spatial representations. Adapted from “Developing an Understanding of External Spatial Representations” (pp. 297–321), by L. S. Liben, in *Development of Mental Representation: Theories and Applications*, I. E. Sigel (Ed.), 1999, Mahwah, NJ: Erlbaum. Reprinted with permission.

Third, an understanding of representational strategies plays an important role in allowing the child to use representations to construct knowledge of the referent. With an understanding of the representational process (e.g., how a Mercator projection works), the child can use the representation to obtain knowledge about the referent. The child thus obtains “mediated” knowledge of the referent (e.g., learning about the relative land sizes of Greenland and Brazil). Absent an understanding of the relevant representational strategies, however, the child runs the risk of inferring the wrong information, or obtaining what I have referred to (Liben, 1999) as “mis-mediated” knowledge of the referent (e.g., thinking that Greenland is larger than Brazil).

The second relevant connection between the map user and the map is the spatial relationship between the person and the space depicted on the map. This connection is relevant any time the map user is within the depicted space. Figure 6.10 illustrates this situation by showing a person in a room that has, within it, a map of that room. The map shows the location of the person “on the map.” This map marks the “self-map relationship” (a relationship that would exist even if the map had not been physically marked). In addition to the self-map relationship, there is also a “self-space relationship.” In

Figure 6.10, this relationship is shown by the drawing of the person in the room. In actuality, this is a representation as well. A real person-space relationship is your current position in relation to the room, town, country, state, region, country, continent, planet, solar system, and universe in which you find yourself as you read this chapter. In addition, whenever there is a map of a space (as depicted in Figure 6.10), there is also a “map-space relationship” that relates the map and the space irrespective of any viewer. In the particular case shown in Figure 6.10, the map-space relationship is unaligned;

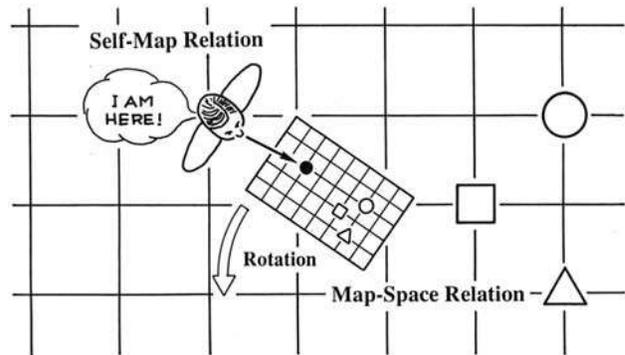

Figure 6.10 The map-space-self relation.

that is, the map and the room are not oriented exactly in the same direction. To bring the map into alignment with the room, the map would need to be rotated as shown by the arrow labeled “rotation.”

Different map tasks vary with respect to the degree to which they call on the user’s understanding of the relationships among map, space, and person. In many uses of maps, one may work successfully within the map space itself. For example, given a map of the United States, someone might be asked whether Chicago or Atlanta is closer to New York City. This question can be answered correctly without attending to the connection between the mapped cities and the real cities. Other map uses require attention only to the map-space relationship. For example, given a map of a room, one might be asked to align the map with the room. If the map and room are as shown in Figure 6.10, one would need to rotate the map as indicated by the rotation arrow to bring the map into alignment. In neither of these two tasks would it be necessary to figure out one’s own location in the room or “on the map.” Still other map uses, however, require attention to the self-map relationship. For example, given a map of a campus, one might be asked to walk from one’s current location to, say, a building marked with a star on the map. To succeed on this task, it would be necessary to find one’s current location and the target building on the map, plan a route on the map, and then relate the mapped space to the real space, updating one’s place “on the map” as one executed the route.

In the two subsections that follow, I describe illustrative findings from our research on children’s developing understanding of various kinds of map-space-person relationships (Downs & Liben, 1991, 1993; Downs et al., 1988; Liben & Downs, 1986, 1989, 1991, 1994). Some of the data come from stand-alone investigations in which children were interviewed or tested in sessions designed to collect research data. Most of the data, however, were collected in the course of teaching children about maps in their regular classrooms. We served as classroom teachers for a 5-week map curriculum given to 265 children in 11 kindergarten and first- and second-grade classes. In addition, we also conducted individual assessments (e.g., on standardized and Piagetian measures of spatial abilities or concepts) of those children from whom we had received signed parental permission (roughly 75% of the sample). Portions of the curriculum (with associated data collection) were also given in smaller units (ranging from a day or two to a week or two) to children in later elementary school grades and in middle schools.

Classroom lessons thus simultaneously served two purposes. One was to introduce students to a wide range of maps and map functions and to give them experience in interpreting and using maps. The second was to collect data that would enable us to characterize children’s developing understanding of maps. These dual goals necessitated some compromises with respect to each. For example, sometimes pedagogical requirements led us to use activities in a fixed sequence even though research design would have dictated counterbalancing orders; sometimes research requirements led us to ask students to work individually even though pedagogical considerations might have led us to ask students to work collaboratively. The findings from this program of research have fed into the design of a number of subsequent educational interventions, ranging from brief consultancies to extended development and evaluation of educational curriculum. Highlights of our research findings are presented in the remainder of the current section. Illustrations of educational interventions from these and other curricula are given in the section that follows.

Developing Representational Map Understanding

As noted earlier, one of the key aspects of map understanding is interpreting the referential content of maps. Fundamental challenges may be inferred from the earlier discussion of the duality principle of maps: the need to (a) distinguish which qualities of the representation are symbolic and which qualities of the representation are incidental, (b) avoid assuming that qualities of the symbol necessarily reflect qualities of the referent, and (c) avoid assuming that qualities of the referent will be evident in qualities of the symbol. In addition, having understood that meaning cannot be determined by inferring qualities of the referent from qualities of the representation, the map user is also challenged by the need to (d) understand how to consult a map key to obtain the necessary information about the assigned meaning of symbolic qualities.

There are two levels of representational meaning that need to be understood (Liben & Downs, 1989). The first level, *holistic*, refers to understanding the referential meaning as a whole, that is, understanding the meaning of the representation at a molar level. At least for familiar map forms, even very young children generally show good holistic understanding of the referential meaning of maps or other place representations. For example, when preschoolers (age 3 to 6 years) were interviewed

and asked what a Rand McNally road map of Pennsylvania showed, virtually all children named some kind of place referent. Where they faltered was in identifying the particular place. Illustrative was one child who responded that the map showed “part of Africa” and another who responded particularly expansively that it showed “California, Canada, the West, and the North Coast” (Downs et al., 1988). Given preschoolers’ lack of reading skills, it is not surprising that they were unable to identify it as Pennsylvania, but what is more telling was their apparent willingness to make assumptions about what the map might depict. Even holistic understanding, however, depends on the child’s familiarity with the map form. A less familiar tourist map of Washington, DC (in which streets were depicted in white on a blue background), that was readily interpreted by adults as showing a city was either entirely uninterpretable to preschool children or was interpreted incorrectly even at the holistic level (e.g., identifying it as, for example, “a cage” or “a space ship”).

The second level, *componential*, refers to understanding the referential meaning of individual pieces or components of the map. Even children who are successful in interpreting the meaning of the map as a whole often show dramatic errors in interpreting individual symbols. Results from our interviews of children (Liben & Downs, 2001) showed that preschool children often inferred meaning on the basis of what the symbol looked like even when the interpretation would be impossible given the holistic meaning of the map they had just identified. For example, preschoolers who had just correctly identified the environmental referent of the road map as a place (even if California rather than Pennsylvania), went on to interpret the yellow symbols for populated regions as “eggs” and “firecrackers,” apparently because the splotchy yellow areas looked like eggs or firecrackers. Errors of this kind suggest that the child assumes that the symbol stands in an iconic relation to a referent and fails to use the referential context to constrain interpretations of resemblance. Even when children interpreted the referential category correctly, they tended to overextend qualities of the symbol to the referent. Illustrative were children who inferred that a red line used to represent a road meant that the road itself was actually red. Similar assumptions informed children’s production of symbols. Illustrative from our classroom studies was the finding that when asked to produce maps of their classrooms, first and second graders almost always generated iconic symbols (Liben

& Downs, 1994). Furthermore, they typically rejected abstract symbols suggested to them, as when children laughed at our suggestion that they might use asterisks to show the file cabinets because “file cabinets don’t look like stars” (Liben & Downs, 1989).

More systematic evidence for the powerful effect of children’s belief in iconicity is provided by an investigation in which 5- and 6-year-old children watched two videotapes of people placing symbols on a map (Myers & Liben, 2005). One videotape showed a person placing green dots on the map with actions and comments that conveyed a symbolic, functional intent. This person commented that her intent was to “use this,” and she explicitly related locations in the room to locations on the map. Before placing each dot, she looked up as if watching someone in the room and made comments about the connection between the room location and the dot location, such as, “Hmm. . . I see that she hid the next one over there in the room, and that means I should draw a green dot here on my paper.” The second videotape showed a person placing red dots on the same map but with actions and comments that conveyed an aesthetic intent. For example, she commented on selecting a red pen because red was her favorite color, mentioned her intent to make it prettier, and explained her plan to hang it on the wall. Furthermore, as she decided where to place the dots, she looked at only the representation itself.

After viewing both videotapes, children were asked about the two characters’ intents, and then asked which of the two drawings they would use to help them find hidden fire trucks. Almost all the children, including those who were able to explain the actors’ aesthetic and symbolic intentions correctly, incorrectly selected the drawing with the red dots, suggesting that they were seduced by the match between the color of the dots and fire trucks.

These data, along with findings that have been reported elsewhere (Liben & Downs, 1989, 1991, 1994), provide evidence that interpreting the full range of representational meaning of maps continues to challenge children at least through the early elementary school grades. This is true not only for maps that are created primarily to present or record location information (as in the road and room maps used in the work described earlier) but also for maps that are created to spatialize other kinds of information (e.g., thematic maps such as the kind illustrated in Figure 6.7). For example, in an investigation of kindergarten through third-grade children’s understanding of thematic maps (Newman & Liben, 1996), children had difficulty interpreting the

graphic symbolization of population density in several kinds of maps.

At first glance, it might seem difficult to reconcile the conclusion that the representational meaning of maps is challenging for children of these ages with the well-known finding from scale-model tasks and related symbol tasks (DeLoache, 1987; Troseth, 2003) that children understand the “stand for” relationship by 3 years of age. The latter tasks, however, typically place only very minimal demands on children’s understanding of symbols because there is usually a unique symbol for each unique referent. When representation tasks include symbols that are less iconic or include multiple instances of the same symbol, performance is significantly worse (see Blades & Spencer, 1994; Liben & Yekel, 1996). In such cases, children may need to rely on spatial understanding to disambiguate which of two or more identical symbols stands for a particular referent. In the next section, I focus on children’s understanding of the spatial meaning of maps more explicitly.

Developing Spatial Map Understanding

The second major set of challenges in map understanding is presented by the spatial qualities of maps shown in the cartographic eye, discussed earlier (see Figure 6.1). As was true in the representational domain, empirical data concerning the spatial domain also show a mixture of understanding and confusion.

Viewing Distance

The first dimension, viewing distance, involves the various scale, proportional, and metric features of maps. Although children are, in general, able to understand the general concept that something small, like a map, can stand for something large, like a room or town, that understanding is somewhat fragile. First, young children are sometimes confused by the disparity between the size of symbols and the size of their referents. In our research with the Pennsylvania road map described earlier, for example, we encountered a number of preschool children who had difficulty interpreting particular symbols because of their size. Illustrative was a child who denied the possibility that the road lines actually showed roads because they were “not fat enough for two cars to go on” (Liben & Downs, 2001). Another child who was shown a plastic relief map of the local area rejected the idea that the raised portions could be mountains, saying that “they’re not high enough” to be mountains.

Second, children in both preschool and early elementary school grades have difficulty completing map tasks that require sensitivity to proportional measurement, even allowing for fairly wide margins of error. One illustration from our research comes from a task in which first- and second-grade children were first given a copy of an aerial photograph of Chicago, reproduced in Figure 6.11 (Liben & Downs, 1991). After class discussions about how the photograph was taken and how it might be used to help create a map of the city, each child was asked to use it as the basis for drawing a sketch map of the city. Each child was then given a copy of a black-and-white map of a portion of Chicago. Children were given some time to try to figure out which section of the aerial photograph was depicted in the map, and were then given an acetate sheet to place over the photograph. The acetate contained a rectangle outlining the area shown on the map as well as eight numbered circles marking locations. Children were asked to place numbered stickers on the map to show the locations analogous to those circled on the photograph. Results are also shown in Figure 6.11. Not surprisingly, second-grade children performed better than first-grade children. What is more interesting, though, are the differential levels of success across the locations. Although there are many potential hypotheses about what might account for the pattern of data, one possible explanation concerns the kind of spatial cues available for given items. When children could use a topological or landmark clue (e.g., the bend in the breakwater), they did very well. When, however, they needed to judge location based on proportional distances on the two representations at different scales, they performed more poorly.

Research by other investigators is consistent with the notion that children find it particularly difficult to understand the scale relation between a space and its representation. For example, in a study in which 6- to 12-year-old children were asked to select symbols of the appropriate size to represent buildings on a map, only those in the oldest group chose symbols that were scaled consistently (Towler & Nelson, 1968). In a task that required children to scale up from a map to the referent space (Uttal, 1996), 4- to 6-year-old children first learned where toy symbols belonged on a map of a room. Once locations were learned to criterion, children were asked to place the real toys in the real room in their analogous locations. Consistent with the idea that scale is challenging was the finding that children generally performed well with respect to reproducing the configurations among the toys,

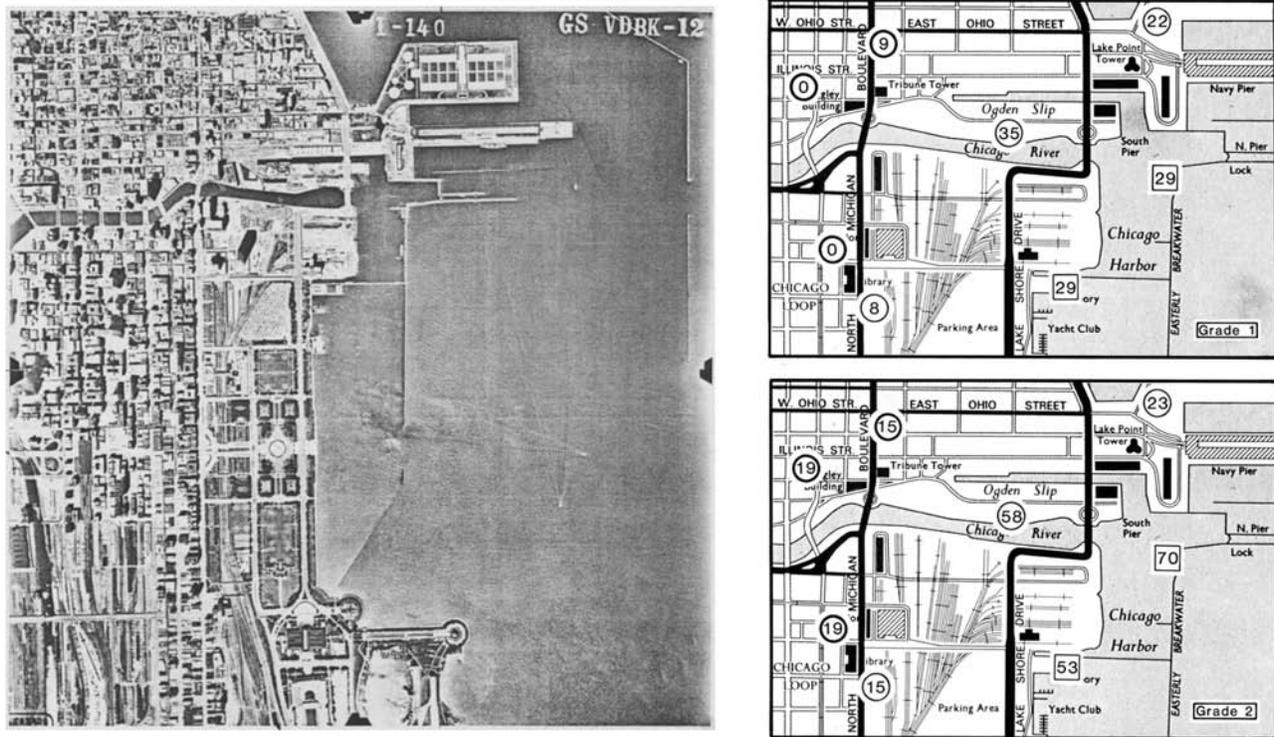

Figure 6.11 Aerial photograph of Chicago (left) on which locations were marked. Maps (right) show percentages of correct responses at each location.

but often performed poorly with respect to scaling the configuration appropriately to the room-size space (e.g., clustering the toys in one corner).

Viewing Angle

The second dimension of the cartographic eye, viewing angle, challenges children's understanding of how changes in vantage point affect the appearance of graphic representations. Again, there are several kinds of data showing that unfamiliar viewing angles make it challenging for children to interpret maps. One line of evidence comes from the spontaneous errors children make in interpreting symbols on plan (overhead) maps. For example, an overhead view of a double sink on a plan map of the preschool classroom was interpreted as a "door" (Liben & Yekel, 1996), an interpretation that makes sense if one assumes that the child thought of the graphic as a straight-ahead view of door panels. Similar findings have been obtained in research using aerial photographs, as, for example, when primary school children identified tennis courts as doors (Spencer, Harrison, & Darvizeh, 1980) and railroad cards lined up in parallel as "bookshelves" (see Liben & Downs, 2001). Another line of evidence that children have

difficulty interpreting representations that depict referents from unfamiliar vantage points comes from their differential performance on maps using different viewing angles. Preschool children were more accurate in placing stickers to show objects' locations on an oblique map of their class that more closely mirrors their own viewing experience than on a plan map that depicts the room in a way that is never experienced directly (Liben & Yekel, 1996).

A third line of evidence comes from production tasks in which children were asked to take an overhead viewing angle in producing maps. Illustrative data come from first- and second-grade children who were asked to draw their school building as it would look to a bird flying overhead and looking straight down. Following the drawing task, children were asked to select the overhead view of their school from among six alternatives. Children's drawings were scored as elevation (eye-level) views, overhead views, mixed elevation and overhead views, or unscorable (because an undifferentiated rectangle could be either a windowless side or a roof of a rectangular building). Figure 6.12 shows two sample responses. One is an elevation view of a generic building

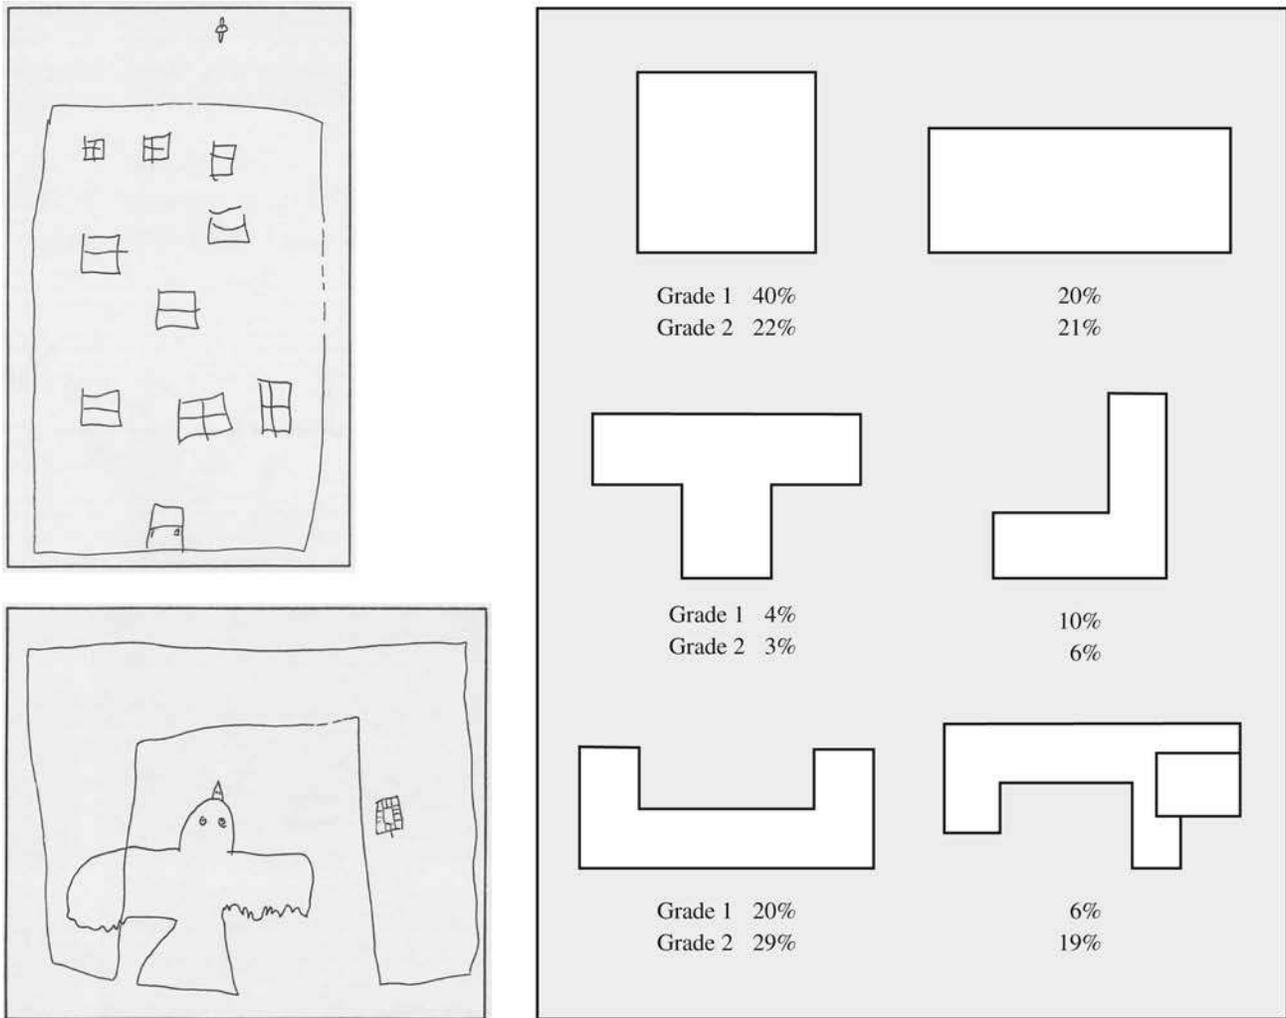

Figure 6.12 Two first-grade children's responses when asked to draw their school as it would look to a bird flying overhead and looking straight down (left) and distributions of choices when asked to select an overhead view of the school (right). Lower right shows the correct response.

that bears no relation to the school other than the fact that both are buildings. The second is a plan view that is remarkably close to accurate except for omitting an enlarged area at the end of one wing of the school. Interestingly, both examples come from students in the same first-grade class, providing a dramatic illustration of the individual differences within chronological age and demographic group discussed in an earlier section of this chapter. Overall, though, second-grade children were systematically better at this task than first-grade children: There was a decrease in the incidence of elevation views from first to second grade (32% to 8%), an increase in plan views (27% to 44%), and little change in either the incidence of mixed view drawings (8% in

each) or unscorable drawings (34% to 40%). Choices given on the selection task are also shown in Figure 6.12. As may be seen from the distributions of selections, as anticipated, children at both grades were better able to select than produce a correct overhead view, and performance improved with age.

Viewing Azimuth

The third dimension, viewing azimuth, refers to the orientation from which the referent space is depicted. One kind of challenge in this domain arises from the need to understand the relationship between the orientation of the map in relation to the space it represents, particularly when the two are unaligned. This situation arises

in many wayfinding or navigation tasks in real life, as when someone is using a map to navigate, and because of a series of turns, the relationship between the map and the space is constantly changing. Under such circumstances, the map user must either mentally compensate for the misalignment (e.g., by mentally rotating the map) or physically compensate (by actively turning the map with each change in physical direction so that the map and space are continually brought back into alignment). In some circumstances, the map cannot be physically moved (as when “You Are Here” maps are mounted on a wall out of alignment with the space; see M. Levine, Marchon, & Hanley, 1984); in these circumstances, the user must accommodate mentally.

In one investigation designed to study children’s ability to respond to challenges raised by unaligned maps (Liben & Downs, 1993), children from kindergarten, first-grade, second-grade, and combined fifth/sixth-grade classes were given maps of their classroom and asked to use colored arrows to mark locations and orientations. Specifically, an adult went to a series of places in the classroom and pointed straight ahead, and children were asked to place colored arrows on their maps to show where he was standing and in which direction he was pointing. After completing the task once with the maps aligned with the classroom, a second set of maps was distributed, but this time maps were placed on children’s desks so that they were 180° out of alignment with the room. Children were told that they were going to be doing the task again, but this time while the map was “turned around.” Children were asked to leave the map on their desks as it was placed, and a colored dot was visible to teachers to ensure that the map remained in the intended orientation. As the task progressed, periodic reminders were given, such as “Remember, think carefully. It’s hard because your map is turned around.”

A summary of children’s accuracy in placing and orienting arrows is given, by grade, in Figure 6.13. As shown, children improved with age, reaching high levels of performance when the map was aligned sooner than when it was unaligned. Also shown in Figure 6.13 are composites of all responses in one first-grade classroom to one location under both aligned and unaligned conditions. What the distribution of the arrow responses suggests is that in the unaligned condition, many children were unable to compensate for the 180° rotation of the map, with a cluster of errors in location exactly opposite the correct one. This impression is supported by examining the directions of arrows for each of the six individual

items (details are given in Liben & Downs, 1993). Among kindergarten children, even for the single item that elicited the best performance, the modal response was an arrow with a 180° error. This is precisely the error that would occur if the child failed to compensate for the map’s rotation. Although by grade 1, the modal response to the easiest item was correct, the modal error was still 180°. By grade 2, the modal response was correct, with some disproportionate appearance of 180° errors for some items. By grades 5 and 6, virtually the only errors that occurred were errors of precision (i.e., off by only a small number of degrees), with 180° errors virtually absent (only 3% of the responses on a single one of the six items). As on other tasks, and consistent with the picture painted of the striking individual differences in spatial thinking discussed earlier, performance varied dramatically even within each age group. Table 6.1 gives the percentages of children receiving each score in each grade. What is perhaps most remarkable is that some (albeit very few) kindergarten children were performing perfectly or nearly perfectly at the same time that some (again, albeit few) second-grade children were incorrect on all or all but one item.

Similar kinds of tasks have been used to examine the developing ability to solve problems that involve different viewing azimuths. For example, in research with first- and second-grade children (Liben & Downs, 1986), participants were shown oblique-angle aerial photographs of their school and asked to place arrow stickers on a plan map of their school neighborhood to show the direction from which the photographs were taken; then they were

TABLE 6.1 Percentage of Children Receiving Each Score on Classroom Person Location Task, by Alignment Condition and Grade

| | Total Number Correct | | | | | | |
|------------------|----------------------|----|----|----|----|----|----|
| | 0 | 1 | 2 | 3 | 4 | 5 | 6 |
| Aligned | | | | | | | |

Reprinted with permission.

shown oblique perspective drawings (Figure 6.3) and asked to place arrow stickers on a contour map of the same local region to show the vantage point of those drawings. In research with high school students (Liben, Carlson, Szechter, & Marrara, 1999; see Liben, 2001), participants were shown a directional arrow pointing to a place shown on one representation of an environment (a plan map or oblique aerial photograph). They were then asked to place a directional arrow on a second representa-

tion of the same environment (in a different scale and azimuth) so that it would point to the same environmental location from the same general direction. The data from these various tasks converge on the conclusion that understanding and coordinating viewing azimuths across representations is challenging, even at older ages, with striking individual differences evident at all ages tested.

The same general conclusion may be drawn from tasks in which individuals must identify their own orientation

on a map or to relate their own position in space to other locations (i.e., the self-map-space relation discussed earlier). Illustrative is research with college students who were tested early in their first semester on campus (see Liben, 2005; Liben, Kastens, et al., 2002). Students were taken to a series of locations. At the first five locations, they were given a campus map (modified slightly from the campus map distributed to visitors and posted at various locations on campus) and asked to place an arrow sticker on the map to show their location and the direction they were facing. At the next five locations, participants were given a map on which one building had been marked and asked to point a spinner arrow to that building (not currently within sight from the participant's location).

Figure 6.14 (top) shows a composite map of the location responses to one item. What is remarkable about the distribution of responses is not only that so many of them are incorrect, but also that so many of them are impossible if one interpreted the referential symbols even at a basic level. For example, in the item used in this example, the participant was positioned at a courtyard-like corner of the building so that there was a wall to the participant's left as well as straight ahead. There were also additional buildings to the right and directly behind. Yet, as evident in the figure, many participants placed their stickers adjacent to a building that had no courtyard-like right angle and that lacked other buildings nearby. Directional data showed the same kind of variability as the location data. To illustrate, Figure 6.14 (bottom) presents data from one of the spinner items. Similar to patterns observed among children, some college students were able to perform almost perfectly on both location and direction tasks, whereas others erred dramatically on every item.

Qualities of the Map User

Implicit in the preceding discussion of research related to individuals' understanding of maps are qualities of the particular map user (depicted by the right arrow of Figure 6.8). One grouping variable that has been used explicitly throughout the discussion is chronological age (or school grade), but from a developmental perspective, age is more appropriately understood as a marker for more differential levels of relevant cognitive development. Some investigators have included direct assessments of the cognitive concepts hypothesized to be relevant to map understanding. Of interest is whether these assess-

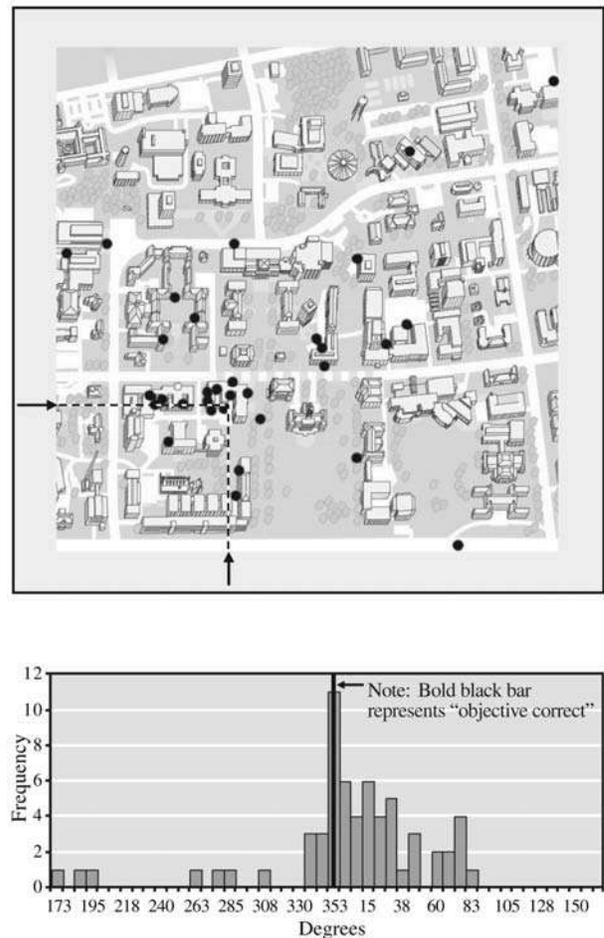

Figure 6.14 Composite of sticker locations by college students asked to show their current location (which was at the intersection of the two arrows) on a campus map (top). Graph shows distribution of pointing directions for a single spinner task item (bottom). Adapted from “Real-World Knowledge through Real-World Maps: A Developmental Guide for Navigating the Educational Terrain,” by L. S. Liben, K. A. Kastens, and L. M. Stevenson, 2002, *Developmental Review*, 22, pp. 267–322. Reprinted with permission.

ments predict to map performance better than age per se, perhaps thereby accounting for the wide range of differences in performance observed within given age groups. In our work, for example, we have assessed children's topological, projective, and Euclidean concepts by using classic Piagetian tasks (see Liben & Downs, 1993). We have made the argument that at the group level, there should be relatively early success on map tasks that can be solved by using landmark features because these theoretically call on developmentally early topological understanding. In contrast, there should be relatively later

success on tasks that require an understanding of, first, viewing angle or azimuth or, second, scale, because these theoretically call on, respectively, developmentally more advanced projective and Euclidean concepts (Piaget & Inhelder, 1956). The data at the individual level should show that within a given age group, the children who perform particularly well on tasks that draw on understanding viewing angle, azimuth, and scale should be the children who are especially far along in their understanding of spatial concepts.

The empirical data were reasonably consistent with the hypothesized links at the level of groups. For example, better performance was elicited in location tasks on items on or near unique landmarks that provided topological cues than on items in undifferentiated regions of a room, neighborhood, or city that require metric understanding (Liben & Downs, 1993). The data were somewhat, but not strongly, consistent with the hypothesized link at the individual level. That is, there were significant correlations between children's performance on the mapping tasks and the Piagetian spatial tasks, a relationship that held even after scores on a more general test of spatial abilities were statistically removed. However, the correlations were only moderate, and although children who performed very well on the mapping tasks were typically those who performed well on the Piagetian spatial tasks (and the reverse), there were some children whose performance was inconsistent with this pattern. Of course, tasks used to assess spatial concepts are not perfect, and participants may be differentially motivated to apply the concepts that they have to any given mapping task. Thus, additional research is needed to further explore the relationship between performance on general spatial tasks and performance on mapping tasks, and to find ways to study the moment-by-moment processing strategies used in solving mapping tasks.

Summary

The research discussed in this section of the chapter converges on the conclusion that understanding of both representational and geometric correspondences improves with age. However, there is also ample evidence of striking individual differences, with some children performing remarkably well, and some adults performing remarkably poorly. Far more research is needed to identify the factors that are responsible for different levels of performance across ages and individuals. Although we are far from understanding all components of map understanding that are

problematic, and why some components are especially problematic for some individuals, we cannot postpone map education until all these factors are understood. As argued in the earlier section, “*Can Spatial Thinking Be Improved?*” there is already considerable evidence that interventions can have positive effects on spatial thinking.

MAP EDUCATION: ILLUSTRATIVE MATERIALS AND ACTIVITIES

In this section of the chapter, I turn to a discussion of interventions addressed at enhancing students' skill in understanding and using maps.

A Time and Place for Map Education

At a broad level of generalization, the prior section on map understanding leads to the conclusion that, at the group level, children of different ages bring different concepts and knowledge to maps. At very young ages (in the preschool years), children typically have some concept of maps and some understanding of their function, but their concepts and associated skills are limited. They tend to make assumptions about shared qualities of maps and their referents that may interfere with their understanding of both the representational content (e.g., falsely presuming that red lines stand for red roads) and the spatial content (e.g., falsely presuming that lines cannot stand for roads because they are not fat enough for two cars to go on). At somewhat older ages (during the elementary school years), children come to recognize that spatial representations can move from generic to specific (e.g., as in the shift from generic to specific representations of their school; see Figure 6.12), they come to understand the consequences of changing viewing angle (again, see Figure 6.12), and they become increasingly facile at understanding viewing azimuths (as in their ability to handle unaligned maps; see Figure 6.13).

Although at still older ages (late elementary and middle school) children routinely perform well on the kinds of tasks that are challenging to younger children (see Figure 6.13), even adults continue to evidence nontrivial limitations in understanding and using maps. When actually out in a real (rather than laboratory) environment and when actually using a real (rather than a simplified) map, many adults are often confused about their current location and the direction of target locations that are represented on the map but physically beyond view (see

Figure 6.14). Furthermore, it is not only college students participating in research studies who evidence confusion. There are also dramatic examples from the everyday world, such as a logger who was taken to court for cutting down trees on the wrong land and who defended himself by arguing, “The way the map was shown to me didn’t help, as it should have been turned the other way” (“Pair Awarded,” 1989), and a case in which a Dutch tourist was killed in an incident in which she “and her husband got lost and stopped to ask for directions in a poor, crime-ridden Miami neighborhood. . . . As her husband got out of their rental car with a map in hand, [one of the men] fired a shot through the car window” (Skipp & Faiola, 1996). It is not only that adults have difficulty using maps for navigation. Students in a professional master’s degree program in environmental policy made serious mistakes in interpreting climate forecast maps that depicted the probability of various precipitation data into the future (Ishikawa, Barnston, Kastens, Louchouart, & Ropelewski, 2005).

At least some confusions evident in adults are likely to stem from incomplete, confusing, or misleading education during early childhood, and thus it is valuable to begin map education during the preschool years. In this context, it is important to point out that the fact that our research shows that preschoolers are confused about some aspects of maps should not be taken to imply that map education is inappropriate during these years. Even a theoretical position such as Piaget’s, which posits that preschoolers lack relevant projective and Euclidean concepts, does not imply that instruction should be postponed until the child acquires these concepts (an implication claimed by Blaut, 1997a, 1997b). Rather, it implies the importance of designing developmentally appropriate curricula that take these developmental trajectories into account (see Downs & Liben, 1997; Liben & Downs, 1997, 2001).

The geography and map education experiences in which I have participated have included working on various aspects of museum exhibits, television programs, academic competitions, and curriculum design. Next, I draw from some of these experiences to illustrate ways that developmental theory and educational practice may productively interact.

Locating Maps within a Broader Framework

Before turning to any specific educational intervention designed to enhance children’s understanding of maps, it is useful to remember that the overarching focus of this

chapter is on spatial thinking. The general argument I have made is that spatial thinking is an important and valuable way of guiding interactions with and thoughts about the world. This includes “the world” not only in the sense of continents and oceans of the planet Earth, as might be studied in geography or geology, but also “the world” in the sense of all its component physical and behavioral systems, as might be studied in fields such as chemistry or economics. In parallel, I have argued that maps are an important tool for spatial thinking, and thus that educating children to understand and use maps is an avenue for educating children to become better spatial thinkers more generally. Thus, it is important to reiterate that the general significance of maps in the context of this chapter lies not their capacity to provide facts about the geographic places that they represent, but in their capacity to model the creation and use of graphic representations for representing and manipulating referents that might otherwise be unseen, unknown, unreal, or untouchable. Thus, one broader framework into which maps must be fit is the framework of spatial thinking.

But there is a second broader framework relevant to maps, and that is how the information that is internal to the map (e.g., the distance and angular relationships among, say, three cities on a map) is related to the broader external world. To operate in space (mentally or physically), it is critical to have a frame of reference. Because there is a magnetic pole and needle technology that permits the identification of magnetic north from any location on Earth, north is a useful external anchor point to which places and maps can be related. North is pervasive (e.g., in language, in graphics, in weather directions, in navigation), and it thus becomes a key concept for maps and education. Especially important, theoretical and empirical work in developmental psychology leads to the expectation that north will be a challenging concept to teach. Given these factors, it is the topic that I focus on in illustrating educational practice. I first describe some of the ways that the concept of north has been covered in others’ educational materials, then describe the way we approached teaching the concept of north in our classroom work and, finally, review the instructional approach to north in the *Where Are We?* curriculum (Kastens, 2000), with which I have recently been working.

Characterizing Traditional Curricula

In addressing the concept of north, it is useful to begin by considering the more general issue of how maps and

the external world are connected in mapping curricula. In general, curriculum materials tend to focus on maps as worlds in and of themselves, rather than on relationships between what is represented in the map and external reality (Liben, Kastens, et al., 2002). When they do address map-reality relationships, the reality is typically very limited in scope. Thus, for example, mapping curricula often begin by having children create maps of their home or classroom and use these maps to teach the importance of map elements, such as scale and keys. They rarely, however, address the relationship between the mapped space and some larger frame of reference, for example, orienting the classroom map in relation to regional landmarks, to distant physical features (e.g., a mountain range), or to magnetic north. Mapping exercises often ask children to create maps of imaginary lands that are not positioned in relation to any earthly frame of reference. When children are asked to use maps for “navigation,” the exercise is typically entirely representational. For example, children may be given a worksheet that shows city blocks, symbolizes and labels buildings such as school, church, and town hall, and asked to draw the route to go from, say, Sally’s house to her school. Such tasks can be solved without regard for links between the map and any referential reality.

One means of summarizing traditional mapping materials is by using a classification scheme that was developed to categorize research methods used to study children’s emerging understanding of spatial place representations (Liben, 1997a). Two of the methods, *production* and *comprehension methods*, ask children to relate representation and reality: in the former, by taking information from the reality and applying it to (or creating) a representation, in the latter, by taking information from the representation and applying it to the real space. In *representational correspondence methods*, children are asked to relate two or more representations, but the task does not really require the child to link either representation to the reality; the link is between the two representations. In *metarepresentational methods*, children are asked to reflect on the purpose of representations or their components or perhaps talk about a representation-referent link, but only in the abstract. This classification system was used to analyze map materials that were available in the Bank Street Bookstore in New York City over a 2-year period (Kastens & Liben, 2004). All materials that required some student pencil-and-paper product and that were marketed for elementary school ages were included in the analysis. In-

terestingly, and parallel to the way the research literature may be characterized (see Liben, Kastens, et al., 2002), these educational materials showed an overwhelming emphasis on representations per se. Production and comprehension exercises were very rare.

Despite the general paucity of attention to the link between mapped spaces and the larger environmental framework, there has been considerable curricular attention to the concept of north in educational materials. Unfortunately, however, this attention is often misguided. A book entitled *How to Read a Highway Map* (Rhodes, 1970, p. 46), for example, explicitly tells children, “North is always at the top of the map.” In a unit entitled “Orienting Ourselves in the Classroom,” Rushdoony (1988, Lesson 1.2, p. 6) instructs teachers to place on the chalkboard “a large chart that shows the four cardinal (main) directions.” The figure provided shows a large cross with north at the top and with each cardinal direction labeled. Teachers are told to “explain that there are four main directions—north, south, east, and west. Have the class read the words aloud. Then put the manila strips on the walls (one on each wall—north on the wall behind your desk).” It is obviously impossible that every teacher using this curriculum will have a desk in front of a north wall. As another example, in a student workbook (Carratello & Carratello, 1990, p. 8), the page labeled “Do You Know Your Directions?” explains that “directions will make it easier to tell where we are and where we would like to go.” The page is illustrated with a picture of a boy from the back, facing the top of the page. Above his head appears “NORTH is at the top,” just below his right hand is “EAST is on the right side,” at his feet is written “SOUTH is at the bottom,” and below his left hand appears “WEST is on the left side.”

In summary, many materials designed to teach maps that are used in school do little to link the child and map to an external frame of reference. Further, there are not only errors of omission. As the examples just given show, there are also errors of commission. Curriculum problems like these are among the reasons that children may be challenged in trying to understand the concept of a fixed external referent like magnetic north.

A Developmentally Motivated Approach to Teaching North

Our approach to map education (Liben & Downs, 1986) was an interdisciplinary one that attempted to bring

together ideas from both developmental psychology and geography. In the process of teaching various lessons that exposed children to a wide range of map forms and functions, we included some instruction on cardinal directions. We were aware that it was likely that at least some of the children in the first- and second-grade classes we worked with had been exposed to the kinds of misleading information about north described earlier. Given this background, we began by asking students to close their eyes and point to north. As expected, common responses included pointing straight ahead and straight up in the air.

When they opened their eyes, children were surprised to see the variety of responses among their peers. We then discussed the idea of magnetic north, and took out a compass. Based on our knowledge of developmental research on egocentrism and the importance of action in cognition, we invited students to come to the front of the room, one at a time, so that they could see the needle and could point to north (which in this classroom was over children's left shoulder). Although most of the children seemed to be prepared to believe that their original notion that north was straight ahead or straight up was wrong, a few of the children were having difficulty giving up their original beliefs. In one of the second-grade classes, a boy became visibly upset and finally jumped out of his seat, walked over to the wall, and pulled down the wall map to show everyone that indeed he was correct and north was pointing toward the ceiling. Errors like these in each class provided us with the opportunity to discuss the relationship between directions in maps and in the real world. In the course of doing so, we included maps in which north was *not* at the top of the page.

We thought we had been successful in conveying to children the need to use a referent outside their own bodies to find north (e.g., the sun, a compass). We tested our impression during a field trip that occurred a few weeks following the original lesson on north. The students were driven out to a recreational center by bus and gathered inside one of the buildings for some additional map work. Once again, we began by asking children to close their eyes and point to north. We were anticipating that they would either ask for a compass or say that they could not tell. Instead, to our dismay, most of the students simply pointed, quite confidently, over their left shoulders. All we had succeeded in doing was to replace one fixed body-centered belief (that north was straight ahead or straight up) with another (that north was over

the left shoulder). Thus, although we were correct in anticipating children's likely confusions, we were not successful in overcoming them.

Where Are We? Curriculum Attempts to Overcome Misconceptions about North

The final example is drawn from the *Where Are We?* (WAW?) curriculum (Kastens, 2000) targeted for second- through fourth-grade children. Two major premises of this curriculum are, first, that the links between reality and map are at the core of understanding maps, and second, that there are practical difficulties in providing children with extensive reality-map experiences. Thus, a key feature of WAW? is computer software designed to provide simulated reality-map experience.

Specifically, and as illustrated by a screen from the WAW? software shown in Figure 6.15, the software shows two representations of a park simultaneously. One is a plan map, and the other is an inset of a color video that shows eye-level views recorded on walks through the park. Users control the video that appears in the inset by clicking on one of three arrows. Clicking on the straight arrow starts the video clip to show what would be seen as one continues walking straight ahead on the path. Clicking on the left or right arrows leads to video

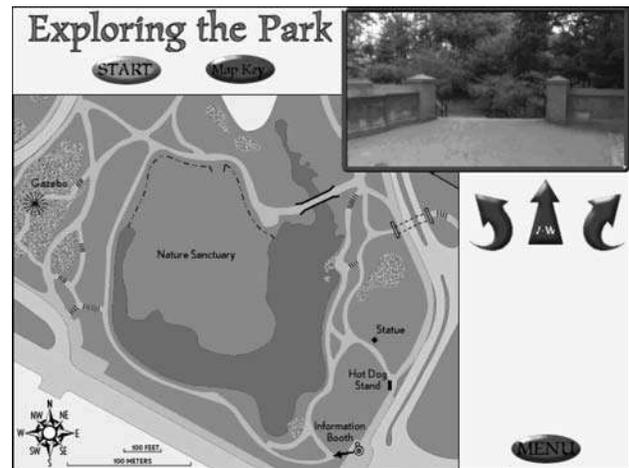

Figure 6.15 Annotated screen from *Where Are We?* in the “Exploring the Park” mode. *Source:* From *Where Are We?* by K. A. Kastens, 2000, Watertown, MA: Tom Snyder Productions. Reprinted with permission from “Real-World Knowledge through Real-World Maps: A Developmental Guide for Navigating the Educational Terrain,” by L. S. Liben, K. A. Kastens, and L. M. Stevenson, 2002, *Developmental Review*, 22, pp. 267–322.

clips showing, respectively, what would be seen if one turned to the left or right.

The software operates in four modes. One, “Exploring the Park,” orients children to the software, the videotaped scenes, and the map. By clicking on one of the arrows, the user sees the park on the video as if walking or turning and, simultaneously, sees a red dot with a directional arrow marker moving on the map. Because of the scale relation between the walk and representation, a long “walk” in the videotape moves the red dot only a short distance on the map. The explicit display of the red dot and orientation arrow is used consistently only in this introductory mode. In a second mode, “Are We There Yet?” the user is given a starting point and orientation (indicated by the red dot and arrow) and asked to reach a given target location by moving through the space via arrow clicks. In “Lost!” the user is simply dropped at some unknown location in the park and is challenged to discover the location by moving around in the park (via arrow clicks). When users believe they have located themselves on the map, they click on the hypothesized location and receive a message that says either “Sorry, try again,” “You’re close,” or “You got it!” Finally, in “Add to the Map,” users again move through the (video) park via arrow clicks and watch for certain objects (e.g., lampposts) that are in the “real” (videotaped) world but not yet on the map. Between clicks, the user drags symbols to the map to show the selected objects’ locations. This mode is meant to parallel the field mapping tasks that are common in many occupations and disciplines (e.g., as when an ecologist records distributions of vegetation data on a base map).

A list of the topics of the classroom lessons that compose the *WAW?* curriculum is given in Table 6.2. Of particular interest for the current focus on north is the two-session Lesson 9 (pp. 66–73), entitled “The Compass Rose.” Many aspects of the lesson are directly relevant for the kinds of body-centered misunderstandings that have been identified in the research discussed earlier. The three overarching goals for the lesson are to “teach students to use a compass rose in conjunction with a compass,” “have students differentiate between North as a region and north as a direction,” and “show students when to use north/south/east/west rather than right/left.”

It is informative to examine some of the specific recommended activities. Unlike the approach to north often found in traditional curriculum materials described earlier, much of the *WAW?* lesson is specifically aimed at re-

TABLE 6.2 List of Lessons Included in the *Where Are We?* Curriculum

1. *Exploring Maps.* Students examine a variety of paper maps and discuss the uses of maps.
2. *Bird's-Eye View Mapping.* Students draw a simple map of the objects on their desks.
3. *Map Symbols.* Students use the key on the *Where Are We?* poster map to identify objects on the map and to imagine what is seen by someone standing at a particular location.
4. *Introducing the Software.* Students learn how the software works by using “Exploring the Park” mode.
5. *Landmarks.* The lesson introduces the value of landmarks in map reading and navigation through guided use of the “Are We There Yet?” mode.
6. *Keeping Track of Where You've Been.* Students keep track of their route in the “Are We There Yet?” mode and practice returning to their starting point.
7. *Planning a Route.* Students plan a route to a destination and anticipate what they should see along that route. Using the “Exploring the Park” mode, students test their predictions and verify their plan.
8. *Map Scale.* By contrasting the distance traveled in the *Where Are We?* video with the distance the dot advances across the map, students see the difference in size (scale) between the map and the represented landscape. They use the map scale to estimate sizes and distances in the *Where Are We?* scene and on other maps.
9. *The Compass Rose.* Students use a compass rose in the classroom and on the computer map to figure out the direction someone is facing or moving.
10. *Putting New Information on the Map.* Students find some features that are in the video but missing from the map, figure out where these should be located on the map, and add the appropriate symbols. This lesson models the use of maps by geologists, ecologists, architects, town planners, and many others who use maps as tools for organizing spatial information.
11. *Lost!* Using map symbols, landmarks, and compass directions, students make observations about the landscape around them to infer their location on the map. This lesson simulates the situation where walkers or motorists realize they are lost, pull the map out of a backpack or glove compartment, and use visual clues in the surrounding terrain to figure out where they are on the map.
12. *Summing Up: Comparing Maps with the Real World.* Students demonstrate their understanding of the similarities and differences between a map and the real world by completing a table.

lating the child’s immediate space and representation to an external frame of reference. For example, after discussing the use of a compass or the sun’s path to establish where north is, the teacher is asked to have a child put a “large paper compass rose on the floor matching its N with the real north. Place a compass on top of the compass rose to check that the norths are aligned.” Signs with cardinal directions are then posted, but unlike the workbook described earlier, north does not automatically get

placed at the front of the room, but rather on the north wall as determined by the compass.

As developmental research and theory would imply is important, activities in the lesson are specifically designed to help children differentiate bodily directional referents (e.g., left and right) from external spatial referents (north). This approach is thus in sharp contrast to the traditional curricula described earlier in which activities and materials conflate, rather than distinguish, bodily referents and external referents (e.g., erroneously teaching that the child's right hand identifies east). In *WAW?*, activities involve children following directions to move a figurine around so that the child learns to differentiate regions from directions (e.g., learning that one can be heading, say, northeast even if one is in, say, the southeast region of a state) and to differentiate left/right from cardinal directions. If students are having difficulty making these distinctions with the figurines, teachers are led to use additional exercises that address common misconceptions. These exercises are particularly well grounded in developmental theory insofar as they require children to move through the real space using alternative referential systems. For example, children are asked to divide up into two lines facing each other, and then everyone is asked to turn to the left. The two lines therefore end up facing in opposite directions. Students are then asked to return to their original positions so that the lines again face one another. Students are then instructed to face east. Now all students face in the same direction. Activities such as these are intended to have children come to appreciate the difference between egocentric, body-centered frameworks and external, stable frames of reference.

The second session of the "Compass Rose" lesson involves using the *WAW?* software, which provides continual information about compass heading as one "walks" through the park. The map, however, remains in the same orientation, thus giving children practice in using unaligned maps, something that the research reviewed earlier shows is typically difficult for children of this age. In short, the theoretical foundations of *WAW?* are similar to those that informed the classroom activities used in our integrated research and teaching efforts (Liben & Downs, 1986). The *WAW?* curriculum, however, is far more sustained and is thus likely to be more effective than our own attempt to teach north. However, evidence of such effectiveness must await additional evaluation efforts currently under way (e.g., Kastens & Liben, 2004).

Summary

In this section, I have described and discussed a number of specific classroom materials and activities that are related in some way to helping students to understand the relationship between a representation and a reality. I have focused on frame of reference because keeping track of representations of spaces or objects in space depends on remaining oriented in some way. An examination of the map education materials that are commonly available suggests that many materials and lessons ignore the connection between representations and reality entirely, and at least some of them address the connection in ways that are seriously misleading. As our own unsuccessful attempt to teach the concept of north demonstrates, even being aware of children's likely misconceptions and even grounding a curriculum in developmental and cartographic principles does not ensure success. The *WAW?* curriculum was enriched by what had been learned in earlier work, but whether it will prove to be adequate awaits evaluation data (see Liben, Kastens, et al., 2002). There are, however, already a number of general conclusions that can be drawn, as discussed in the next section of the chapter.

CONCLUSIONS AND QUESTIONS

In this chapter, I began with the argument that spatial thinking plays an important role in a wide range of educational, occupational, and everyday activities. I reviewed data showing that spatial thinking varies markedly between groups (e.g., those defined by age and sex) and within groups (i.e., individual differences), and that these differences are linked to differential success in both general and specialized curricula (e.g., mathematics, engineering). I described research showing that interventions can enhance spatial performance and associated educational outcomes across the curriculum. Given the conclusion that skilled spatial thinking is important but does not develop to high levels automatically and universally, I considered educational routes that might be used to facilitate spatial thinking. For both practical and conceptual reasons, the approach recommended (consistent with the recommendation of the report *Learning to Think Spatially*; NRC, 2005) was to infuse spatial education within courses already taught in our schools. I identified geography as one potential target for infusion because it places spatial reasoning at its

disciplinary core and because it routinely includes lessons on maps (which are prototypical exemplars of spatial thinking). As currently configured, however, map lessons are often geared simply to helping children use maps to obtain specific factual information (e.g., to find state capitals, to identify which cities are near which rivers, to find the locations of countries in the news). Map education has the potential to offer much more. The myriad map forms and functions described earlier suggest some of the ways that maps draw on and may thereby facilitate more general spatial and representational skills. I reviewed research showing the developmental emergence of map understanding and sampled from educational curricula designed to teach the concept of north.

In this final section, I revisit my opening paragraph, in which I noted that the material in this chapter is relevant to three audiences. The first is composed of traditional cognitive-developmental psychologists whose primary interests are in basic research on the development of spatial cognition. The second includes applied developmental psychologists who aspire to move their work from the laboratories of the academy to the lives of children in the real world. The third encompasses educators who design or provide educational experiences for children. I highlight some key points relevant to each audience and close by commenting on the need to consider the challenges and opportunities presented by the changing technological environment.

Scholars of the Development of Spatial Cognition

For those readers whose primary interest is in studying the development of spatial cognition, the key lessons from this chapter largely concern the existence and implications of variability. First, the work reviewed here highlights variability among individuals. When one is describing children in the abstract, it is relatively simple to place the primary focus on the commonalities of children within age groups and the distinctions between children across age groups. However, when one takes these abstract descriptions into real classrooms with real children trying to master real lessons, it is the variability rather than the similarity among children that is striking. Data show variability not only with respect to levels of performance, but often also with respect to the cognitive strategies that underlie performance. Differences among individuals with respect to the rates at which they pass through developmental milestones or

with respect to the end points they ultimately reach provide potential windows into developmental processes. That is, detailed observation of natural correlates of different developmental rates and outcomes (e.g., different parental behaviors, different toy play) may illuminate microgenetic changes in spatial development, and, when possible, these correlates may be manipulated experimentally to test their impact on later spatial thinking. Thus, one conclusion from the work described throughout this chapter is that even as there are age progressions in spatial development, there are also individual and group differences in spatial development, differences that imply the need for observational and experimental research that goes beyond descriptions of age-linked differences in spatial thinking.

Second, the work reviewed in this chapter highlights variability in performance across tasks. There is a temptation for developmental psychologists who work primarily within the walls of the academy to assume that the most (or perhaps even the only) important questions about cognitive functioning are those that address the *emergence* of some cognitive skill. From this perspective, for example, it is particularly important to find that young infants encode metric information about objects' locations because these findings appear to discredit the Piagetian proposition that metric concepts do not emerge until middle or late childhood. However, when developmental psychologists look outside the laboratory and turn to the kinds of educational, occupational, and daily tasks discussed in earlier sections of this chapter, they confront fascinating and nontrivial questions concerning the ways cognitive competencies, task demands, and environmental contexts interact to facilitate or impede success. It is arguably as intriguing to study the range of conditions under which an underlying competency can be activated and applied as it is to study the conditions under which an underlying competency emerges in the first place. At a more general level, this conclusion is a reminder of why it is better to avoid conceptualizing developmental phenomena as dichotomies in which children either do or do not have some competency (see Liben, 1997b; Overton, 1998).

Applied Developmental Psychologists

For those readers whose primary interest is in taking theoretical work from developmental psychology and applying it to the world of education, the key lessons from this chapter largely concern challenges of communication and

implementation of concepts and the associated need for appropriate assessment. That is, although there are many important connections between what has been learned in cognitive-developmental research and a wide range of educational goals, it is often difficult to bridge the gap between theory and application and to know when one has succeeded in doing so. One striking illustration described earlier was our own failed attempt to teach children the concept of north (Liben & Downs, 2001). Despite our theoretical understanding of children's potential overreliance on body-centered frames of reference, we provided a classroom lesson that led some children to replace their erroneous belief that north was invariably straight ahead with the erroneous belief that north was invariably over their left shoulder.

This illustration carries with it another key lesson: the importance of including assessments to monitor communicative and instructional success. In the previous example, had we not assessed children's understanding of north in an entirely new context during a field trip, we would have been unaware of continued misunderstandings. It is critical that assessments require students to apply their knowledge in new ways and in new contexts rather than to repeat information in exactly the same way and context in which it was initially presented. A classic example of the importance of this caveat in the domain of spatial thinking comes from the work of Vosnoidou and Brewer (1992). They found that elementary school children were extremely proficient in responding to questions about Earth when the questions tapped information as taught. Thus, when asked about the shape of Earth, almost all children were able to answer correctly by responding verbally that Earth is round or spherical and by drawing a round shape. When asked novel questions (e.g., what would happen if one were to keep walking and walking and walking), responses revealed that many children were actually working from faulty mental models (e.g., a pancake rather than spherical model of Earth).

It is particularly important that assessments tap something other than rote learning or near transfer when the lesson is intended to enhance some general understanding or skill. For example, in the context of the overarching goal of educating spatial thinkers, lessons about north are aimed not only at teaching cardinal directions per se, but also at teaching the use of stable distal frames of reference even in the face of changing proximal referents. Thus, assessments of instructional suc-

cess must go beyond testing whether children know that west is to their left and east is to their right under the imposed condition (or incorrect assumption) that they are facing north.

The communicative challenges encountered when bridging theory to practice and the need to monitor understanding applies not only when trying to teach children directly, but also when trying to convey to other professionals the information that they need to design educational materials. One illustration comes from a project mentioned earlier in which we (Liben & Downs, 1994, 2001) consulted with Children's Television Workshop as they planned to introduce geography to *Sesame Street*. Based on our knowledge that young children would be likely to have difficulty understanding representations that depict referents from unfamiliar vantage points, we suggested showing objects or vistas from views other than the prototypical child's-eye view. In particular, we suggested using bird's-eye views (perhaps Big Bird's-eye views) and worm's-eye views. We had intended that our suggestion be translated into video clips of the same objects or vistas viewed from straight ahead (child's-eye views), from above (bird's-eye views), and from below (worm's-eye views).

Our suggestion for bird's-eye views was cleverly implemented. In one clip, for example, the school playground was shown, sequentially, from a child's-eye view of what would be seen while walking onto the playground, then from a tree top, and then from a distant crane. Playground objects (e.g., the basketball hoop) were then shown being transformed into plan-map symbols that were located on a map. The implementation of our suggestion for a worm's-eye view was less successful. We were surprised to find that the worm-related geography video clip showed two worms racing across the United States (by crawling on a small-scale map of the United States) as their progress was narrated (e.g., "They are arriving in Chicago!" "They are crossing the Rockies!"). Not only did this video clip fail to offer children the chance to view the same referent from varying vantage points, but it conflated representational and referential space and symbols. For example, the worms simply moved across the paper without regard to whether they followed roads, crawled over lakes, and so on, and clearly the scale relation between movement on the map and travel through the referent country was grossly misleading. This example serves as a reminder of the importance of continually monitoring understand-

ing of the theoretician's intended message, whether the message is directed to students or to the professionals designing materials to teach them.

Educators

For readers whose primary interest is in educating children, either directly (e.g., teachers or parents) or indirectly (e.g., faculty members in colleges of education or members of school boards), the central messages of this chapter are that spatial thinking is important and pervasive, that many children do not develop strong spatial thinking skills in their natural home and school environments, and, thus, that explicit spatial education is needed. Although the relevant research base is somewhat restricted, those data that are available support the conclusion that educational interventions can be successful in enhancing at least some spatial skills, and that these improvements have positive consequences for at least some broader educational goals. Illustrative are studies cited earlier by Pallrand and Seeber (1984) showing that college students given various kinds of spatial experiences (e.g., drawing outdoor scenes, instruction in geometry) received higher scores on tests of visual skills and higher grades in physics, and by Casey et al. (1997, 2001) showing significant relationships between spatial skills and mathematics motivation and performance.

For an audience of educators, however, there are some extremely important questions that remain unanswered and that must be addressed in future work. One group of questions is pedagogical. First, from an instructional perspective, there remains the practical question of how to implement the recommendation to infuse spatial education into existing school subjects. It will be necessary to catalogue spatial concepts and skills (see NRC, 2005), identify individual courses that are relevant at each grade level, select concepts within those courses that could be infused with spatial education, and design specific materials and activities that can simultaneously facilitate spatial thinking and deliver specific course content.

Undoubtedly, these steps are easier to list than to follow. Again, I draw from our own research to illustrate this point. In one study (Liben & Szechter, 2002), we hypothesized that children's understanding of vantage points might be facilitated by digital photography lessons. Our reasoning was that digital photography would

repeatedly expose children to the representational consequences of changes in viewing position. For the experimental condition, adult research assistants were asked to take individual children (8 to 10 years old) on a campus walk while children took photographs of their own choosing. These adults were asked to guide the child's photographic experience in a way that would emphasize the role of vantage point. However, pilot testing revealed that research assistants found it exceedingly difficult to devise, spontaneously, experiences that would serve this purpose. For the investigation itself, we therefore substituted a method in which photographic requests were scripted (e.g., every child was asked to take a photograph of a lion sculpture so that only one of two paws would be visible in the image). For the current discussion, what is relevant is the observation that adults do not necessarily find it easy to identify opportunities for spatial education.

Another line of evidence leading to the same conclusion comes from a study (Szechter & Liben, 2004) in which parents were given a picture book that was based on a spatially challenging concept (each page progressively zoomed away from the initial scene). When asked to read the book to their preschool child, some parents attempted to explain the spatial premise of the book in multiple and creative ways. Others, however, entirely ignored the spatial challenge of zooming and instead simply labeled individual objects depicted in the book. The examples from both studies suggest that many adults find it difficult to recognize and use potential opportunities to encourage spatial thinking, a difficulty that must be anticipated among classroom teachers as well. Ideally, professional development (e.g., in-service workshops on spatial education) might help to foster these skills, but at a minimum, curriculum development would need to involve collaboration between those who have expertise in teaching the specific course content and those who have expertise in developmental spatial cognition.

Apart from the need to identify concrete opportunities to teach spatial thinking within specific courses, future work must address other general pedagogical questions. One question is whether teachers should make the spatial components of their classes explicit. For example, would it suffice to have children use maps that show the same referent space from many different viewing distances, angles, and azimuths, or would it be necessary for children to learn metacognitive formalisms (e.g., the cartographic eye shown in Figure 6.1)

and use these to analyze individual maps? Another question is whether teachers should link spatial instruction across domains. For example, should teachers be facilitating children's use of spatial thinking within the confines of individual courses (e.g., within art, geography, and biology), or should teachers guide children to see common spatial operations and representations across disciplines (e.g., highlighting the use of coordinate axes across disciplines)?

In addition to questions about how to implement the curricular recommendations, there are also questions about how to evaluate the effectiveness of whatever programs are implemented. The core claim of this chapter is that infused spatial education will enhance spatial thinking skills, and that these, in turn, will facilitate success in problem solving in a wide range of school, occupational, and life contexts. Thus, evaluation must address both categories of outcomes. The first, for example, could be assessed by examining children's performance on standardized tests of spatial skills (e.g., solving mental rotation tasks or linking two- and three-dimensional representations); the second could be assessed by testing children's ability to master novel problems in educational, daily, or occupational settings (e.g., interpreting mineral crystal structure in a geology course, assembling furniture from a manufacturer's graphic instructions, or reading an architectural blueprint).

Before leaving the topic of assessment, it is also important to acknowledge that spatial assessment is critical not merely as a means of curriculum evaluation, but also as a marker of, and an influence on, the judged importance of the domain. This statement reflects the common adage "We assess what we value and we value what we assess." In the contemporary educational era defined by the No Child Left Behind [NCLB] legislation (U.S. Department of Education, 2002), it is particularly clear that a decision about what is assessed is a decision about what is taught. As children's performance on English and math assessments has become the criterion by which not only children, but also teachers, schools, and districts are judged, the classroom time devoted to English and math has grown, while the time devoted to other curricula (e.g., social studies, languages, and the arts) has been reduced (e.g., see Goldsmith, 2003). It is possible that the recent addition of science to NCLB assessments may provide an opening for intentional and focused spatial education given that so much of science draws on spatial skills (see NRC, 2005).

It should be obvious that it would take significant human and financial capital to insert specific spatial goals into the implementation of NCLB, to answer the pedagogical and evaluation questions raised in this chapter, and to develop, implement, and sustain spatial education programs themselves. The justification for those resources is equally obvious: We need only join Monsieur Jourdain in contemplating how we operate in our daily lives. Spatial thinking, like verbal and mathematical thinking, is central to our intellectual world, and it deserves to be central to our educational world as well.

Evolving Questions in Evolving Environments

In closing, it is important to note that just as individual children change over time, so, too, the environment that surrounds them changes over time. Changes are particularly rapid in the representational environment. Although societies have long had spatial-graphic representations such as maps and charts (Harvey, 1980; Tversky, 2001), it is only during recent decades that we have had the representational technology to build and rotate images (e.g., computer-assisted design [CAD] software), combine data from multiple geo-referenced databases (e.g., geographic information systems), image internal organs and workings of the human body (e.g., computer-assisted tomography scans), and identify positions within meters on Earth's surface (e.g., global positioning systems), to name only a subset of the burgeoning technology. Indeed, the twenty-first century has been labeled "The Spatial Century" (Gould, 1999).

These changes raise fascinating questions about development and education. In some ways, technologies like these place new spatial demands on users (e.g., an image of a cross section of the brain requires the surgeon to understand where the cross section fits into the patient's head), but in other ways, they may reduce spatial demands (e.g., a car navigation system allows the driver to know whether to turn right or left even without attending to the self-map-space relations shown in Figure 6.10). Thus, just as people have off-loaded spelling functions from their long-term memory to their word processing programs and their multiplication tables to their calculators, it may be that people will off-load mental rotation to their CAD programs and wayfinding to their in-car navigation systems. Much research will be needed to discover which new technologies serve to exercise and hence foster children's spatial skills and which new technologies serve to take over and hence di-

minish children's spatial skills. What this research is likely to reveal is that, as with most tools, a given technology can be used profitably or badly. The challenge for educators will be to find ways to achieve the former rather than the latter. Although it is impossible to predict precisely where new technologies will lead and the effects they will have on human cognition, it is safe to predict that they will require users who are facile in spatial as well as verbal thinking. The traditions of developmental psychology must be combined with the traditions of education to prepare spatial thinkers who can meet the challenges and opportunities of our evolving world.

Character education is both popular and controversial. In this chapter, a psychological approach to understanding its central constructs is proposed. We review philosophical conceptions of virtues and conclude that character education cannot be distinguished from rival approaches on the basis of a distinctive ethical theory. We review several educational issues, such as the manner in which the case is made for character education, the implications of broad conceptions of the field, whether character education is best defined by treatments or outcomes, and whether character education is

best pursued with direct or indirect pedagogies, a debate that is placed into historical context. We note that character education requires robust models of character psychology and review several new approaches that show promise. Six general approaches to character education are then considered. Integrative Ethical Education is described as a case study to illustrate theoretical, curricular, and implementation issues. We summarize issues of implementation that are challenges to research and practice. We conclude with several challenges to character education, chief of which is the need to find a distinctive orientation in the context of positive youth development. Problem-free is not fully prepared, but fully prepared is not morally adept.

The moral formation of children is one of the foundational goals of socialization. The ambitions that most parents have for their children naturally include the development of important moral dispositions. Most parents

We express our appreciation to the following colleagues, who read and commented on previous versions of this chapter: Jack Benninga, Jerrell Cassady, Kathryn Fletcher, Lisa Huffman, Jim Leming, Tom Lickona, Kristie Speirs Neumeister, Sharon Paulson, Ben Spiecker, Jan Steutel, Larry Walker, and Marilyn Watson.

want to raise children to become persons of a certain kind, persons who possess traits that are desirable and praiseworthy, whose personalities are imbued with a strong ethical compass. Moreover, other socialization agents and institutions share this goal. The development of moral character is considered a traditional goal of formal education. It is a justification for the work of youth organizations, clubs, and athletic teams. It is the object of homily and religious exhortation. It shows up in presidential speeches. It has preoccupied writers, educators, curriculum experts, and cultural scolds. The number of titles published on character and its role in private and public life has increased dramatically over past decades. So have curricula for teaching the virtues in both schools and homes. Several prominent foundations have thrown their resources behind the cause, and professional meetings dedicated to character education are marked by significant commitment, energy, and fervor. In 2003 a new periodical, the *Journal of Research in Character Education*, was launched to bring focus to scholarly inquiry.

Yet, for all the apparent consensus about the need to raise children of strong moral character, and for all the professional attention devoted to the cause, it is a striking fact that character education occupies contested ground in American society. Indeed, the issues that surround character education are riven with such partisan rivalry that the very terms of reference seem to function like code words that betray certain ideological and political commitments. Whether one is for or against the character education movement is presumably a signal of whether one is a liberal or a conservative, whether one is sympathetic toward traditional or progressive trends in education, whether one thinks the moral life is more a matter of cultivating excellence than submitting to obligation or whether moral evaluation is more about agents than about acts, or whether one prefers the ethics of Aristotle and classical philosophy to that of Kant and the “Enlightenment Project.”

This ideological division sometimes surfaces as a technical argument about pedagogy, for example, whether one should endorse direct or indirect methods of instruction. It shows up in how one conceives fundamental questions concerning, for example, the source of our moral values or the epistemological status of our moral claims. It shows up in our understanding of the very goals and purposes of education in liberal democratic polities and in our understanding of what an ethical life consists of: what it means to be a moral agent,

to possess virtue, and to live well the life that is good for one to live. It shows up, too, in the sort of developmental literatures, constructs, and metaphors that one finds compelling.

There is a certain value, of course, in casting large, fundamental, and deeply felt perspectives into such stark relief. It often is useful to draw sharp boundaries around contesting points of view to discern better their strengths and weaknesses. Yet Dewey (1938) warned of the folly of construing educational options in terms of either/or. In so doing, he argued, one runs the danger of advancing one’s view only in reaction against the rival, which means that one’s vision is controlled unwittingly by that which one struggles against. “There is always the danger in a new movement,” he writes, “that in rejecting the aims and methods of that which it would supplant, it may develop its principles negatively rather than positively and constructively” (p. 20), with the result that it fails thereby to address “a comprehensive, constructive survey of actual needs, problems and possibilities” (p. 8).

In this chapter, we review the literature on character education but in a way that avoids, we hope, the dangers of either/or. It is necessary, of course, to sketch the contours of the great debates that have characterized this field. Fortunately, however, there has emerged in recent years a literature that has attempted to bridge the conceptual and ideological divide (e.g., Benninga, 1991a, 1991b; Berkowitz & Oser, 1985; Goodman & Lesnick, 2001; Nucci, 1989; Ryan & Lickona, 1992), or at least to face it squarely. Our search is for the via media that provides, in Dewey’s words, the “comprehensive, constructive survey of actual needs, problems and possibilities.”

We do not approach our task in complete neutrality. Our own view is that character education would profit from advances in other domains of psychological science (Lapsley & Narvaez, 2005). Indeed, character is a concept with little theoretical meaning in contemporary psychology, although it has been the source of ethical reflection since antiquity. An approach to character education that is deeply “psychologized” would look for insights about moral functioning in contemporary literatures of cognitive and developmental science, in the literatures of motivation, social cognition, and personality. Researchers in these areas rarely draw out the implications of their work for understanding the moral dimensions of personality and its formation. Yet it is our contention that a considered understanding of what is

required for effective character education will be forthcoming only when there emerges a robust character psychology that is deeply informed by advances in developmental, cognitive, and personality research. Moreover, effective character education will require deep integration with the educational psychology literatures that constitute the knowledge base for instructional best practice. In short, *character* education must be compatible with our best insights about psychological functioning; *character education* must be compatible with our best insights about teaching and learning (Lapsley & Power, 2005; Narvaez, 2005a).

In the next section, we take up important preliminary issues that establish the context for our review. First, we attempt to understand the various ways character has been conceptualized. Second, we discuss what is at stake with these different conceptualizations for the various theoretical, philosophical, and educational perspectives that have taken up positions on the question of moral character. Third, we attempt to place this discussion in a historical context. As we will see, there is an enduring quality to much of the debate around character education. Fourth, we review recent research on moral personality that could serve as a basis for an integrated psychology of character. Following this discussion, we review promising character education strategies, describe an integrative approach to ethical education, discuss various implementation issues that are common to character education, and outline possible futures for the field.

HOW IS CHARACTER DEFINED?

Character is derived from a Greek word that means “to mark,” as on an engraving. One’s character is an indelible mark of consistency and predictability. It denotes enduring dispositional tendencies in behavior. It points to something deeply rooted in personality, to its organizing principle that integrates behavior, attitudes, and values. There have been numerous attempts to define character more precisely. It is a “body of active tendencies and interests” that makes one “open, ready, warm to certain aims and callous, cold, blind to others” (Dewey & Tufts, 1910, p. 256). It is made up of a set of dispositions and habits that “patterns our actions in a relatively fixed way” (Niegorski & Ellrod, 1992, p. 143). It refers to the good traits that are on regular display (Wynne & Ryan,

1997). Character is an individual’s “general approach to the dilemmas and responsibilities of social life, a responsiveness to the world that is supported by emotional reactions to the distress of others, the acquisition of prosocial skills, knowledge of social conventions and construction of personal values” (Hay, Castle, Stimson, & Davies, 1995, p. 24). It includes the capacity for self-discipline and empathy (Etzioni, 1993; 1996). It allows ethical agents, as Baumrind (1999, p. 3) put it, “to plan their actions and implement their plans, to examine and choose among options, to eschew certain actions in favor of others, and to structure their lives by adopting congenial habits, attitudes and rules of conduct.”

As one can see, defining character is no straightforward matter. Still, one can point to habits, traits, and virtues as three concepts that are foundational to most traditional accounts of moral character. These concepts are interdependent and mutually implicative. Moral character, on this view, is a manifestation of certain personality *traits* called *virtues* that dispose one to *habitual* courses of action. Habits and traits carry a heavy semantic load in the history of psychology that complicates their being used in the context of character education with much conceptual clarity. Virtue is a notion derived from ethics but has very little traction in psychological science unless it is translated into terms such as “habits” and “traits” that are themselves larded with conceptual implications that are controversial.

The Problem with Habits

According to a traditional view, a habit is a disposition to respond to a situation in a certain way. Repeating a behavior or set of procedures over the course of socialization develops this disposition. But not only does right behavior serve to establish habits; they are its consequence as well. Persons of good character behave well without much temptation to do otherwise (W. J. Bennett, 1980), nor is their right behavior a matter of much conscious deliberation: “They are good by force of habit” (Ryan & Lickona, 1992, p. 20). Habits are sometimes used as synonyms for virtues and vices, as in the claim that “character is the composite of our good habits, or virtues, and our bad habits, or vices” (Ryan & Bohlin, 1999, p. 9), and habits also stand in for the dispositional (or “trait”) qualities of character.

The appeal for character educators of the role of habits in the moral life has important classical sources. In Book

II of the *Nicomachean Ethics*, Aristotle (350/1985) takes up the nature and definition of virtues. He argues that moral virtue is not a natural part of the human endowment but must come about as a result of habituation. We acquire virtues, on this account, by exercising them. We learn what virtue requires by acting virtuously. No one has the prospect of becoming good unless one practices the good. This would not be unlike the acquisition of skill in the arts or in crafts. Just as individuals become “builders by building and harp players by playing the harp, so also, then, we become just by doing just actions, temperate by doing temperate actions, brave by doing brave actions” (I. 1103b).

According to Steutel and Spiecker (2004; Narvaez & Lapsley, 2005), the Aristotelian notion of habituation is best understood as learning by doing with regular and consistent practice under the guidance and authority of a virtuous tutor. This is not unlike the cultivation of skills through coached practice, although the affinity of skills and virtues is controversial (Peters, 1981; Ryle, 1972). The habits that result from Aristotelian habituation are permanent or settled dispositions to do certain kinds of things on a regular basis but automatically, without reflective choice, deliberation, or planning (Steutel & Spiecker, 2004). In our view, there is a way of understanding Aristotelian habits that is completely compatible with contemporary models of social cognition and cognitive science, including the requirement of automaticity (Lapsley & Narvaez, 2004). For example, Aristotelian habituation can be understood by reference to developing expertise and skill development, notions that underwrite an integrative approach to ethical education that we discuss later (Narvaez, 2005a).

However, retaining the language of habits comes at a cost. When the notion of habits is invoked in the present context, what comes to mind is not classical ethical theory but a certain strand of behavioral learning theory whose core epistemological assumptions have long been challenged. It is linked with an epistemology that locates the developmental dynamic solely in the environment and not with the active child. It is linked with a mechanistic worldview that understands the person to be reactive, passive in his or her own development, and shaped by external contingencies arranged by others. It suggests that learning takes place from the outside *in*, where learning is the acquisition of a repertoire of conditioned responses—habit family hierarchies—that take little notice of the child’s own initiative in transforming

the learning environment in constructive acts of cognitive mediation.

Hence, an unvarnished behavioral account of habits is belied by contemporary models of developmental science that emphasize the cognitive-constructive activity of the developing child, who is in dynamic interaction with changing ecological contexts across the life course. Consequently, when the notion of habits is invoked to account for moral character, it seems at odds with what is known about developmental processes and constructivist best practice in education (Kohn, 1997). Although invoking habits seems to keep faith with a certain understanding of character in the classical sources, it also has made it more difficult for educators and researchers who reject the behaviorist paradigm to rally around the cause of character education with much enthusiasm (Nucci, 2001). This is unfortunate, in our view, because Aristotelian habits are not coterminous with the habits of behavioral theory. Aristotelian habituation is not coterminous with behavioral laws of learning that use the same term. Aristotelian perspectives contribute much of value to our current understanding of character and its formation, although an understanding adequate for psychological analysis will require translation into contemporary models of developmental and cognitive science.

The Problem with Traits

The language of traits also presents a terminological challenge. The notion that the dispositional features of character are carried by a set of personality traits called *virtues* is both deeply entrenched and controversial. In one sense, there is something completely obvious about trait language, at least in common parlance. Human personality is marked by important continuities. We are disposed to reach certain cognitive interpretations and judgments of events and to experience certain affective and behavioral responses in ways that are predictable and consistent, and these dispositional patterns we designate with the language of traits. We use trait terms to pick out the dispositional tendencies that serve as the basis for charting individual differences. Moreover, our differential valuation of these trait differences provides the basis for moral evaluation of persons. Some displays of individual differences warrant praise and encouragement, and we designate them virtues; others warrant condemnation and admonishment, and we designate those vices.

This view of traits typically comes with two additional assumptions. One is that traits denote stable behavioral patterns that are evident across situations. Another is that traits coalesce as a unity within the person of moral or vicious character. Both assumptions are problematic. The first follows from a traditional understanding that traits-of-character generate dispositional tendencies that are on “regular display.” They are adhesive, deeply constitutional aspects of our personality, elements that are engraved “on our essence” (Ryan & Bohlin, 1999, p. 10) that bid us to respond to situations in ways typical of our character. Ryan and Bohlin’s example of character is instructive:

If we have the virtue of honesty, for example, when we find someone’s wallet on the pavement, we are characteristically disposed to track down its owner and return it. If we possess the bad habit, or vice, of dishonesty, again our path is clear: we pick it up, look to the right and left, and head for Tower Records or the Gap. (p. 9)

This example illustrates what we take to be the received view: Dispositions are habits; some habits are good and carry the honorific title “virtues,” other habits are bad and are designated vices; and habit possession clears the path to predictable and characteristic action. Indeed, a dispositional understanding of traits seems part of our folk theory of human personality and would seem to translate into a straightforward goal for character education: See to it that children come to possess the virtues as demonstrable traits in their personality; see to it that children come to possess good habits.

Yet, to say that moral dispositions coalesce in individuals as traits (or even as “habits”) strikes many researchers as a peculiar thing to say. Indeed, in personality research, the nomothetic trait approach has not fared well. This is because the cross-situational generality and consistency of trait behavior has not been demonstrated empirically, nor do trait models have much to say about how dispositions are affected by situational variability. As Mischel (1968, p. 177) put it, “Individuals show far less cross-situational consistency in their behavior than has been assumed by trait-state theories. The more dissimilar the evoking situations, the less likely they are to produce similar or consistent responses from the same individual.”

This is remarkably close to conclusions reached by Hartshorne and May (1928–1930) in their classic *Studies in the Nature of Character*, published in three volumes. In one “terse but explosive statement” (Chap-

man, 1977, p. 59), Hartshorne and May (1929) concluded that the

consistency with which he is honest or dishonest is a function of the situations in which he is placed so far as (1) these situations have common elements, (2) he has learned to be honest or dishonest in them, and (3) he has become aware of their honest or dishonest implications or consequences. (p. 379)

These studies indicated that the virtue of honesty is not an enduring habit marked indelibly on the essence of a child’s character, nor is dishonesty a similarly enduring vice. Children cannot be sorted cleanly into behavioral types on the basis of presumptive traits, habits, or dispositions. In these studies, traits associated with moral character showed scant cross-situational stability and very pronounced situational variability, which is precisely the findings that later personality researchers would report for other traits.

The pessimistic conclusions of Hartshorne and May (1928–1930) have been described variously as a “body blow” (Leming, 1997, p. 34) or “death blow” (Power, Higgins, & Kohlberg, 1989a, p. 127) to the cause of character education. Indeed, they are often cited by partisans of the cognitive developmental tradition as evidence of the poverty of the character approach (e.g., Kohlberg, 1987). Certainly these studies, along with Mischel’s (1990, 1999) analysis, seemed to cast doubt on the fundamental assumption of the received view of character traits. Consequently, the ostensible failure of traits in the study of personality made recourse to virtues an unappealing option for many researchers in moral psychology (Lapsley & Narvaez, 2004).

Still, one should not draw the wrong conclusions from evidence that traits show significant situational variability. What is doubted is not the fact that personality shows important dispositional continuity; what is doubted is the implausible view that trait possession invariably trumps the contextual hand that one is dealt. The reality of cross-situational variability is not a failure of the dispositional approach to personality; it is a failure only of the received view of traits. There is, indeed, coherence to personality, but personality coherence cannot be reduced simply to mere stability of behavior across time and setting (Cervone & Shoda, 1999). Instead, coherence is evident in the dynamic, reciprocal interaction among the dispositions, interests, and potentialities of the agent and the changing contexts

of learning, development, and socialization. Person variables and contextual variables dynamically interact in complex ways, and both are mutually implicated in behavior. It is here, at the intersection of person and context, where one looks for a coherent behavioral signature (Mischel, 2005; Mischel & Shoda, 1995; Mischel, Shoda, & Mendoza-Denton, 2002; Shoda, Mischel, & Wright, 1994).

The inextricable union of person and context is the lesson both of developmental contextualism (Lerner, 1991) and social cognitive approaches to personality (Cervone & Shoda, 1999; Mischel, 1999), and a robust character psychology will have much in common with these paradigms. Indeed, recent research already vindicates the promise of this perspective. For example, Kochanska's research program shows that the development of conscience and internalization in early childhood requires a goodness-of-fit between styles of parental socialization and children's dispositional temperament (Kochanska, 1993, 1997; Kochanska & Thompson, 1997). In one study, toddlers (age 2 to 3 years) who were temperamentally fearful showed strong evidence of internalization when maternal discipline was mildly coercive, whereas toddlers who were temperamentally fearless profited from mother-child interactions that were mutually cooperative, positive, and responsive (Kochanska, 1995), a pattern that was longitudinally stable 2 years later (Kochanska, 1997). Other studies showed that the quality of the parent-child relationship, as reflected in attachment security, can itself moderate the relationship between parenting strategies and moral internalization (Kochanska, Aksan, Knaack, & Rhines, 2004), and that power assertion can have heterogeneous outcomes for moral behavior and moral cognition (Kochanska, Aksan, & Nichols, 2003). Similarly, Eisenberg and her colleagues showed that a prosocial personality disposition emerges in early childhood and is consistent over time (Eisenberg et al., 2002), although the manifestation of the "altruistic personality" is mediated by individual differences in sympathy (Eisenberg et al., 1999) and the demand characteristics of social contexts (Carlo, Eisenberg, Troyer, Switzer, & Speer, 1991). Finally, Mischel and his colleagues (Shoda, Mischel, & Wright, 1994; Wright & Mischel, 1987) showed that dispositional aggression in children is not, in fact, on regular display across settings but is observed typically when aggressive children are placed in settings of a certain kind, in settings, for example, where demands are placed on their sense of competence. In these exam-

ples, evidence of dispositional coherence requires contextual specification.

A second assumption is that traits hang together to form a unitary consistency within a person. On this view, the various virtues cohere in unified practice. One cannot adequately display courage unless one is also prudent; one cannot be just without temperance; one cannot display any one virtue without all the others. The unity of virtues is a notion that has classical sources, and it is at least implicitly assumed in many discussions about the role of character in public life. Carr (1991, p. 266) points out that the unity-of-virtues perspective is simply the claim that "if a quality of character is a *genuine* virtue it is not *logically* inconsistent with any other real virtue," and that virtues "form a unity because they stand in a certain direct relationship to the *truth* in human affairs." The unity of virtues is a logical possibility; it is an ideal aspiration of the virtuous life.

Still, there are doubts about the adequacy of the unity thesis on both ethical (Carr, 2003; Kent, 1999; MacIntyre, 1981) and psychological grounds. One is not so much concerned with whether the various virtues cohere as a logical possibility, but with whether the unity thesis satisfies a basic criterion of minimal psychological realism that it be a possibility for creatures like us (O. Flanagan, 1991). It is possible after all, given the exigent contingencies of human development, that not all good qualities are equally compatible, or that a good life lived well requires the full range of human excellence. Rather, we become specialists in limited domains of application as a result of the particularities of our developmental experiences, the choices we make, and the environments we select. Our choices canalize the development of dispositions proper to our commitment and to our aspiration, while leaving others unselected, undeveloped, and unobserved in our behavioral repertoire. As a result, certain character blind spots might well be the price one pays for cultivating excellence in other domains of one's life. It may even be the case that our virtues are made possible *just because* other aspects of our character have gone undeveloped.

The Problem with Virtues

The "Character Education Manifesto" (Ryan & Bohlin, 1999, p. 190) asserts that the business of character education "is about developing virtues—good habits and dispositions which lead students to responsible and mature adulthood." We have seen that the appeal to habits

and dispositions is not entirely satisfactory given the status of these notions in contemporary psychology. But talk about virtues is also fraught with difficulties. One problem for virtue is the specification of what it entails. How does one “fill out” a particular virtue? How should any virtue be manifested in concrete situations? Aristotle argued famously that virtue lies in the mean between excess and defect. Virtue aims for the intermediate of passions, appetites, and actions: “To feel them at the right times, with reference to the right objects, toward the right people, with the right motive, and in the right ways, is what is both intermediate and best, and that is characteristic of virtue” (1985, l. 1106b). Of course, it is a complication that some actions and passions have no mean, and many states of character have no name: “Now most of these states also have no names, but we must try, as in other cases, to invent names ourselves” (l. 1108a). Kupperman (1999) points out that Aristotle’s main point here is not moderation, as many assume, but judgment and flexible response to individual cases. The virtuous person does not follow habits or rules inflexibly but adapts conduct to particular circumstances.

Noddings (2002) noted that the specification of the content of virtue often derives from one’s religion or philosophy. Take, for example, Lickona’s (1991a, p. 364) view that character education must take a stand on whether it’s a good idea for adolescents to masturbate, use condoms, or engage in sexual activity, all behaviors “which [are] clearly wrong for students to do.” “The truth is,” he writes, “that sexual activity by unmarried teenagers is harmful to them and harmful to society. The morally right value is for young people to avoid such activity” (p. 364). Although this makes the content of virtue quite clear, and quite possibly correct, it does not entirely settle the matter, and one suspects that very different calculations of what is “clearly wrong” and “harmful to society” are possible given a different starting point.

At other times, the moral basis for a specification of virtue is not entirely apparent. One account of the characteristics of a moral teacher suggests, for example, that teacher morality is made evident by small actions, such as “presenting well-planned, enthusiastically taught classes,” not being petty, not gossiping, getting homework and test papers returned to students promptly, removing the wad of gum from the water fountain, planning a surprise birthday party for a fellow teacher, or going the extra mile for a struggling student (Wynne & Ryan, 1997, p. 123). Good student character is simi-

larly reflected in small acts: being a member of the math team, tutoring, cleaning up the classroom, joining a sports team, serving as an aide or monitor. One should not minimize praiseworthy behavior or gainsay the value of small kindnesses and good deeds well done, yet the present examples either underspecify the content of moral virtue (insofar as these behaviors could be motivated by a consideration not of virtue but of duty and obligation) or else link it with such commonplaces that virtue is indistinguishable from any behavior that is simply well regarded by others.

Most approaches to character education stress the importance of practical reasoning in the life of virtue (e.g., Lickona, 1991a; Ryan & Bohlin, 1999). Knowing the good, sizing up the situation, gaining insight about how to apply or use moral rules are the work of practical wisdom. Its importance to virtue is evident in Aristotle’s (350/1985, l. 1107a) definition of virtue: “It is a state [of character] concerned with choice lying in a mean relative to us, which is defined by reference to reason and in the way in which the person of practical wisdom would determine it.” Moreover, Aristotle seems to acknowledge that the proper display of virtue would require keen attention to situational complexity, “to know the facts of the case, to see and understand what is morally relevant and to make decisions that are responsive to the exigencies of the case” (Sherman, 1999, p. 38). Or, as Aristotle put it, “For nothing perceptible is easily defined, and since these circumstances of virtuous and vicious actions are particulars, the judgments about them *depend on perception*” (l. 1109b, emphasis added).

So, if virtues are habits, they must be habits of a certain kind. The kind of habituation proper to virtues is a critical facility; it includes learning how to discern, make distinctions, judge the particulars of the case, and make considered choices (but sometimes automatically). They are dispositions of interpretation (Rorty, 1988) that cognitive psychologists might conceptualize as schemas, prototypes, or scripts whose accessibility and activation make possible the discriminative facility that allows one to act in ways appropriate to the situation (and whose functional readiness could approach automaticity).

The context specificity that attaches to the work of virtues would suggest that one goal of character education would be to help children sort through moral ambiguity by learning when and how to activate what virtue requires given the concrete requirements of a specific context (Noddings, 2002). Of course, what the concrete situation requires of us, say, by way of honesty might

well conflict with the demands of compassion, for example. This means that no account of the virtues can be absent the lesson of developmental contextualism, which is that person and context interpenetrate in complex ways and cannot be separated. One must learn, during the course of character development, that the exercise of virtue requires contextual specification; it requires *triage* with respect to the dispositions required for particular settings and an ordering of priorities for their expression given the requirements of the situation. The work of virtues is not unlike the work of any dispositional quality in that the coherence of moral character, its dispositional signature, is to be found at the intersection of person and context (Mischel, 2005).

PHILOSOPHICAL CONSIDERATIONS

Character is fundamentally an ethical concept that struggles for psychological specification. Consequently, the nature of character, both as the moral dimension of personality and as an object of education, invites significant philosophical reflection. In this section we take up two fundamental issues. First, we describe the role that character education plays in responding to concerns about ethical relativism. Second, we examine whether character education can be distinguished from other educational objectives by its commitment to a particular ethical theory associated with Aristotle and the virtue ethics tradition.

Bag of Virtues and Foundations

One suspects that there is deep ambivalence among theorists of character education to consider how virtue works in context for fear that it invites comparison to “situational ethics” and ethical relativism. This is a charge that character education has had to fend off ever since Kohlberg derisively characterized character education as the “bag of virtues” approach. For Kohlberg and the cognitive developmental tradition, the study of moral development was a way to provide the psychological resources by which to defeat ethical relativism. In answer to the ethical relativist who claims that moral perspectives are incommensurable, Kohlberg (1969, p. 352) asserted Piaget’s “doctrine of cognitive stages,” which provides a developmental criterion for assessing the adequacy of moral judgment. Moral judgments that approach the moral ideal represented by the final stage

of moral reasoning were more adequate on both psychological and ethical grounds (Kohlberg, 1971, 1973). Moreover, justice reasoning at the highest stages made possible a set of operations that could generate consensus about hard case moral quandary. One defeats ethical relativism, then, by motivating justice reasoning to higher stages of development (Lapsley, 2005).

But Kohlberg’s project left no room for traits, virtue, or character, for two reasons. First, there was no sensible way to talk about virtues if they are conceptualized as traits-of-character. After all, the Hartshorne and May (1928–1930) studies appeared to show that the psychological reality of traits could not be empirically confirmed (see also Puka, 2004, for trenchant doubts about the reality of virtues) or else could not be relied on to document dispositional consistency in moral behavior. Second, and perhaps more to the point, the language of traits did not provide what was wanted most, which was a way to defeat ethical relativism on psychological grounds. For Kohlberg, any compilation of favored or approved virtues is completely arbitrary. It entails sampling from a “bag of virtues” until a suitable list is produced that has something for everyone. What’s more, and worse, given Kohlberg’s project, the meaning of virtue trait words is relative to particular communities, for, as Kohlberg and Mayer (1972) put it, one person’s integrity is another person’s stubbornness; one person’s honesty in expressing true feelings is another person’s insensitivity to the feelings of others. Not surprisingly, the character education movement uniformly rejects the notion that character education gives comfort to ethical relativism. Indeed, as we will see shortly, the reconstruction of educational history favored by advocates of character education typically pins the blame for “youth disorder” on the ethical relativism promoted by other trends in American culture and education, for which character education is the remedy.

If the problem of settings and context specificity is taken up at all, it takes the form of addressing the question of “whose values” are to be taught in the schools. But this is unproblematic for many character educators because, it is asserted, there are objective values universally agreed on that schools should address with confidence (Lickona, 1991a). For example, one might appeal to natural law theory to “define morality in rational terms agreeable to all” (p. 141). One might distinguish between universal core values that we all do agree on (e.g., respect, responsibility, honesty, justice, caring), possibly because they meet certain canons of objectivity

(e.g., Kant's categorical imperative or Kohlberg's "Piagetian" criteria of reversibility) and additional values that are unique to certain communities, such as the Amish, who might endorse, in addition to core values, such things as piety, simplicity, and modesty (Davidson, 2005). Although the list of "common moral values" might differ among communities, there is, nonetheless, a "core" and a "large overlap in the content that emerges" (Ryan & Bohlin, 1999, p. 50).

Still, we think this debate has gone on long enough. The specter of ethical relativism has been a bogey haunting moral psychology and education for decades, but it has been a distraction, and it has distorted the work of both the cognitive developmental and character education paradigms. It has prevented the cognitive developmental tradition from considering the role of personality and selfhood in moral reasoning because these variables could not secure the autonomy of reason or the universality of judgments (Lapsley, 1996; Walker, 2002; Walker & Hennig, 1998). It has distracted character education with worries about moral objectivity and foundations, and with the seeming necessity to show that it is just as sternly antirealist as the committed stage theorist. However, whether moral claims are universal or incommensurable, whether there is anything like objective moral facts that vouchsafe our moral convictions, are ethical-philosophical or theological issues that psychological research is ill equipped to address with its armamentarium of empirical tools (Blasi, 1990). The attempt to resolve philosophical problems with empirical data has been a big mistake, in our view, and has led to cramped and truncated research programs restricted by perceived philosophical restrictions and boundaries.

Carr (1991) suggested that much of the anxiety about foundations in moral education has got things the wrong way round. In his view, we do not start with principles and then derive practices; rather, the principles are induced from within the practices and experiences of our social life. The principles, in other words, are underwritten by practices, not practices by the principles. Practices are the "product of a fallible human attempt to understand the web of moral association by reference to consideration of . . . what sort of conduct conduce to good and ill, well-being and harm" (p. 4). One can reject the balm of foundationalism and still affirm that workable criteria of right and wrong, of good and evil, of virtue and vice can be discovered "in the rough and tumble of human interpersonal relations and conduct"

(p. 4). Virtues, then, are not foundational axioms or first principles; they are not

hard and fast principles which may be applied to any conceivable circumstance but general patterns or tendencies of conduct which require reasonable and cautious adjustment to particular and changing circumstances and which may even, in some situations, compete with each other for preference and priority. (p. 5)

And although different communities may well flesh out the meaning of virtues (e.g., courage, caring) in different ways, "it is hard to envisage a human community in which these qualities are not needed, recognized or held to be of any value at all" (p. 6), given the affordances of our shared biological and social nature (see also Nussbaum, 1988).

One appreciates in Carr's (1991) account of virtues and foundations the notion broached earlier, that virtues, and traits generally, do not trump invariably the contextual hand one is dealt; that virtues must be contextually specified and situationally ordered; that virtues are socially implicated dispositions; and that the desired schedule of virtues, their meaning and mode of expression, are deeply embedded in the practices, customs, and expectations of communities—and that none of this should give comfort to the ethical relativist (or else the issue of ethical relativism is a different sort of conversation). This also suggests, as we will see later, that moral education can never be simply about the character of children without also addressing the context of education, that is to say, the culture, climate, structure, and function of classrooms and schools (Berkowitz & Bier, 2005). Persons and contexts are inextricably linked and cannot be separated.

If Carr's (1991) view is correct, that virtues are dispositional templates induced from social practices, whose meaning can be discovered in the "rough and tumble of human interpersonal relations" (p. 4), then one way to approach the problem of whether there are "core values" that overlap is to determine if such templates are evident in the way ordinary people think about character. That is, rather than nominate core values from some alleged objective standpoint, from natural law or the perspective of eternity, one might proceed inductively from the standpoint of individual informants.

There have been recent attempts to address the matter empirically. Lapsley and Lasky (1999) provided evidence that conceptions of good character are organ-

ized as a cognitive prototype, and that this prototype has a significant influence on recognition memory and information processing. In this study, the top 10 traits with the highest prototypicality ratings are honest, trustworthy, genuine, loving, dependable, loyal, trusting, friendly, respectful, and caring.

Similarly, Walker (2004; Walker & Pitts, 1998) has pursued naturalistic studies of the prototype structure of a “highly moral person” and has identified clusters or themes that commonly show up in people’s understanding of moral maturity. One cluster, for example, is a set of “principled-idealistic” commitments to strongly held values. Another includes themes of “fairness.” Other clusters identify dependable-loyal, caring-trustworthy, and confident-agency themes. Subsequent research examined the prototype structure of conceptions of just, brave, and caring persons (Walker & Hennig, 2004). Although these attributes differ somewhat from the prototypical good character, as one might expect with different targets, it would appear that a common core of trait attributes for character and moral personality can be identified empirically.

Character and Virtue Ethics

It is widely assumed that Kohlberg’s cognitive developmental approach to moral education represents an instantiation of an ethical theory associated with Kant, whereas character education focuses on a different set of ethical concerns represented by Aristotelian virtue ethics. Indeed, Steutel and Carr (1999; Carr & Steutel, 1999; Steutel, 1997) argued that if character education is to be distinguished from other forms of moral education, such as Kohlberg’s, it must be grounded in an explicit commitment to virtue ethics and not to other ethical theories. If character education is in fact committed to virtue ethics, what might that entail?

G. Watson (1990) suggested a useful tripartite division of ethical theory: the ethic of requirement (where the primary moral considerations concern rational judgments of obligation and duty and the moral appraisal of action), the ethic of consequences (various forms of utilitarianism), and the ethic of virtue. An ethics of virtue is distinguished from the others by its claim that the basic moral facts are facts about the quality of character (*arête*); that judgments about agents and their traits have explanatory primacy over judgments about duty, obligation, and utility; and that deontic judgments

about obligation and action appraisal are, in fact, derived from the appraisal of character and ancillary to it. “On an ethics of virtue,” he writes, “how it is best or right or proper to conduct oneself is explained in terms of how it is best for a human being to be” (p. 451).

Hence, a virtue ethics has two features: (1) It makes a claim of explanatory primacy for aretaic judgments about character, agents, and what is required for flourishing; and (2) it includes a theory about “how it is best or right or proper to conduct oneself” in light of what is known about human excellence. Surprisingly, neither feature has much resonance in character education. In most accounts of character education, one cultivates virtues mostly to better fulfill one’s obligation and duty (the ethics of requirement) or to prevent the rising tide of youth disorder (character utilitarianism, or the ethics of consequences). Although one can conceive of virtues as providing action-guiding prescriptions just as deontological theory does (Hursthouse, 2003), the point of virtues in most accounts of character education is to live up to the prescriptions derived from deontic considerations: to respect persons, fulfill one’s duty to the self and to others, and submit to the natural law. When the goal of character education is to help children “know the good,” this typically means coming to learn the “cross-cultural composite of moral imperatives and ideals” (Ryan & Bohlin, 1999, p. 7). Rather than emphasize agent appraisal, the animating goal of many character educators is appraisal of actions, for, as Wynne and Hess (1992, p. 31) put it, “Character is conduct,” and the best test of a “school’s moral efficiency” is “pupils’ day-to-day conduct, displayed through deeds and words” (Wynne 1991, p. 145).

It would appear, then, that character education and cognitive developmental moral education cannot be distinguished on the basis of the ethical theory that animates them. Character education, for all its appeal to virtues, seems to embrace the ethics of requirement just as surely as does moral stage theory, rather than an ethics of virtue. The most important moral facts for both paradigms are still facts about obligation, universal principles, and duty. The most important object of evaluation for both paradigms is still action and conduct; it is still deciding the good thing to do rather than the sort of person to become. The fact that character education is so thoroughly deontological and utilitarian with so little in common with virtue ethics is not inherently problematic, although it does attenuate some hope that virtue

ethics would open up a new front in moral psychology and education (Campbell & Christopher, 1996; Campbell, Christopher, & Bickhard, 2002; Punzo, 1996).

EDUCATIONAL CONSIDERATIONS

If character education cannot be distinguished from rival approaches in terms of its justifying ethical theory, then perhaps its singularity is to be found elsewhere, say, in terms of its educational practices or in the way that it frames its educational mission. There does seem to be something quite distinctive about the way the case is made for character education, what has been called the *genre of discontent* (Lapsley & Power, 2005) and the *litany of alarm* (Arthur, 2003).

Typically, the first move in making the case for character education is to review a long list of social ills that characterize children and adolescents to document the rising tide of youth disorder. Brooks and Goble (1997, p. 6) point to youth crime, violence, drug addiction, and “other forms of irresponsible behavior.” Wynne and Hess (1992; also Wynne & Ryan, 1997) review the statistics for homicide, suicide, out-of-wedlock births, premarital sex, illegal drug use, delinquency and crime rates, and plunging academic achievement test scores. Lickona (1991a) notes the increase in violence and vandalism, stealing, cheating, disrespect, peer cruelty, bigotry, bad language, self-centeredness, and use of illegal substances.

After cataloguing these trends, there is an attempt to understand their source. Lickona’s (1991a) account is paradigmatic. Like other writers in this genre, he draws attention to troubling evidence of cultural decline that is attributed to broad changes in American education. In the early days of the republic children were instructed intentionally on matters of character by the exhortation, discipline, and example of teachers, by the models of virtue encountered in the Bible and the McGuffey Reader, and elsewhere in the curriculum. Eventually, however, this “old-fashioned character education” was forced into retreat by a convergence of larger forces that undermined the confidence of schools in taking on their traditional moral educational responsibilities.

The influence of Darwin’s theory, for example, led people to wonder if even moral sensibilities could be uprooted from fixed and static foundations and regarded as something changeable and evolutionary. Einstein’s theory of relativity encouraged a kind of moral perspectivism that viewed moral claims as relative to a certain

point of view. The Hartshorne and May (1928–1930) studies highlighted the role of situations in moral behavior. And the general rise of logical positivism encouraged the view that the only sensible things to say were those amenable to publicly verifiable empirical demonstrations (as “facts”), whereas everything else (“values”) was held to be subjective, personal, and quite literally “nonsense” (see, e.g., Ayer, 1952).

These four trends, then, according to Lickona (1991a), forced character education into retreat. “When much of society,” he writes, “came to think of morality as being in flux [Darwin], relative to the individual [Einstein], situationally variable [Hartshorne and May] and essentially private [logical positivism], public schools retreated from their once central role as moral educator” (p. 8).

This reconstruction of history, and others like it, has been called the “cultural declinist” perspective (Nash, 1997) for perhaps the obvious reason that it sees an empirical relationship between the neglect or abandonment of intentional character education and the rise of disorder and immorality among young people. This way of making the case serves as a preface for three additional issues that we will consider here. The first issue concerns whether the singularity of character education can be identified on the basis of the sort of problems it attempts to address, or the manner in which it attempts to address them, or whether any conceivable intervention targeting problematic behavior would qualify as an instance of character education. Second, is character education identified by a commitment to direct or indirect methods of instruction? We will see that this debate is best understood in the context of much larger histories of teaching practice and of the idea of liberal education. Third, in what sense is the cultural declinist genre itself a recurring movement in educational history, and how can we understand its resurgence over the past 2 decades? An examination of the historiography of character education will show that there are recurring cycles of concern about character education during periods of rapid change, and that character education movements typically fail without well-attested models of self and personality.

Broad Character Education

When the case is made for character education by appealing to troubling social trends or to the epidemiology of adolescent risk behavior, there is an implication that

any program that attempts to drive down these trends or ameliorate the incidence of risk behavior might reasonably fall under the broad umbrella of character education. If getting bad grades, cheating, dropping out of school, having sex, bearing children, using drugs, getting into fights, committing status offenses, breaking the law, attempting suicide, showing disrespect, being a bully—if these are the mark of poor moral character, then programs designed to encourage school persistence, prevent teen pregnancy, discourage the use of drugs and alcohol, improve social skills and social problem solving, increase resilience to social-affective problems, and the like might qualify as moral character interventions. There is evidence for such a sweeping view of character education. In her study of the character education practices of 350 Blue Ribbon schools, Murphy (1998) reported a wide range of practices, including self-esteem programs, general guidance counseling, drug education, citizenship, discipline, and conflict management. However, in only 11% of schools was there explicit mention of any program called “character education.”

Similarly, Berkowitz and Bier (2004b) identified 12 recommended and 18 promising practices in a review of what works in character education. These practices covered a wide range of purposes, including problem solving, health education, empathy, social skills and social competence training, conflict resolution, peace making, life skills training, developmental assets, and positive youth development. Although Berkowitz and Bier (2004a) concluded that these programs work, they also noted that most of them do not use the term “character” to describe their intentions and objectives. Very few of them were designed with any notion of virtues, character, or morality in mind, and were not described as instances of moral or character education. Nonetheless, the success of these programs is claimed for character education because their methods, outcomes, and justifications are similar to what might be expected of character education programs. “After all,” they write, “they are all school based endeavors designed to help foster the positive development of youth” (p. 5).

By these criteria it is difficult to imagine what would *not* count as character education or be excluded from its purview. If character education is all of these things, and if the success of character education is parasitic on the success of any well-designed intervention or prevention program, then the singularity of character education as a distinctive educational objective or pedagogy,

with unique curricular and programmatic features, appears to vanish.

It would seem paradoxical that the manner in which the case has been made for character education actually results in its disappearance as a distinctive educational objective in its own right. If the case is made on the basis of disturbing trends in the epidemiology of adolescent risk behavior, then it bids one to look for the success of character education in the diminution of this behavior. But then character education becomes any program that has a positive outcome with respect to adolescent risk behavior. It becomes a catalogue of psychosocial intervention, promotion, and prevention programs whose objectives are framed by reference to an entirely different set of theoretical literatures that make no reference to morality, virtue, or character. Moreover, there is little reason to appeal to character education, or use the language of moral valuation, to understand the etiology of risk behavior or how best to prevent or ameliorate exposure to risk or promote resilience and adjustment.

The problem with the broad view, then, is that it does not point to anything distinctive about character education. Yet, perhaps the problem of singularity derives from the fact that all good causes in education, from social-emotional learning to positive youth development, risk reduction, psychosocial resilience, academic achievement, and character education, are driven effectively by a common set of school practices. Just as problem behaviors are interrelated and are predicted by a similar profile of risk factors, so, too, are adaptive and prosocial behaviors interrelated and linked to a common set of developmental factors and instructional practices. Indeed, Berkowitz and Bier (2004b) nominate “positive youth development” as the inclusive term to cover all of the program objectives and suggest that these objectives are simply part of “good education” generally. The downside of this maneuver is that character education appears to lose its singular focus. But the loss of conceptual distinctiveness for character education is offset by the gain in instructional clarity for practitioners. The problem for the practitioner is not the problem of knowing which program “works” or of correctly labeling curricular and programmatic activities, but of mastering the instructional best practices that are common to all of them (see Howard, Dryden, & Johnson, 1999, for a similar point with respect to promoting resilience).

Yet, there is a case to be made for character education that has little need for troubling epidemiological

trends. The case is made simply by pointing to the fact that moral considerations are immanent to the life of classrooms and schools, that teaching and learning are value-laden activities, and that moral aims are intrinsic to education (Bryk, 1988; Goodlad, 1992; D. T. Hansen, 1993; Strike, 1996). The case is made by reference to the developmental objectives of schools and to the role of schools in inculcating the skills proper to democratic citizenship and to full participation in the life of the community. The immanence of values and the inevitability of moral education is an argument almost always found in the character educator's brief, but mostly for countering the charge of indoctrination rather than for making the case. Yet the immanence-and-inevitability thesis would seem to arm the character educator with all the resources that are needed to defend an intentional and transparent commitment to the moral formation of students. Moreover, the case that is made from this standpoint is a positive one; it makes reference to developmental purposes, to a conception of what it means to flourish, to the skills, dispositions, and excellences that are required to live well and competently, the life that is good for one to live in a democratic society. This is in contradistinction to the traditional argument that builds the case negatively by making character education just another prevention program, viewing character education as a kind of prophylaxis or cultural defense against "youth disorder."

Direct and Indirect Methods

In an early essay, Dewey (1908) defined the terms of this debate. It "may be laid down as fundamental," he asserted, "that the influence of direct moral instruction, even at its very best, is *comparatively* slight in influence, when the whole field of moral growth through education is taken into account" (p. 4, emphasis in original). Rather, it is the "larger field of indirect and vital moral education, the development of character through all the agencies, instrumentalities and materials of school life" (p. 4), that is far more influential. This larger field of indirect education reproduces within the school the typical conditions of social life to be encountered without. "The only way to prepare for social life is to engage in social life" (p. 15).

Moreover, this sort of moral education is possible only when the school itself becomes an "embryonic typical community" (Dewey, 1908, p. 15). Indeed, for

Dewey, the school has no moral aim apart from participation in social life. The rules of school life must point to something larger, outside of itself, otherwise education becomes a mere "gymnastics exercise" that trains faculties that make no sense and have no moral significance just because they are disconnected from larger purposes. Absent these purposes, moral education is pathological and formal. It is pathological when it is alert to wrongdoing but fails to cultivate positive service, when it stresses conformity to school routines that are arbitrary and conventional but lack inherent necessity. Moral training is formal when it emphasizes an ad hoc catalogue of habits that are "school duties," not "life duties." To the extent that the work of schools is disconnected from social life, insistence on these moral habits is "more or less unreal because the ideal to which they relate is not itself necessary" (p. 17). The moral habits of interest to Dewey concern an interest in community welfare, in perceiving what is necessary for social order and progress, and in the skills necessary to execute principles of action. All school habits must be related to these "if they are to be animated by the breath of life" (p. 17).

Dewey (1908) was critical of a traditional pedagogy of exhortation, didactic instruction, and drill. Such pedagogy fails to cultivate a social spirit; it emphasizes individualistic motives, competition, comparative success, dispiriting social comparison; it encourages passive absorption and emphasizes preparation for life but in the remote future. It reduces moral instruction to simply teaching *about* virtues or in instilling certain attitudes about them. What is required instead is an approach to education that links school subjects to a social interest; that cultivates children's ability to discern, observe, and comprehend social situations; that uses methods that appeal to the "active constructive powers" of intelligence; that organizes the school along the lines of a genuine community and selects curricular materials that gives children a consciousness of the world and what it will demand. Only if schools are prepared to take on these principles can they be said to meet their basic ethical requirements.

Dewey's vision of moral education is sometimes called a "progressive" or "indirect" approach because it eschews traditional pedagogy that relies on didactic instruction and direct transmission of moral content. Instead, indirect approaches emphasize the child's active construction of moral meaning through participa-

tion in democratic practices, cooperative groupings, social interaction, and moral discussion (e.g., DeVries & Zan, 1994).

In contrast, the direct approach to instruction is widely associated with traditional character education (Benninga, 1991b; Solomon, Watson, & Battistich, 2001). In a defense, Ryan (1989, p. 15) asserted that “character development is directive and sees the teacher in a more active role than does the cognitive developmental tradition.” There is sympathy for what is called the Great Tradition that views the educational encounter as one of transmission from adults to children (Wynne & Ryan, 1997). For traditional character education, morality is ready-made and good character requires submission to its preexisting norms. It is suspicious of indirect or constructivist approaches that seemingly allow adults to abdicate their role as moral teachers in favor of “consensual” democratic practices in schools. Such practices are antitradition because they seem to allow students to engage in “highly relativistic discussions about value laden issues” where alternative views might emerge with respect to such things as obedience or the limits of loyalty to one’s country (p. 35). These practices seem to let the kids decide what important values are and naively assumes that children will choose well when given opportunities for self-direction. “Is it wise,” writes Wynne (1991, p. 142, emphasis added), “to ‘teach’ pupils that basic moral principles and conventions generally accepted by responsible adults should be considered *de novo*, and possibly rejected, by each successive adolescent cohort? *Must each generation try to completely reinvent society?*”

Mimesis and Transformation

The debate over direct and indirect methods of character education has a much longer history and, when properly considered, points to a middle way for practitioners. Jackson (1986) captures much of this history in his useful distinction between mimetic and transformative traditions of education. Both traditions are centuries old and describe a complex worldview about the nature of teaching and learning. These traditions are at the nexus of partisan rivalry not simply because they articulate different perspectives on what constitutes proper teaching, but because they each comprise a different “form of life” (following Wittgenstein, 1968), a fact that raises the stakes considerably.

The mimetic tradition embraces a transmission model of teaching and learning. Knowledge is considered something detachable (it can be preserved), secondhand (it first belongs to someone else before it is transmitted), and reproducible (which facilitates its transmission). As such, knowledge is presented to the learner, rather than discovered by the learner. It can be judged as right or wrong, correct or incorrect. The mimetic teacher is directive, expert in the substantive bodies of knowledge and in methodological competence. The student is a novice, without knowledge of what teachers know, and hence the object of transmission. “In more epigrammatic terms, the slogan for this tradition might be: ‘What the teacher knows, that shall the student come to know’” (Jackson, 1986, p. 119).

In contrast, the transformative tradition intends a qualitative change in that which is deeply foundational in a person: in one’s character, set of traits, or other enduring aspects of one’s psychological makeup. The goal of teachers in this tradition is to:

bring about changes in their students (and possibly in themselves as well) that make them better persons, not simply more knowledgeable or more skillful, but better in the sense of being closer to what humans are capable of becoming—more virtuous, fuller participants in the evolving moral order. (Jackson, 1986, p. 127)

And transformative teachers attempt to bring about these changes not through dogmatic presentation of foundational texts, not by means of didactic instruction, but by discussion, argumentation, and demonstration. The transformative teacher, in other words, attempts to influence students by philosophical means. As Jackson put it, “Armed only with the tools of reason the transformative teacher seeks to accomplish what can be attained in no other way” (p. 127).

Oratorical and Philosophical Traditions

The distinction between direct and indirect character education can be framed historically not only by reference to (mimetic and transformative) traditions of teaching, but also by reference to the history of liberal education. According to Kimball (1986), the history of liberal education from the ancients to the present is the struggle between two distinct traditions that he termed “philosophical” and “oratorical.” Moreover, the value

conflicts between these traditions have resulted in recurring cycles of educational reform as first one then the other tradition becomes ascendant.

The “philosophical” tradition is aligned historically with Socrates, Plato, and Aristotle. It asserts that the pursuit of knowledge and truth is the highest good; that because truth is elusive and because there are many uncertainties, one must cultivate the philosophical dispositions, be open-minded, judge fairly, reason critically. In this tradition, it is freedom of the intellect and diligent inquiry that is the goal and purpose of education.

The “oratorical” tradition is aligned historically with Isocrates and Cicero. It is committed to the public expression of what is known through classic texts and tradition. One becomes a virtuous citizen-orator by becoming acquainted with the wisdom evident in rhetoric and in the classics. If the philosophical tradition saw truth and goodness as something elusive and unsettled, as something not yet realized or achieved, but that can be grasped only by the critical discernment of speculative reason, the oratorical tradition locates truth and goodness in the great texts and past traditions. If the philosophical tradition conceives the search for truth as an act of discovery, it is an act of recovery for the oratorical tradition. If the philosophical tradition intends to equip individuals to face an uncertain future, the oratorical tradition intends to equip individuals with the certain and settled verities of the past.

Featherstone (1986) points out that the great strength of the philosophical tradition is its emphasis on the free exercise of reason in pursuit of the truth, but that its weakness as an educational philosophy is its silence on just what is to be taught. It urges one to seek the truth like a philosopher, but cannot say what truth is with much certainty. It is strong on method, weak on content. This is where the oratorical tradition has an advantage. The educational point of the oratorical tradition is to master the content of traditional texts. In the oratorical tradition, the task of education is to impart the truth, not to help students seek it (Featherstone, 1986). It is strong on content, weak on method.

It would seem, then, that the contemporary debate concerning direct and indirect methods reflects deeper and longer-standing conflicts over the role of mimesis or transformation in teaching, or the relative value of preparing orators or philosophers in education. Yet it also seems clear that the modern expression of direct character education reveals a fundamental confusion

about its sources, aims, and traditions. For example, although direct character education intends to transform students’ character in the direction of virtue, it attempts to do so with teaching that is mimetic rather than transformative. Moreover, in spite of its frequent invocation of classical sources such as Socrates, Plato, and Aristotle, it is apparent that direct approaches to character education are not, in fact, the heirs of the philosophical tradition but of the oratorical tradition. Indeed, the direct approach is largely mimetic and oratorical, whereas the indirect approach is transformative and philosophical.

Of course, it is not hard to see the middle way in this debate. There are occasions in teaching for both mimesis and transformation. We need both orators and philosophers. The best teachers are experts in pedagogical content knowledge (Shulman, 1987; Wilson, Shulman, & Richert, 1987) and are able therefore to use instructional methods appropriate for teaching specific content. The best approaches to character education flexibly balance the philosophical methods of inquiry, discussion, and discernment with the oratorical respect for text and tradition; both direct and indirect approaches find a place in the curriculum (Benninga, 1991b). Lickona’s (1991a, 1991b, 1992, 1997; Lickona & Davidson, 2004) integrated approach to character education is a good example. Although this approach has decided oratorical sympathies and resorts to the genre of discontent to make its case, there is also significant and welcome appreciation of the constructivist nature of learning and of the necessity for transformative approaches to teaching. Alongside directive advocacy of certain value positions there is use of indirect strategies as well, including cooperative learning, conflict resolution, classroom democratic processes, moral discussion and reflection, and the need to build a sense of moral community within the school.

Historical Lessons

We noted earlier that a “cultural declinist” reading of American history is commonly used to make the case for character education. And that the debate between traditionalists and progressives, between advocates of direct and indirect methods of character education, is just the contemporary manifestation of more fundamental conflicts concerning the nature of teaching (mimesis versus transformative) and of liberal education (oratorical ver-

sus philosophical) that have quite long-standing historical roots. But what of the history of character education itself? Chapman's (1977) observation summarizes a common theme. "It is curious to note," he writes, "how the concern for character seems to have been associated with times of rapid social change" (p. 65).

McClellan (1999) notes, for example, in his influential history of moral education, that the nineteenth century ushered in a revolution in moral education that was motivated by massive social upheaval and the collapse of the old order brought about by urbanization, mobility, and immigration. "Traditional sources of social order—stable hierarchical social structures, patterns of cultural and political deference, webs of extended kinships and tight-knit communities—weakens as images of control and orderly change gave way to visions of movement and opportunity" (p. 15). The response was to urge early instruction of a common moral code, taught largely through a new genre of children's stories and by the suffusion of maxims and moral lessons throughout textbooks. Typical themes included the certainty of progress and the perfection of the United States, love of country, duty to parents, the importance of thrift, honesty, and hard work for accumulation of property.

In the early twentieth century, the demands of modernity further sundered the seamless weave of the community into largely disconnected sectors of home, employment, marketplace, church, and recreation, each operating with seemingly different value systems. Schools were now required to prepare students to take up "a variety of roles across the differentiated spheres of a segmented social order" (McClellan, 1999, p. 47). Schools became complex institutions with varied purposes, only one of which was moral education.

Among character educators there was a sense that modernity presented important challenges to traditional values that could be mastered only by vigorous teaching of specific virtues and character traits, not just in school but in a variety of clubs and youth organizations that proliferated in the early twentieth century. Codes of conduct were promulgated, and teachers were expected to use these codes to provide themes for instruction. Much like today, these themes were exhibited in classroom posters and laws of the month. Citizenship and comportment grades were commonly taken as signs of character development. Moral education itself was directed largely to the problem of motivation and will rather than to reasoning. The problem was how to make moral conduct ha-

bitual rather than to teach ethical decision making, a notion that has a familiar ring a century later.

The progressive alternative, as we have seen, rejected the emphasis on teaching particular virtues as being unsuited to help children meet the demands of a changing social order, and it rejected, too, the direct approaches to instruction as pedagogically ineffective. Instead, it emphasized ethical sensitivity to the demands of changing society, the ability to make moral judgments, and the larger civic and political purposes of moral education as opposed to the traditional emphasis on private virtue and conduct. Hence, rather than focus on traditional texts, the progressive alternative encouraged democratic decision making, critical thinking, and scientific inquiry as the methods best able to equip students to take up their obligations in modern society. These are the very terms of reference for the current debate concerning character education.

Indeed, Cunningham (2005) points to many common themes between the current popularity of character education and its predecessor movements earlier in the twentieth century. He notes that many modern proponents of character education who ardently look back to the Great Tradition, when traditional character education was allegedly pervasive, widely embraced, and successfully implemented, might be surprised to learn that the educational "tradition" they seek was not apparent to contemporaries. Widespread anxiety about social disintegration was as common to the first decades of the twentieth century as to the later decades. Both periods exhibited alarm at the sorry state of moral character among business leaders and politicians, as well as youth. Both periods saw evidence of cultural decline, loss of traditional values, and abandonment of foundational principles. Both periods saw the formation of character education lobbies, pressure groups, and professional societies; both saw state action by legislatures to mandate character education in the schools; both saw the need for experiential or service learning; both saw the promulgation of widely divergent lists of urgently needed virtues, debates about direct and indirect methods, and the proper place of coercion and democratic practices in the schools. Moreover, the chasm between educators and researchers, between the ardent confidence of character educators in their favored curriculum and the skepticism of researchers about its efficacy, also has a long history (see Leming, 1997). Moreover, Cunningham argues that whereas the "rise" of traditional character education in

the twentieth century typically accompanied periods of great social ferment and rapid social change, when there were profound challenges to national identity and widespread anxiety about social cohesion and the unsettling forces of modernity, its “fall” was inevitable without an adequate character psychology to guide curricular development and instructional practice. “Unless psychology can provide a better model of human development,” he writes, “character will continue to receive sporadic and faddish treatment and the public’s common school will continue to be undermined” (p. 197).

We return, then, to a central claim of this chapter, which is that the conceptual grounding required for any minimally adequate character education must be found in robust models of character psychology (Cunningham, 2005; Lapsley & Power, 2005). Although ideological commitments are notoriously immune to influence, it is our view that consensual frameworks for addressing character education will be forthcoming when controversies are anchored to appropriate psychological literatures. In the next section, we take note of relatively recent approaches to character psychology that provide new ways of conceptualizing the moral dimensions of personality.

NEW APPROACHES TO CHARACTER PSYCHOLOGY

There are at least two new approaches that have emerged for conceptualizing moral character. One approach argues that a moral identity results when the self identifies with moral commitments or a moral point of view. A second approach conceptualizes character in terms of the literatures of cognitive and personality psychology. We briefly consider each approach in turn.

Identity, Exemplars, and the Moral Self

One way to conceptualize character is in terms of moral identity. According to Hart (2005), moral identity includes self-awareness, a sense of self integration and continuity over time, a commitment to plans of action and an attachment to one’s moral goals. Moreover, he argues that the contours of moral identity are constrained by stable aspects of personality but also by characteristics of family and neighborhood. Moral identity is a joint product of personal and contextual factors. Indeed, moral identity is influenced by factors beyond the con-

trol of the adolescent, which introduces an element of “moral luck” in the sort of commitments a young person might identify with. Yet there is plasticity in moral identity development. Moral identity is open to revision across the lifecourse, particularly when one is given opportunities to engage in moral action. This possibility underscores the importance of providing youth with opportunities for service learning and community service, a topic we take up later.

Blasi’s (1984, 1985, 1995) account of moral identity shares some similarity with Hart’s (2005). According to Blasi one has a moral identity to the extent that the self is organized around moral commitments. One has a moral identity when moral notions are central, important, and essential to one’s self-understanding. This yields a personality imbued with a deep, affective, and motivational orientation toward morality. Blasi (1984) insists, however, that any account of the moral personality be grounded on the premise that rationality is the core of the moral life. To have a moral identity is to have good moral reasons for the identity-defining commitments that one makes.

Of course, not everyone has a self-concept that is constructed by reference to moral reasons. Some individuals organize self-related information around moral categories, others do not. Some individuals let moral notions penetrate to the core of what and who they are as persons; others have only a glancing acquaintance with moral notions but choose to define the self in other ways, by reference to other values and commitments (Walker, Pitts, Hennig, & Matsuba, 1995). Even those who define the self in moral terms may do so in different ways, emphasizing different sets of moral priorities. In this way, moral identity is a dimension of individual differences; it is foundational to the moral personality (Blasi, 1995). When moral commitments are vital for one’s self-understanding, and one commits to live in a way that keeps faith with these identity-defining commitments, one has a moral identity. Indeed, not to act in accordance with one’s identity is to put the integrity of the self at risk. Not to act with what is essential, important, and central to one’s self-understanding is to risk losing the self, a possibility that introduces a motivational property to the moral personality (Bergman, 2002; Blasi, 1999; Hardy & Carlo, 2005).

Blasi (2005) recently proposed a psychological approach to moral character that trades on these themes. According to this view moral character is best described not by reference to lower-order virtues, such as honesty,

generosity, and humility, among numerous others, but by three sets of higher-order virtues that include willpower (as self-control), integrity, and moral desires.

Willpower as self-control is a toolbox of strategic and metacognitive skills that allow one to break down problems, set goals, focus attention, delay gratification, avoid distractions, and resist temptation. These virtues are necessary to deal with obstacles that we encounter invariably in the pursuit of long-range objectives. The cluster of integrity virtues connects our commitments to a sense of self and is responsible for feelings of responsibility and identity. Integrity is felt *as responsibility* when we constrain the self with intentional acts of self-control, effort, and determination in the pursuit of our moral desires; when we make the self conform to the moral law out of a felt sense of necessity and obligation; and when we hold the self accountable for the consequences of actions. Integrity is felt *as identity* when a person constructs the very meaning of the self by reference to moral categories. In this case, living out one's moral commitments does not feel like a choice; living in ways that offend what is central and essential about oneself is unthinkable self-betrayal.

But the virtues of self-control and integrity do not have inherent moral significance. Both are morally neutral unless they are attached to moral desires. Both require a will that desires and tends toward the moral good. The language of moral desires is distinctive of Blasi's (2005) theoretical system, but "moral desires" is an expression he prefers to the closely related notion of moral motivation, and for three reasons. First, the expression connotes an intensity of affect that connects to traditional notions of character as that gives direction to one's life. Second, insofar as moral desires clearly belong to a person, they are preferred over other psychological accounts that treat motivation as an impersonal regulatory system or in terms of cybernetic models of self-control. Third, the notion of desires aligns closely with Frankfurt's (1988) concept of will and his distinction between first- and second-order desires. A person certainly has (first-order) desires, but one can also reflect on them, order them, and have desires about some of them (second-order desires). One has a will when one desires to implement and put into effective action that which is a first-order desire. Here one transforms impulses into something that is reflected on from a greater psychological distance. The will is an intervention on oneself that turns a first-order impulse into something that can be rejected or accepted, and on this foundation

rests the possibility of a moral self if the distancing and appropriating is governed by a consideration of the moral good.

Blasi's approach to moral self-identity is associated with an important line of research on moral exemplars. Colby and Damon (1992) interviewed 23 individuals whose lives demonstrated exceptional moral commitment in such areas as civil rights, civil liberties, poverty, and religious freedom. Although the specific commitments of each exemplar were a unique adaptation to the situational challenges that each faced, one of the most important common characteristics of exemplars was the fact that moral goals were so closely aligned with personal goals. There was an identification of self with moral commitments. Moral goals were central to their self-understanding, to their sense of identity, to such a degree that moral choices were not seen as a burden but simply as a way to advance one's personal objectives. Exemplars also were characterized by a sense of certainty and clarity about what was right and wrong, of their own personal responsibility, and by a sense of optimism about how things would turn out.

A similar theme is evident in the research by Hart and his colleagues (Hart, Atkins, & Ford, 1998; Hart & Fegley, 1995; Hart, Yates, Fegley, & Wilson, 1995), who studied inner-city adolescents who had been nominated by community organizations for their uncommon prosocial commitment. In contrast to matched comparison adolescents, care exemplars more often included moral goals and moral traits in their self-descriptions; and ideal self-representations and parental representations in their actual self-descriptions; articulated a mature self-understanding whereby beliefs generated coherence among elements of the self; and perceived continuity of the self that extended from the remembered past into the projected future. Moral exemplars also have been reported to show advanced moral reasoning, more mature faith and identity development, and an affinity toward agreeableness (Matsuba & Walker, 2004).

In a separate line of research, Aquino and Reed (2002) designed an instrument that measures the degree to which having a moral identity is important to one's self-conception. They assumed, following Blasi (1984, 1985), that moral identity varies in content and in the degree to which moral traits are central to one's self-understanding. They identified nine moral traits (caring, compassionate, fair, friendly, generous, helpful, hardworking, honest, kind) that individuals regard as characteristic of a moral person, which then served as

“salience induction stimuli” to activate a person’s moral identity when rating the self-importance of these traits on their instrument. Factor analysis revealed two factors: a Symbolization factor (the degree to which the traits are reflected in one’s public actions), and an Internalization factor (the degree to which traits are central to one’s private self-concept).

Aquino and Reed (2002) showed that both dimensions predict the emergence of a spontaneous moral self-concept and self-reported volunteering, but that internalization showed the stronger relation to actual donating behavior and to moral reasoning. Subsequent research (Reed & Aquino, 2003) showed that individuals with a strong internalized moral identity report a stronger moral obligation to help and share resources with outgroups, to perceive the worthiness of coming to their aid, and to display a preferential option for outgroups in actual donating behavior. Hence, individuals with internalized moral identity are more likely to expand the circle of moral regard to include outgroup members. Moreover, moral identity is thought to mediate the relationship between deviant organizational norms and deviant behavior. If moral identity is highly salient in comparison to other identities within the self-system, then internalized moral identity is likely to inhibit the motivation to respond to deviant norms within the culture of organizations (R. J. Bennett, Aquino, Reed, & Thau, in press). The authors have in mind employee behavior in business organizations, but there is no reason to limit the identity-moderator hypothesis solely to this context.

Research on moral self-identity and on the qualities of individuals who demonstrate exceptional moral commitment is a promising avenue for character psychology, although the implications for character education are not clearly understood. One implication of Blasi’s theory is that character education should encourage children and adolescents to develop the proper moral desires and master the virtues of self-control and integrity. But how is this possible? How do children develop self-control and a wholehearted commitment to moral integrity? There are intriguing clues about possible pathways to moral identity from research on the development of conscience in early childhood. For example, Kochanska and her colleagues (Kochanska, 2002; Kochanska et al., 2004; Kochanska, Aksan, & Koenig, 1995) proposed a two-step model of emerging morality that begins with the quality of parent-child attachment. A secure, mutu-

ally responsive relationship with caregivers characterized by shared, positive affect orients the child to be receptive to their influence and eager to comply with parental suggestions, standards, and demands. This encourages wholehearted, willing, self-regulated, and “committed” compliance on the part of the child to the norms, values, and expectations of caregivers, which, in turn, motivates moral internalization and the emergence of conscience. The model moves, then, from security of attachment to committed compliance to moral internalization. Moreover, the child’s experience of eager, willing, and committed compliance with the parents’ socialization agenda is presumed to influence the child’s emerging internal representation of the self:

Children who have a strong history of committed compliance with the parent are likely gradually to come to view themselves as embracing the parent’s values and rules. Such a moral self, in turn, comes to serve as the regulator of future moral conduct and, more generally, of early morality. (Kochanska, 2002, p. 340)

Indeed, children are more likely to regulate their conduct in ways that are consistent with their internal working model of the self.

This model of the emergence of conscience in early childhood suggests that the source of wholehearted commitment to moral considerations, and the cultivation of the proper moral desires characteristic of what Blasi requires of a moral personality, lie in the mutual positive affective relationship with socialization agents and the quality of the child’s network of interpersonal relationships. The source of self-control, integrity, and moral desires is deeply relational. It is motivated by the sense of moral self-identity that emerges within a history of secure attachment. If true, such a model underscores the importance of school bonding (Catalano, Haggerty, Oesterle, Fleming, & Hawkins, 2004; Libby, 2004; Maddox & Prinz, 2003), caring school communities (Payne, Gottfredson, & Gottfredson, 2003; Solomon, Watson, Battistich, Schaps, & Delucchi, 1992), and attachment to teachers (M. Watson, 2003) as a basis for prosocial and moral development. For example, Payne et al. showed that schools that were organized and experienced as a caring community had higher levels of student bonding to school and greater internalization of common norms and goals, which, in turn, was related to less delinquency. Similarly, the Seattle Social Development Project has documented its theoretical claim that strong

bonds of attachment and commitment to school and clear standards of behavior create a press toward behavior consistent with these standards (Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999; Hawkins, Guo, Hill, Battin-Pearson, & Abbott, 2001). Evidence from the Child Development Project showed that elementary school children's sense of community leads them to adhere to the values that are most salient in the classroom (Solomon, Watson, Battistich, Schaps, & Delucchi, 1996). Moreover, perceptions of moral atmosphere in high school promote prosocial and inhibit norms-transgressive behavior (Brugman et al., 2003; Power, Higgins, & Kohlberg, 1989). These findings are quite close to Kochanska's model of early conscience development: Secure attachment promotes committed compliance, which leads to internalization of norms and standards. Hence, there appears to be continuity in the mechanisms of socialization in both families and schools in early and middle childhood and adolescence.

The moral exemplar research holds out another goal for character education, which is to encourage the sort of prosocial commitment observed in care exemplars. This would certainly be a welcome alternative to the more typical understanding of character education as a risk-and-deficits prevention program. How do individuals come to align personal goals with moral ones, or to identify the actual self with ideal representations? One mechanism suggested by Colby and Damon (1995) is social influence. In their view, social influence plays a decisive role in transforming personal goals into important moral commitments. Social influence instigates moral development. It provides a context for reappraisal of one's current capabilities, guidance on how best to extend one's capabilities, and the strategies required to pull it off. "For those who continually immerse themselves in moral concerns and in social networks absorbed by such concerns, goal transformation remains the central architect of progressive change throughout life" (p. 344). Other mechanisms include participation in voluntary organizations (C. Flanagan, 2004; Hart et al., 1998), school attachment (Atkins, Hart, & Donnelly, 2004), and service learning opportunities more generally (Waterman, 1997; Youniss, McLellan, Su, & Yates, 1999; Youniss, McLellan, & Yates, 1997; Youniss & Yates, 1997).

These mechanisms may provide not just the means for the transformation of personal into moral goals, but also an opportunity for adolescents to experience other char-

acteristics of moral exemplars, such as coming to see moral concerns with greater clarity, developing a greater sense of personal responsibility for the welfare of their communities, and developing a sense of optimism and efficacy that personal effort pays off and makes a difference. We will have more to say about community service and service learning. But if these mechanisms are critical to the formation of moral identity (Hart, 2005), then the challenge for character educators is how best to transform the culture of schools so that they become places where social networks are absorbed by moral concerns, where attachment to school is encouraged, where opportunities abound for broad participation in the sort of voluntary associations that predict prosocial engagement with the community.

Models of Personality Psychology

One strategy for framing models of moral personality is to appeal to the theoretical resources, constructs, and mechanisms of personality psychology. Yet, personality psychology is not a unified domain. According to Cervone (1991), there are two disciplines of personality psychology that are distinguished by how the basic units of personality are conceptualized. One discipline favors trait/dispositional constructs and understands personality structure in terms of between-person variation that is described by "top-down" abstract latent variable taxonomies, such as the Big 5. The second discipline favors cognitive-affective mechanisms, or social cognitive units, and understands personality structure in terms of "bottom-up" within-person processes (Cervone, 2005). Each discipline of personality psychology is reflected in recent attempts to understand the moral personality.

For example Walker and his colleagues examined the personality structure of moral exemplars by reference to the Big 5 trait dimensions. In one study (Walker & Hennig, 2004, Study 2) prototype descriptors of moral exemplars was examined with the interpersonal circumplex and the five-factor model of personality. The prototype of the just person was described as a moderate blend of nurturance and dominance, and aligned with conscientiousness and openness to experience. An earlier study (Walker & Pitts, 1998) reported a relationship between trait dimensions and three kinds of moral exemplars. The brave exemplar was linked with a complex of traits associated with extraversion; the caring exemplar was associated with agreeableness; while the just

exemplar was a complex mixture of conscientiousness, emotional stability, and openness to experience. Hart (2005) reports an association between the care exemplar and three of the Big 5 trait dimensions (openness to experience, agreeableness, and conscientiousness), while Matsuba and Walker (2004) showed that the personality structure of young adults who were nominated for their moral exemplarity was characterized by traits associated with agreeableness.

In contrast to trait taxonomic approaches, we have attempted to understand moral personality from the perspective of social cognitive theory, the second discipline of personality psychology (Lapsley & Narvaez, 2004; Narvaez & Lapsley, 2004). Social cognitive theory draws attention to cognitive-affective mechanisms (scripts, schemas, prototypes, and other cognitive frameworks) that influence social perception but also serve to create and sustain patterns of individual differences. If schemas are readily primed and easily activated (“chronically accessible”), for example, then they direct our attention selectively to certain features of our experience at the expense of others. This selective framing disposes one to choose compatible or schema-relevant life tasks, goals, and settings that are congruent with one’s social perceptions. Repeated selection of schema-congruent tasks, goals, and settings serves over time to canalize and sustain dispositional tendencies and to result in highly practiced behavioral routines that provide “a ready, sometimes automatically available plan of action in such life contexts” (Cantor, 1990, p. 738). According to Cantor, this makes one a “virtual expert” in highly practiced regions of social experience demarcated by chronically accessible schemas and allows schemas to function as the cognitive carriers of dispositions.

In our view, the moral personality can be understood similarly in terms of the accessibility of moral schemas for social information processing (Narvaez & Lapsley, 2005). A moral person, a person who has a moral character or identity, is one for whom moral constructs are chronically accessible. These chronically accessible categories provide a dispositional preference or readiness to discern the moral dimensions of experience, as well as underwrite a discriminative facility in selecting situationally appropriate behavior. Recent research has shown, for example, that moral chronicity is a dimension of individual differences that influences spontaneous trait inferences as well as the kind of evaluative moral inferences that are generated when reading stories (Nar-

vaez, Lapsley, Hagele, & Lasky, in press). Moreover, available constructs can be made accessible by situational priming as well as by chronicity, which combine in an additive fashion to influence social perception (Bargh, Bond, Lombardi, & Tota, 1986). This supports the social cognitive view that dispositional coherence is to be found at the intersection of person (chronicity) and context (situational priming), and that stable behavioral signatures are to be found in patterns of situational variability rather than cross-situational consistency (Mischel, 2005; Shoda & Mischel, 2000).

A social cognitive approach to moral character has a number of benefits. It provides an explanation for moral identity. For Blasi (2005), one has a moral identity when moral notions are central, essential, and important to one’s self-understanding. We would add that moral notions that are central, essential, and important to self-understanding would also be chronically accessible for appraising the social landscape. The social cognitive approach also accounts for at least one characteristic of moral exemplars. As Colby and Damon (1992) have shown, individuals who display extraordinary moral commitment rarely report engaging in an extensive decision-making process. Rather, they “just knew” what was required of them, automatically as it were, without recourse to elaborate and effortful cognitive exertion. This is also experienced by exemplars as a kind of moral clarity or as a felt conviction that one’s judgments are appropriate, justified, and true. Yet, this is precisely the outcome of preconscious activation of chronically accessible constructs: that it induces strong feelings of certainty or conviction with respect to one’s social judgments (Bargh, 1989; Narvaez & Lapsley, 2005). Moreover, the automaticity of schema activation contributes to the tacit, implicit qualities often associated with Aristotelian and traditional understanding of the “habits” of moral character. To put it differently, the moral habits of virtue theory are social cognitive schemas whose chronic accessibility favors automatic activation.

One challenge for a social cognitive theory of moral character is to specify the developmental sources of moral chronicity. Indeed, our preference for the social cognitive option reflects a strategic bet that it will more likely lead to integrative developmental models of moral personality than would the taxonomic approach (Narvaez et al, in press). One speculation is that moral personality development is built on the foundation of generalized event representations, behavioral scripts,

and episodic memory that characterize early socioper-sonality development (Kochanska & Thompson, 1997; Lapsley & Narvaez, 2004; Thompson, 1998). Event representations have been called the “basic building blocks of cognitive development” (Nelson & Gruendel, 1981, p. 131), and it is our contention that they are the foundation as well of emergent moral character. They are working models of how social routines unfold and of what one can expect of social experience. These prototypic knowledge structures are progressively elaborated in the early dialogues with caregivers who help children review, structure, and consolidate memories in script-like fashion (Fivush, Kuebli, & Chubb, 1992). But the key characterological turn of significance for moral psychology is how these early social cognitive units are transformed from episodic into autobiographical memory. Autobiographical memory is also a social construction elaborated by means of dialogue within a web of interlocution. Parental interrogatives (“What happened when you pushed your sister?”; “Why did she cry?”; “What should you do next?”) help children organize events into personally relevant autobiographical memories which provide, as part of the self-narrative, action-guiding scripts (“I share with her” and “I say I’m sorry”) that become frequently practiced, overlearned, routine, habitual, and automatic. These interrogatives might also include moral character attributions so that the ideal or “ought” self becomes part of the child’s autobiographical narrative. In this way, parents help children identify morally relevant features of their experience and encourage the formation of social cognitive schemas that are chronically accessible (Lapsley & Narvaez, 2004). Moreover, as Kochanska’s (2002) model suggests, there is every reason to suppose that this developmental process is affected both by variations in the quality of the parent-child relationship and its goodness-of-fit.

One implication of this account, and of Kochanska’s (2002) research on the emergence of conscience, is that character education is not something that takes place initially in schools as a formal curriculum, but rather is embedded within the fabric of family life and early socialization experiences. In the next section, we take up school- and community-based programs that are of significance to character education.

APPROACHES TO CHARACTER EDUCATION

In this section, we review promising or prominent school- and community-based approaches to character

education. The range of programs that are claimed for character education is quite diverse, and there are very many of them. Our intention here is not to review the full range of specific programs but to identify general categories of programs that make some claim for character education. Some of the programs that we review might also be considered examples of one or more of the 11 Principles of Effective Character Education (Lickona, Schaps, & Lewis, 2003) adopted by the Character Education Partnership (CEP). We begin our review by a consideration of these principles given their prominence among character educators.

Eleven Principles of Effective Character Education

The Character Education Partnership is a coalition of organizations and individuals dedicated to helping schools develop moral and character education programs. Many school districts embrace approaches to character education that are guided by principles developed by the CEP. The first principle asserts that good character is built on the foundation of core ethical values, such as caring, honesty, fairness, responsibility, and respect. Sometimes core values (alternatively, traits or virtues) are selected by school districts after broad consultation with the community. More often, the core values are those endorsed by national advocacy organizations, such as the six “pillars” of character (trustworthiness, respect, responsibility, fairness, caring, citizenship) articulated by the Aspen Declaration and the Character Counts movement. What is critical is that the values selected for character education be universally valid, promote the common good, affirm human dignity, contribute to the welfare of the individual, deal with issues of right and wrong, and facilitate democratic practices.

Accordingly, programs should teach core values holistically with cognitive, affective, and behavioral components (Principle 2) and in a way that engages school personnel in an intentional, proactive, and comprehensive way (Principle 3). It is particularly important to create caring school communities (Principle 4) and to provide students with opportunities to engage in moral action, such as service learning and community service (Principle 5). Effective character education does not neglect rigorous, challenging academic curricula (Principle 6). It fosters intrinsic motivation to do the right thing by building a climate of trust and respect, by encouraging a sense of autonomy, and by building shared

norms through dialogue, class meetings, and democratic decision making (Principle 7). Moreover, the core values that animate student life should engage the school staff as well (Principle 8). For character education to take root it must result in shared educational leadership that makes provision for long-term support of the initiative (Principle 9); it must engage families and community stakeholders (Principle 10); and it must be committed to ongoing assessment and evaluation (Principle 11).

This remarkable set of principles provides a useful guidepost for the design and implementation of intentional, programmatic, and comprehensive character education. It insists that ethical considerations be the transparent rationale for programmatic activities and, on this basis (e.g., Principle 3), would not support efforts to broaden the definition of character education to include all manner of prevention and intervention programs absent an explicit, intentional concern for moral development. It endorses a set of well-attested pedagogical strategies that are considered educational best practice, including cooperative learning, democratic classrooms, and constructivist approaches to teaching and learning. It endorses practices that cultivate autonomy, intrinsic motivation, and community engagement (Beland, 2003c). Indeed, the CEP Principles look like a blueprint for progressive education, and would seem to settle the historical debate concerning direct and indirect approaches to character education in favor of the latter paradigm.

Yet, the Principles are not without their discontents. Principle 1 insists on core values that are foundational, objectively true, universally valid, immanent to human dignity, and crucial to democratic practice, yet its elision of familiar anxieties about the source and selection of favored values gives one pause. This insistence that character education first be grounded on objectively valid core values is, in our view, a misleading and unnecessary distraction. It is misleading because it assumes that practices are derived from principles rather than the other way around (see, e.g., Carr, 1991). It is distracting because it forces educators to defend a transparent and intentional approach to the moral formation of children on grounds other than its immanence and inevitability in the life of schools.

Moreover, the first Principle smuggles a premise into character education; for example, that core values are objectively true, foundational, and universally valid is itself a deeply contentious matter for epistemology and

ethics, and attempts to settle an argument about ethical relativism that it is ill equipped to address except by dogmatic assertion.

But the necessity, inevitability, and desirability of character education does not hinge on the outcome of this argument. Indeed, to suggest that it does is to repeat the mistake on the educational front that the cognitive developmental tradition commits on the psychological front. Just as Kohlberg (1981, 1983) attempted to use stage theory to provide the psychological resources to defeat ethical relativism, so, too, does the first Principle of the Character Education Partnership attempt to take up arms against the bogey of relativism on the educational front.

Although the Principles call for comprehensive infusion of ethical concerns throughout the curriculum and in all facets of school life, and although the *Eleven Principles Sourcebook* (Beland, 2003c) encourages a variety of pedagogical strategies that are compatible with best instructional practice, we observe that not much of contemporary character education gets past the first Principle, or else reduces character education to simply teaching *about* values and the *meaning* of trait words. The broad school reform and commitment to best practice required by the remaining Principles are too often neglected in favor of fussing over the meaning of words denoting core values (leaving aside the problem of how one fills in the meaning of these words). The hard work of character education is not *learning about* core value words, but *learning to* engage the range of developmental and educational experiences countenanced by the remaining Principles.

Although there is value in a first Principle that requires educators to make explicit the moral implications of school practices, it would be far better, in our view, if CEP's first Principle articulated a commitment to a distinctly virtue-centered approach to education that gave primacy to aretaic concerns about agents and flourishing rather than Kantian concerns about universality and objectivity. What is required as a first Principle is not a disguised stance on the epistemological status of "values"—that certain of them are foundational, universal, and objectively valid—but a statement that makes explicit the ethical commitments immanent to educational practices endorsed in the remaining Principles. The goal of character education, in other words, is less about enlisting children in the battle against ethical relativism, and more about equipping them with the moral disposi-

tions and skills required for effective citizenship in a liberal democracy.

A Conceptual Framework

We think there is a better way to make the case for character education that has little to do with taking a stance on the question of ethical foundations. The conceptual framework for character education is adequately anticipated by a commitment to a developmental systems orientation. A developmental systems approach to character education draws attention to embedded and overlapping systems of influence that exist at multiple levels, to the fact that dispositional coherence is a joint product of personal and contextual factors that are in dynamic interaction across the life course. As Masten (2003, p. 172) put it, “Dynamic multisystem models of human learning, development and psychopathology are transforming science, practice and policies concerned with the health, success and well-being of children and the adult citizens of society they will become.” A credible character education must resemble dynamic multisystems models of development and be located within contemporary theoretical and empirical frameworks of developmental science if it is going to understand adequately the mechanisms of change, plasticity, prevention, resilience, and the very conditions and possibilities of what it means to flourish—to live well the life that is good for one to live.

Moreover, a developmental systems perspective already underwrites more specific approaches to youth development. For example, Lerner and his colleagues (Lerner, Dowling, & Anderson, 2003; Lerner, Fisher, & Weinberg, 2000) make the case for “thriving” as a basis for understanding the role of adaptive person-context relations in human development. “An integrated moral and civic identity,” they write, “and a commitment to society beyond the limits of one’s own existence enables thriving youth to be agents both in their own healthy development and in the positive enhancement of other people and of society” (Lerner et al., 2003, p. 172). Indeed, thriving and character education point to the same end, as do other notions derived from developmental contextualism, such as developmental assets, resilience, and positive youth development. Moreover, developmental contextualism provides not only a basis for understanding the dispositional qualities of personality (“character”), but also a vision of what it means to flourish (e.g., thriving and positive development). These developmen-

tal considerations already carry the conceptual load for understanding constructs that are crucial to broad conceptualizations of character education and thus would serve much better as a first principle of character education than the CEP’s current emphasis on foundational core values.

Educating for Character

Lickona (1991a, 1991b, 1997, 2004) has developed an integrative approach to character education that is largely congruent with CEP principles. Along with a commitment to core values, he also advocates a variety of strategies that are broadly compatible with instructional best practice for elementary (Lickona, 1992) and high schools (Lickona & Davidson, 2004). A distinction is drawn between two aspects of character: performance character and moral character. Performance character is oriented toward mastery of tasks and includes such qualities as diligence, perseverance, a positive attitude, and a commitment to hard work. Performance character is what is required to develop talents, skills, and competencies. Moral character, in turn, is a relational orientation that is concerned with qualities of integrity, caring, justice, respect, and cooperation. It is an ethical compass that guides the pursuit and expression of performance character. If performance character makes it possible to live a productive life, moral character is required to live an ethical life (Lickona & Davidson, 2004). Effective education should aim to develop both aspects of character.

Lickona and Davidson (2004) recently articulated seven principles of schools that effectively address elements of moral and performance character. These schools:

1. Make the development of character the cornerstone of the school’s mission and identity.
2. Cultivate an ethical learning community that includes staff, students, and parents, who share responsibility for advancing the school’s character education mission.
3. Encourage the professional staff to form a professional ethical learning community to foster collaboration and mutual support in advancing the ethical dimensions of teaching and student development.
4. Align all school practices, including curriculum, discipline, and extracurricular activities, with the goals of performance excellence and moral excellence.

5. Use evaluation data to monitor progress in the development of strength of character and to guide decision making with respect to educational practices.
6. Integrate ethical material into the curriculum while encouraging lifelong learning and a career orientation.
7. Treat classroom and schoolwide discipline as opportunities to support the ethical learning community by emphasizing the importance of caring, accountability, shared ownership of rules, and a commitment to restitution.

One salutary feature of this framework is that it urges schools to understand their educative mission in terms of a moral framework. A second salutary feature is that many of its instructional strategies are informed by the research literatures of developmental and educational psychology. It promotes, for example, instructional practices that encourage mastery motivation, metacognitive instruction, and cooperative learning. It sanctions constructivist strategies that embrace the active participation of students in learning. It advocates strategies (e.g., dilemma discussion, just community) more commonly associated with development of a moral education. Indeed, many of the suggested practices that attempt to link home and school, influence school culture, involve community stakeholders, or capitalize on the unique developmental needs of students could be underwritten by a developmental systems orientation.

Caring School Communities

The fourth of the CEP's Principles of Effective Character Education states, "Effective character education creates a caring school community." (Beland, 2003a, p. 1). There is a strong consensus that effective character education must include efforts to promote "communities of caring" in classrooms and schools (Battistich, Solomon, Watson, & Schaps, 1997; Berkowitz & Bier, 2005). A school climate that encourages social and emotional bonding and promotes positive interpersonal experiences is one that provides the minimum necessary grounding for the formation of character (Schaps, Battistich, & Solomon, 1997). Indeed, as Berkowitz (2002, pp. 58–59) put it, "Relationships are critical to character education, so character education must focus on the quality of relationships at school."

Research has shown, for example, that the quality of early teacher-student relationships can have a strong influence on academic and social outcomes that persist

through eighth grade (Hamre & Pianta, 2001). Moreover, in schools where there is a strong perception of communal organization there is less student misconduct (Bryk & Driscoll, 1988) and lower rates of drug use and delinquency (Battistich & Hom, 1997). Student attachment or bonding to school also improves school motivation (Goodenow, 1993) and counterindicates delinquency (Welsh, Greene, & Jenkins, 1999) and victimization of teachers and students (Gottfredson & Gottfredson, 1985). In a study of a nationally representative sample of 254 high schools, Payne et al. (2003) found a connection between communal organization and student bonding to school. Schools characterized by communal organization, that is, by mutually supportive relationships among teachers, administrators, and students, a commitment to common goals and norms, and a sense of collaboration, tend to have students who report an attachment to school (an emotional bond to teachers or school and a sense of belonging), a belief in the legitimacy of rules and norms, and a high value placed on schoolwork. Moreover, bonding to school was related, in turn, to lower levels of student misconduct and victimization. Payne et al. suggested that by "improving the relationships among school members, the collaboration and participation of these members and the agreement on common goals and norms, schools could increase students' attachment to school, commitment to education and belief in school rules and norms" (p. 773) and thereby reduce misconduct, delinquency, and victimization.

The work of two research teams, the Social Development Research Group at the University of Washington and the Child Development Project of the Developmental Studies Center (Oakland, CA), has provided particularly impressive evidence on the role of school bonding and caring school communities for a range of outcomes of interest to character educators.

Social Development Research Group

This group launched the Seattle Social Development Project (SSDP) in 1981 in eight Seattle public elementary schools. The project initially provided an intervention to first-grade pupils, but the program expanded by 1985 to include all fifth-grade students in 18 elementary schools, with additional intervention components that targeted parents and teachers as well. The longitudinal assessments of participants continued throughout adolescence and subsequently every 3 years after graduation until age 27. The SSDP was guided by a social

development model that assumes that behavior is learned within social environments. One becomes socialized within the norms of a social group to the extent that (a) one perceives opportunities for involvement, (b) becomes actually involved, (c) has the skill for involvement and interaction, and (d) perceives that it is rewarding to do so. When socialization goes well, a social bond of attachment and commitment is formed. This social bond, in turn, orients the child to the norms and expectations of the group to which one is attached and to the values endorsed by the group. "It is hypothesized that the behavior of the individual would be prosocial or antisocial depending on the predominant behaviors, norms and values held by those individuals and institutions to which/whom the individual bonded" (Catalano, Haggerty, et al., 2004, p. 251).

The SSDP included interventions that targeted three primary socialization agents of school-age children: teachers, parents, and peers. Teachers were given training in proactive classroom management, interactive teaching to motivate learners, and cooperative learning. The intervention for children targeted social and emotional skill development, including interpersonal cognitive problem-solving skills and refusal skills. Parent training targeted behavior management, how to give academic support, and skills to reduce risk for drug use.

Research showed that training teachers to use targeted teaching practices was successful in promoting both school bonding and academic achievement (Abbott et al., 1998). Moreover, the SSDP demonstrated long-term positive effects on numerous adolescent health-risk behaviors (e.g., violent delinquency, heavy drinking, sexual intercourse, having multiple sex partners, pregnancy, and school misconduct) and on school bonding (Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999; Hawkins, Guo, Hill, Battin-Pearson, & Abbott, 2001). For example, school bonding at grade 12 and increases in school bonding between grades 7 and 12 was negatively correlated with use of alcohol, cigarettes, marijuana, and other drug use at grade 12. Students bonded to school at grades 5 and 6 were less likely to become minor or major offenders in middle school. Students with a lower sense of school attachment and commitment were twice as likely to join gangs as were students with a stronger sense of school bonding. Moreover, school bonding also had positive academic outcomes. For example, an increase in school bonding between grades 7 and 12 was associated with higher GPA and lower student misconduct at grade 12. Students with greater bonding

to school at grade 8 were less likely to drop out of school by grade 10 (see Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2004, for a review).

Thus, the intensive, multicomponent interventions of the SSDP had clear effects on school bonding and on a range of outcomes of traditional interest to character educators, including substance use, delinquency, gang membership, violence, academic problems, and sexual activity. But is this character education? It depends on whether character education is defined by treatment or by outcomes. The SSDP has generated empirical outcomes that are claimed for character education broadly defined, although the SSDP "treatment" is guided by the theoretical considerations of the social development model and not of virtue, morality, or character. Still, if character education is to be considered a treatment or intervention in its own right, then it must possess the characteristics of successful interventions like the SSDP: It must be guided by explicit theory; it must be comprehensive; it must involve multiple components; and it must be initiated early in development and sustained over time.

Developmental Studies Center

The Developmental Studies Center (DSC) has been particularly influential in documenting the crucial role that children's sense of community plays in promoting a wide range of outcomes commonly associated with character education, including altruistic, cooperative, and helping behavior, concern for others, prosocial conflict resolution, and trust in and respect for teachers (Solomon, Watson, Delucchi, Schaps, & Battistich, 1988; M. Watson, Battistich, & Solomon, 1997). The research agenda of the DSC assumed that children have basic needs for belonging, autonomy, and competence and that their engagement with school depends on whether these needs are adequately met (Battistich et al., 1997). It was assumed further that "when children's needs are met through membership in a school community, they are likely to become affectively bonded with and committed to the school, and therefore inclined to identify with and behave in accordance with its expressed goals and values" (Schaps et al., 1997, p. 127).

In 1982, the DSC initiated the Child Development Project (CDP) in three program schools in suburban San Francisco to examine these core assumptions. It was first implemented by teachers in kindergarten, with one grade level added each year until 1989. Program evaluation followed the cohort annually from kindergarten to

sixth grade, with a 2-year follow-up assessment when the program cohort was in eighth grade. The evaluation also included students and teachers from three demographically similar comparison schools.

The programmatic focus of the CDP was designed to enhance prosocial development by creating the condition for a caring school community (Battistich et al., 1997). A sense of community was encouraged through activities such as collaborating on common academic goals; providing and receiving help from others; discussion and reflection on the experiences of self and others as these relate to prosocial values such as fairness, social responsibility, and justice; practicing social competencies; and exercising autonomy by participating in decisions about classroom life and taking responsibility for it. Moreover, the CDP encouraged an approach to classroom management that emphasized induction and developmental discipline (M. Watson, 2003).

Hence, the CDP provided numerous opportunities for children to collaborate with others in the pursuit of common goals, to give and receive help, to discuss and reflect on prosocial values, to develop and practice prosocial skills, and to exercise autonomy through democratic classroom structures.

Research studies of CDP implementations indicate that in comparison to control schools, students make positive gains in targeted areas. In classroom observations, individual interviews, and student questionnaires, program students exhibited more prosocial behavior in the classroom (Solomon et al., 1988), more democratic values and interpersonal understanding (Solomon, Watson, Schaps, Battistich, & Solomon, 1990), and more social problem-solving and conflict resolution skills (Battistich, Solomon, Watson, Solomon, & Schaps, 1989). Students in CDP schools were more likely to view their classrooms as communities, which led them to adhere to whatever norms and values were salient in the classroom. For example, in classrooms that emphasized teacher control and student compliance, student reasoning about prosocial dilemmas was oriented toward heteronomy and reward and punishment. In contrast, in classrooms that emphasized student participation, autonomy, democratic decision making, and interpersonal concerns, student prosocial reasoning emphasized autonomy and other-oriented moral reasoning (Solomon et al., 1992, 1996). When program and control students entered the same intermediate school, former program students were rated higher by teachers at eighth grade in conflict resolution skills, self-esteem, assertion, and popularity (Solomon, Watson, & Battistich, 2002).

The most important variable positively influenced by participation in CDP programs is students' sense of community, which is promoted through structures of the classroom and the school (Watson et al., 1997). For example, teachers who hold class meetings, use cooperative learning strategies, and discuss prosocial values are more likely to foster a sense of community in students. Schools that provide cross-age buddies, homework that links school and family, and schoolwide projects also promote a sense of community. Student sense of community is positively related to self-reported concern for others, conflict resolution skills, altruistic behavior, intrinsic prosocial motivation, trust in and respect for teachers, enjoyment of helping others learn, and positive interpersonal behavior and academic engagement (Battistich, Solomon, Watson, & Schaps, 1996; M. Watson, Battistich, & Solomon, 1997).

Other Approaches

Other approaches have focused similarly on building a sense of community within classrooms and schools. For example, the *Don't Laugh at Me* curriculum attempts to sensitize children to the painful effects of peer ridicule, ostracism, and bullying and to help them transform their classroom and school into "ridicule-free zones" characterized by a climate of respect. A recent efficacy study using a within-school quasi-experimental methodology showed that program participants (fourth and fifth graders) reported significant gains in a psychological sense of school membership, increases in quality of relational experiences and in the desire to stop dising and ridicule, and declines in bullying, compared to youngsters in the control group (Mucherah, Lapsley, Miels, & Horton, 2004).

Similarly, the Resolving Conflicts Creatively Program (RCCP) attempts to build peaceable schools and classrooms through an emphasis on conflict resolution and positive communication skills (Lantieri & Patti, 1996). The curriculum cultivates a selected set of skills that target conflict resolution, cooperation, caring, appreciating diversity and countering bias, responsible decision making, and appropriate expression of feelings. The curriculum emphasizes the importance of adults coaching these skills as students practice them across a variety of contexts. Students learn to give "I" messages about their feelings, listen actively to others, mediate peer conflict, and become interculturally competent. An evaluation of RCCP performed by the National Center for Children in Poverty at Columbia University (Aber, Brown, & Heinrich, 1999; Aber, Pedersen, Brown, Jones,

& Gershoff, 2003) showed that students from grades 2 through 6 who were involved in an average of 25 lessons per year had a significantly slower growth rate in self-reported hostile attributions, aggressive fantasies, and greater problem-solving strategies than students who received fewer lessons. High-exposure students also showed greater improvement on academic achievement scores in the 2-year study.

Service Learning and Community Service

As we have seen, classroom practices that include democratic cooperation, problem solving, and decision making encourage the cultivation of skills and dispositions that are crucial for citizenship, and hence are an important component of character education. The fifth of the CEP's Principles of Effective Character Education (Beland, 2003c) urges schools to provide students with opportunities for moral action. In some sense, democratic classrooms include important moral lessons concerning fair play, civility, civic friendship, and cooperation. Children learn how to sustain moral conversation in the context of joint decision making. They develop a "deliberative competence" (Guttman, 1987) in solving problems, resolving conflict, establishing shared norms, balancing perspectives, and other skills crucial for effective citizenship (Power et al., 1989a). But the effort to cultivate democratic dispositions and a sense of community within classrooms is being joined by efforts to connect students to the larger community through service learning and community service.

According to Tolman (2003):

Service learning is rooted in the notion that acts of "doing good" for others—anything from cleaning up neighborhoods, to teaching younger students, to spending time with elderly community members—are the basis for significant learning experiences, for community development and for social change. (p. 6)

Service learning is distinguished from community service by the degree to which it links service activities to clearly defined learning objectives and to an academic curriculum (Pritchard, 2002). Both kinds of activities are now a ubiquitous and pervasive feature of American education. A national survey conducted by the National Center for Educational Statistics estimates that 64% of all public schools, including 87% of public high schools, had students participating in community service activities. About a third of these organized service learning as part of their curriculum, which is typically justified

by the desire to strengthen relationships among students, the school, and the community (Skinner & Chapman, 1999).

The desire to strengthen connections among home, school, and community is supported by ecological perspectives on human development. There are adaptational advantages for children whose developmental ecology is characterized by a richly connected mesosystem (Bronfenbrenner, 1979). Indeed, Warter and Grossman (2002) appeal to developmental contextualism to provide a justification for the specific case of service learning and its implementation. Yates and Youniss (1996b; Youniss & Yates, 1997) argue similarly for a developmental perspective on service learning that is strongly influenced by Erikson's (1968) conceptualization of identity. According to this view, service learning opportunities provide an important context for helping adolescents sort out identity issues. For Erikson, identity work requires psychosocial reciprocity between the characteristics, identifications, and ideals of the young person and the affirmation of the community that give these choices significance and meaning. Identity is deeply characteristic of persons, to be sure, but like dispositional coherence of any kind, it plays out in dynamic interaction with community, culture, and context. In this way, identity is compatible with the person-context interactionism that is characteristic of a developmental systems approach.

Research has documented outcomes that are of interest to character education. Service learning experiences and participation in voluntary organizations increase one's sense of social agency, responsibility for the moral and political dimensions of society, and general moral-political awareness (Youniss et al., 1997). Indeed, youth who participate in service experiences often report significant transformation in personal values and orientations, an increased civic-mindedness and sense of social responsibility, along with enhanced learning and better grades (Markus, Howard, & King, 1993; Pancer & Pratt, 1999; Pratt, Hunsberger, Pancer, & Alisat, 2003; Scales, Blyth, Berkas, & Kielsmeier, 2000). They report higher levels of trust and more positive views of others in their communities (Hilles & Kahle, 1985). Similar findings were reported in national evaluations of two federally funded national service learning initiatives (Serve America, Learn and Serve). Melchior and Bailis (2002) report, for example, positive effects of service learning on the civic attitudes of adolescents. In addition, there was a reduction in school absenteeism for program participants and a

lower incidence of teenage pregnancy. High school participants showed more school engagement, better math and science achievement, and a lower incidence of course failure. Middle school participants did more homework, got better grades in social studies, and got into serious legal and disciplinary problems less often.

Moreover, service learning and community service may be critical to political socialization and the process of forming a moral-civic identity (C. Flanagan, 2004; Yates & Youniss, 1999a). In one study, Yates and Youniss (1996a) examined the reflective narratives of Black parochial high school juniors who worked at a soup kitchen for the homeless as part of a service learning commitment. Over the course of a year, the researchers noticed that these youth came to invest their service with greater meaning and at a higher level of transcendence. Initially, participants tended to view the homeless in terms of stereotypes; then, at a higher level of transcendence, they started to think about the consequences of homelessness for their own life, or to compare the lot of the homeless to theirs; finally, they were able to reflect on homelessness from the perspective of social justice or in terms of appropriate political action. Over the course of a year, then, serving the homeless in a soup kitchen motivated reflective judgments about weighty matters of justice, responsibility, and political engagement.

In addition to promoting moral-civic identity, there is evidence that participation in service activities and voluntary organizations also increases civic participation in later adulthood (Youniss et al., 1997). Indeed, C. Flanagan (2004, p. 725) argued that membership in community-based organizations, along with extracurricular activities at school, provides a “sense of place” wherein youth “develop an affection for the polity.” “Affection for the polity,” she writes, “and engagement in community affairs are logical extensions of the sense of connection youth develop from involvement in community-based organizations” (p. 725).

Service learning and community service, then, are significant components of a school’s commitment to character education (Hart, 2005). They are justified on the grounds that service significantly transforms moral-civic identity and predicts civic engagement in later adulthood (Youniss & Yates, 1999), both of which are foundational goals of character education. Of course, much depends on how service learning is implemented. It is generally agreed that successful service learning programs include opportunities for significant student

reflection as part of the experience. Matching students to projects consistent with their interests and holding them accountable for outcomes but giving them autonomy in selecting goals are also important program elements (Stukas, Clary, & Snyder, 1999; Warter & Grossman, 2002). There is evidence that service learning is particularly effective at high school compared to middle school, and that positive outcomes are most likely to be evident in areas directly related to the service learning experience (Melchior & Bailis, 2002).

Positive Youth Development

We noted earlier that a developmental systems approach (Lerner et al., 2003) might well serve as a conceptual framework for character education, as opposed to the current epistemological preoccupation with core values. A developmental systems orientation is foundational to the positive youth development perspective that has emerged as a counter to a risks-and-deficits model of adolescent development. Although adolescents certainly do face risks and obstacles, there is an emerging consensus that effort to ameliorate risk exposure, overcome deficits, or prevent problems is not sufficient to prepare young people adequately for the competencies that will be required of them for successful adaptation to adulthood. The mantra of positive youth development is “Problem-free is not fully prepared.” Children and adolescents must be equipped with the strengths that will allow them to thrive, be resilient, take initiative, and contribute productively to society (Larson, 2000). This will require programmatic efforts to help children develop what Lerner (2001, 2002) calls the “5C’s of positive youth development”: competence, confidence, character, caring and compassion, and connection to the institutions of civil society.

The work of the Search Institute on the developmental assets is one instantiation of this general approach (Benson, Scales, Leffert, & Roehlkepartain, 1999; Scales & Leffert, 1999). Developmental assets are those features of a developmental system that promote positive outcomes. Forty assets have been identified on the basis of research, 20 of which are external and contextual, and 20 of which are internal and personal. The external assets are grouped into four categories: support (assets 1 to 6), empowerment (assets 7 to 10), boundaries and expectations (assets 11 to 16), and constructive use of time (assets 17 to 20). These refer to the positive developmental experiences that result from the

network of relationships that youth have with adults in their family, school, and community. The internal assets are grouped similarly into four categories: commitment to learning (assets 21 to 25), positive values (assets 26 to 31), social competencies (assets 32 to 36), and positive identity (assets 37 to 40). These refer to endogenous skills, dispositions, and interests that emerge over the course of education and development.

In many ways, the developmental assets approach already constitutes a richly articulated conceptual framework for character education that has little need for epistemological wrangling over foundational core values. Virtually all of the internal assets are familiar targets of character education, such as the positive values assets (caring, equality and social justice, integrity, honesty, responsibility), social competency assets (decision making, interpersonal competence, cultural competence, resistance skills, conflict resolution), and identity assets (personal power, self-esteem, sense of purpose, positive view). The external assets are similarly crucial for any comprehensive approach to character education insofar as it targets sources of mesosystem support for positive development (e.g., family support, caring schools and neighborhoods, parental involvement in schooling), ways to empower youth (perceptions of communal support, service learning), the importance of setting appropriate boundaries and expectations (e.g., adult role models, positive peer influence, and high expectations), and constructive use of time (e.g., creative activities, youth programs, participation in a religious community, and time spent at home away from peer influence).

Moreover, all of the CEP Principles of Effective Character Education (Beland, 2003c), save the first Principle, are well in evidence among the 40 developmental assets. Principle 10 is of particular interest. It states, "Effective character education engages families and community members as partners in the character-building effort" (Beland, 2003b). The Search Institute has argued similarly that the success of positive youth development depends on community resolve to construct the building blocks ("assets") of its developmental infrastructure. However, communities vary in the assets that are available to support positive youth development (Benson et al., 1999).

One study assessed the perceived availability of assets in a 1996–1997 survey of more than 99,000 youth in grades 6 through 12 from 213 cities and towns across the United States (Benson, Leffert, Scales, & Blyth, 1998). In this sample, 62% of adolescents experience at

most half of the developmental assets associated with positive youth development. The mean number of assets for the aggregate sample was 18, and the least and most affluent communities in the sample differed by only three assets (in favor of the more affluent community), indicating that students typically experience less than half of the developmental assets and that even wealthy communities have work to do on building their developmental infrastructure. Notably, from the perspective of positive youth development and character education, three of the least experienced assets are a caring school, youth being treated as a resource, and community valuing youth (Scales, 1999).

Benson et al. (1998) reported dramatic differences in the percentage of youth with low (0 to 10) and high (31 to 40) assets who engage in risk behavior: Low asset youth are more likely than high asset youth to use alcohol (53% versus 3%); to smoke tobacco (45% versus 1%); to use illicit drugs at least 3 or more times in the past year (45% versus 1%); to have had sexual intercourse at least 3 or more times (42% versus 1%); to report frequent depression or to have made a suicide attempt (40% versus 4%); to report at least 3 incidents of antisocial behavior (52% versus 1%); to engage in at least 3 acts of violence (61% versus 6%); to report school problems (43% versus 2%); to drink and drive (42% versus 4%) and gamble (34% versus 6%). The conclusion is inescapable: Youth who report fewer developmental assets tend to engage in more risk behavior; youth who report more assets engage in fewer risk behaviors (see also Oman et al., 2004). Moreover, youth who are more vulnerable, that is, who have more deficits and risk factors (e.g., experience physical abuse, violence, unsupervised time), profit the most from assets (Scales, 1999).

Benson et al. (Benson, Leffert, Scales, & Blyth, 1998) also report a strong connection between asset levels and thriving factors. High asset youth are more likely than low asset youth to report getting mostly As in school (53% versus 7%); to place a high value on cultural diversity (87% versus 34%); to help friends or neighbors at least 1 hour a week (96% versus 69%); to be a leader in a group or organization in the past year (87% versus 48%); to resist doing dangerous things (43% versus 6%); to delay gratification by saving money rather than spending it right away (72% versus 27%); and to overcome adversity and not give up when things get tough (86% versus 57%). Although not as dramatic in every instance as in the comparison of risk behavior,

these data indicate that youth who report the fewest assets also report fewer thriving factors and, conversely, that youth who report more developmental assets also report more thriving indicators.

These data underscore the importance of Principle 10 for effective character education. It requires a fundamental mobilization of the community. There must be an intentional commitment to become an asset-building community, to construct the developmental infrastructure to support the positive development of all youth. The Search Institute suggests some core principles of asset-building communities. There must be broad *collaboration* among all of the socializing systems within a community. The community initiative must be *comprehensive*; it should seek to promote all 40 assets and not just a subset. It should promote the *civic engagement* not just of traditional leaders but of all the residents within the boundaries of a community. It should involve *youth as partners* with adults.

Many adolescents participate in largely community-based youth programs that are guided by a positive youth development orientation. Roth and Brooks-Gunn (2003) surveyed 71 youth-serving organizations to determine the characteristics of programs designed to promote healthy adolescent development. Consistent with the youth development philosophy, 77% of the programs said that their primary goal was to build competencies; 54% also indicated prevention goals. However, prevention goals were strongly in evidence when asked specifically about whether the program was designed as prevention against high risk behaviors, such as substance abuse (76%), school dropout (63%), violence (73%), and gang activity (59%). Interestingly, not one of the youth development programs apparently viewed their competency-building and prevention work in terms of moral or character development.

Another perspective is what adolescents themselves report learning in organized youth activities. In one study (D. M. Hanson, Larson, & Dworkin, 2003), 450 adolescents in a medium-size, ethnically diverse school responded to the Youth Experiences Survey (YES), which asks respondents to report their experiences in several domains (identity, initiative, basic emotional, cognitive, and physical skills, teamwork and social skills, interpersonal relatedness, connections with adults, and negative experiences). Learning in these contexts was compared against “hanging out with friends” and with academic classes. The results showed that organized youth activities were a better context for learning initiative skills (e.g., goal setting, problem

solving, effort, time management), exploring identity and reflection, and learning to manage anger, anxiety, and stress than hanging out with friends or taking required classes. Moreover, adolescents reported learning about teamwork, social, and leadership skills in organized youth activities. Interesting learning differences emerged among program activities. For example, the development of identity, prosocial norms, and ties to the community were said to be learned in faith-based, community service, and vocational activities, but participation in sports was associated with mostly gains in personal development (e.g., self-knowledge, physical skills, and emotional regulation) but not teamwork, social skills, prosocial norms, or positive peer interactions. Perhaps the competitive nature of sports works against the development of skills required for interpersonal competence (see Shields & Bredemeier, 2005).

Two reviews have attempted to gauge the effectiveness of youth development programs. Roth, Brooks-Gunn, Murray, and Foster (1998) examined 15 program evaluations that met criteria for methodological rigor. Six programs largely met the goals of the positive youth development framework by focusing on competency and asset building. Six programs were designed as preventions against specific problem behaviors, albeit by strengthening competencies and assets. Three programs were preventions designed to teach skills for avoiding risk behaviors (e.g., assertiveness training, peer resistance, planning for the future) and were the least representative of the ideal youth development program. In general, all 15 programs showed evidence of effectiveness, although a number of general distinctions emerged. For example, programs that are more comprehensive and sustained tend to result in better outcomes. Program effectiveness was also linked to the continuity of caring adult-youth relationships and the extent and quality of youth engagement with program activities.

Catalano, Berglund, et al. (2004) identified 25 programs that addressed one or more positive youth development constructs (e.g., bonding, resilience, socioemotional, cognitive, behavioral or moral competence, self-efficacy, self-determination, spirituality, identity, belief in the future, recognition for positive behavior, prosocial norms, and prosocial involvement) in multiple socialization domains (or many constructs in a single domain), using children from the general or at-risk population (but not in treatment). These studies also met strong methodological criteria. The analysis of program characteristics showed that effective programs addressed a minimum of five positive youth de-

velopment constructs. Competence, self-efficacy, and prosocial norms were addressed in all 25 programs; opportunities for prosocial involvement, recognition for positive behavior, and bonding were noted in over 75% of the programs; and positive identity, self-determination, belief in the future, resiliency, and spirituality were noted in 50% of the programs. Effective programs also measured both positive and problem outcomes, had a structured curriculum and frequent youth contact for at least 9 months, and took steps to ensure fidelity of implementation.

Social-Emotional Learning

We noted earlier that a developmental systems orientation that focused on positive youth development would constitute a powerful conceptual framework for character education. A similar claim can be made for social-emotional learning (SEL). The Collaborative to Advance Social and Emotional Learning (CASEL) has developed a unifying framework to promote the development of important competencies that both enhance strengths and prevent problem behaviors (Graczyk et al., 2000; Payton et al., 2000; Weissberg & Greenberg, 1998). Its focus on competence and prevention place it well within the positive youth development framework (Catalano, Hawkins, Berglund, Pollard, & Arthur, 2002), although its long-standing concern with school-based implementation makes it particularly attractive for character education (CASEL, 2003; Elias, Zins, Graczyk, & Weissberg, 2003; Elias et al., 1997). Indeed, CASEL insists that effective programming for SEL competencies has an instructional component with well-designed and organized lesson plans that are sequenced in a coherent curriculum that is programmatic over consecutive grades (Payton et al., 2000), as well as broad parent and community involvement in planning, implementation, and evaluation (Weissberg & O'Brien, 2004).

The key SEL competencies identified by CASEL include self-other awareness (awareness and management of feeling, realistic self-assessment of abilities, perspective taking), self-management (self-regulation of emotions, setting goals, persevering in the face of obstacles), responsible decision making (identifying problems, discerning social norms, accurate and critical appraisal of information, evaluation solutions, taking responsibility for decisions), and relationship skills (cooperation, expressive communication, negotiation, refusal, help seeking, and conflict resolution skills). All of these competencies are familiar targets of character education.

A substantial research base links these competencies to effective and adaptive functioning and to prevention of risk behavior. For example, evidence cited earlier for the Child Development Project and the Seattle Social Development Project are claimed as support for school-based SEL objectives (Greenberg et al., 2003; Weissberg & O'Brien, 2004). Similarly, a substantial literature shows that programs that address SEL competencies are effective in preventing problem behaviors (Durlak & Wells, 1997; D. B. Wilson, Gottfredson, & Najaka, 2001), drug use (Tobler et al., 2000), and violence (Greenberg & Kusche, 1998; Greenberg, Kusche, Cook, & Quamma, 1995). SEL is also a strong predictor of academic outcomes (Elias et al., 2003). One study showed, for example, that the best predictor of eighth-grade academic achievement was not third-grade academic achievement but indices of social competence (Caprara, Barbanelli, Pastorelli, Bandura, & Zimbardo, 2000).

One crucial issue that CASEL has taken on concerns program implementation and sustainability. As Elias et al. (2003, p. 308) put it, "Even widely acclaimed evidence-based approaches to classroom organization and instruction that integrate both academics and SEL are dependent for their success on the delivery systems into which they are embedded." We review various implementation issues in a later section.

Character and Higher Education

Character education does not end with high school. Indeed, a developmental systems perspective on moral character would lead us to expect opportunities for dynamic change across the life course. Although there has been comparatively less programmatic emphasis or research on character development in postsecondary institutions, there are notable recent efforts to explore the contributions of the collegiate experience to the moral formation of undergraduates (e.g., Colby, Ehrlich, Beaumont, & Stephens, 2003; Mentkowski & Associates, 2000). One survey, for example, identified an honor roll of 134 colleges and universities to serve as exemplars of character-building institutions (Schwartz & Templeton, 1997; Sweeney, 1997). These institutions emphasized students' moral reasoning skills, community-building experiences, and spiritual growth, while advocating for a drug-free environment. They also conducted critical assessments of their character-building assets and programs.

The emphasis on moral reasoning skills is premised on the expectation that the critical engagement and inquiry that is ideally characteristic of postsecondary education

will stimulate moral deliberation to higher stages of complexity. Indeed, one of the best-documented changes that results from the collegiate experience is a significant increase in the quality and complexity of moral reasoning (Pascarella & Terenzini, 1991), demonstrating the effect of college on humanizing “values and attitudes concerning the rights and welfare of others” (Pascarella & Terenzini, 2005, p. 348). College environments that encourage questioning, inquiry, and openness to evidence and argument foster the largest gains in moral reasoning (e.g., Rest & Narvaez, 1991; Rogers, 2002), although this relationship is attenuated in collegiate environments that are narrowly careerist and where critical inquiry is not valued (McNeel, 1994).

There are indeed differences among colleges and universities in the degree to which they make moral and civic education a central institutional commitment. Colby et al. (2003) noted that moral and civic development is not a high priority for most American universities and colleges. “We have been struck again and again,” they write, “by the very many lost opportunities for moral and civic growth in curricular and extracurricular programs on most campuses” (p. 277). In their study of 12 universities that do make moral and civic growth an institutional commitment, Colby et al. identify (a) the important dimensions of moral and civic maturity that should be addressed, (b) the sites where these dimensions can be exploited, and (c) the thematic perspectives that a fully rounded commitment to moral and civic education should embrace.

With respect to the dimensions of moral and civic maturity, Colby et al. (2003) nominated three categories: *understanding* (e.g., key ethical and civic concepts, knowledge of democratic principles, expertise in one’s field), *motivation* (e.g., hope and compassion, desire to be an engaged citizen, sense of political efficacy, sense of civic responsibility as a part of self-understanding), and *skills* (e.g., communication skills, ability to collaborate, forge consensus, compromise). These dimensions are exploited in the curriculum, in extracurricular activities, and in the general campus culture. The curriculum, for example, presents numerous opportunities to cultivate moral and civic maturity. Moral and civic understanding, motivation, and skills can mutually enhance academic learning (e.g., Markus et al., 1993). A wide range of pedagogical strategies, including service learning, project-based learning, field placements, site-based practicum experiences, and collaborative work, encourages student engagement with the broader community

and has significance for moral learning (Brandenberger, 2005). Moral and civic issues can be framed in core courses and in the coursework of one’s major and can be the target of faculty development.

Finally, a comprehensive and intentional commitment to moral and civic growth by universities and colleges takes on three themes: community connections, moral and civic virtue, and social justice (“systemic social responsibility”). According to Colby et al. (2003, p. 284), “Moral and civic education is incomplete if it does not somehow take account of all these themes.” Feeling a connection to a community cultivates a sense of allegiance and duty, where the benefits and burdens of cooperation, and of citizenship, can be experienced and practiced. Postsecondary institutions are also places where the virtues proper to democratic citizenship can be cultivated. Although these dispositions have been variously conceived, there is a strong consensus that a deliberative character (Guttman, 1987) is minimally required, a character that is able to carry on the public conversation in a way that is tolerant, respectful, and generous. Nash (1997) has noted, too, that democratic dispositions are essentially “conversational virtues” that take on moral significance because they are necessary for living well in a democracy. The democratic citizen must engage in public discourse with toleration, fairness, and respect for different perspectives and for the canons of civility. Civic engagement in a democratic society requires a disposition to listen with generosity, to compromise, to argue on the basis of factual evidence, to abide by outcomes, and to affirm the validity of a democratic process even if it results in outcomes that are contrary to one’s own preferences (Knight Higher Education Collaborative, 2000). Moreover, the democratic citizen must have hope and confidence in the value of deliberation and be able to engage in adversarial discussion in a way that does not compromise civic friendship, mutual respect, and sense of common purpose. Hence, an important moral responsibility of higher education is to cultivate “dialogic competence in public moral language” (Strike, 1996, p. 889), and to provide occasions, in the context of scholarly engagement and intellectual inquiry, where these virtues are on frequent display and avidly practiced.

The third theme encourages curricular and extracurricular activities that allow undergraduates to take on “systemic social responsibility”: to be active in the democratic process, to take a stand, to take an interest in social policy, and to view the life of the community through the lens of social justice and one’s own respon-

sibility as an engaged citizen. Postsecondary institutions vary in how they address these three themes, but what is crucial is that colleges and universities make moral and civic maturity an explicit, intentional, and comprehensive part of their educational mission.

Character and Professional Education

“Professional practice,” according to Bebeau (2002, p. 271), “is predominantly a moral enterprise.” Indeed, ethical development is a concern for schools across the professional landscape, including business, law, medicine, dentistry, nursing, and education. An increasing number of professional schools are adopting ethics education with greater frequency.

Rest and Narvaez (1994a) point out specific methods that promote moral reasoning development in professional educational programs. First, following Dewey’s advocacy of immediate experience and active problem solving, one of the most effective methods is deliberative psychological education, reading academic theory, providing direct experience, and reflection that integrates theory with the direct experience (Sprinthall, 1994). The individual’s conceptual frameworks developed from these integrated experiences are not only more sophisticated but are resilient. Studies have documented that the most popular and successful methods of instruction for moral reasoning development involves student discussion about dilemmas and cases in the field (e.g., Hartwell, 1995). Moral dilemma discussion is particularly effective when students are coached to develop the skills necessary for expert moral problem solving, using profession-specific ethical constructs (Bebeau & Thoma, 1999), such as role taking and logical analysis for determining valid and invalid arguments (McNeel, 1994; Penn, 1990). However, even less experiential courses such as film-based courses and writing-intensive courses can have positive effects (e.g., Bebeau, 1994, 2002; Self, Baldwin, & Olivarez, 1993).

The most integrative programs have moved beyond a sole focus on moral reasoning to include other aspects of moral functioning, such as those described by the four component model (Rest, 1983). For example, programs at the University of Minnesota assist nursing and dentistry students in developing the four components: ethical sensitivity, ethical motivation, and ethical implementation as well as ethical judgment (Bebeau, 1994; Duckett, 1994). Recently, Bebeau (2002) has addressed the importance of developing a professional

moral identity. She suggests that “the conceptual frameworks of professional identity are not part of an initial self-understanding, and must be revisited frequently during professional education” (p. 286). The study of professional exemplars is a useful method for providing concrete models for professional ethical identity formation (Rule & Bebeau, 2005). Such studies offer glimpses to novices of what a virtuous professional looks like and how to conduct oneself in typical and nontypical situations and provide role models for initiates.

A CASE STUDY: INTEGRATIVE ETHICAL EDUCATION

Integrative Ethical Education (IEE) is a conceptual framework that attempts to incorporate insights of developmental theory and psychological science into character education (Narvaez, 2005a; Narvaez, Bock, & Endicott, 2003). It is integrative in several senses. It attempts to understand character and its development in terms of cognitive science literatures on expertise and the novice-to-expert mechanisms of best practice instruction. It attempts to keep faith with classical sources by linking Greek notions of *eudaemonia* (human flourishing), *arête* (excellence), *phronesis* (practical wisdom), and *techne* (expertise) with developmental and cognitive science. It is compatible with positive youth development in its claim that the goal of integrative ethical education is the development of important competencies that contribute to productive adaptation to the demands of adulthood, but that these competencies are understood as clusters of skills that one may learn or practice to varying degrees of expertise. It assumes that the best context for expertise development is a caring relationship with teacher-mentors wherein skills are learned by means of coached practice and “guided autonomy.” In delineating the elemental skills of good character, IEE addresses *character* education by integrating the findings from developmental psychology, prevention science, and positive psychology. In proposing the best approach to instruction, IEE addresses *character education* by integrating contemporary findings from research in learning and cognition.

In this section, we outline some of the key features of IEE. Integrative Ethical Education is predicated on the importance of caring classroom environments, but we focus on just three components of the model: character as expertise development, the cultivation of

character as the cultivation of expertise, and the importance of self-regulation for developing and maintaining virtuous character.

Character as Expertise Development

Human learning is increasingly conceptualized as a matter of novices developing greater expertise in domains of study (Ericsson & Smith, 1991; R. Sternberg, 1998). A domain expert differs from a novice by having a large, rich, organized network of concepts or schemas that include declarative, procedural, and conditional knowledge. Unlike novices, experts know what knowledge to access, which procedures to apply, and how to apply them and when. Expertise refers not to mere technical competence but to the multitrack capacities and sensibilities of an exemplar, the refined, deep understanding built from lived experience that is evident in practice and action (Hursthouse, 1999, 2003; Spiecker, 1999).

In the *Republic*, Plato describes virtue as a type of *techné*, or “know-how” that is characteristic of experts (e.g., painters, writers, politicians) in specific domains. Similarly, the virtuous person has ethical know-how, that is, ethical skills honed to a high degree of expertise. Ethical expertise refers not only to behaviors, sensibilities, and orientations but also to feelings, motives, and drives. Ethical expertise is not just what a person does but that which the person *likes* to do (Urmson, 1988). It is a complex of characteristics, skills, and competencies that enable ethical behavior and sustain one in pursuing the life that is good for one to live.

Rest (1983; Narvaez & Rest, 1995) identified four psychologically distinct processes that must occur to enable ethical behavior: ethical sensitivity, ethical judgment, ethical motivation/focus, and ethical action. The four-process model provides a holistic understanding of the ethical exemplar, one who is able to demonstrate keen perception and perspective taking, skilled reasoning, ethical focus, and skills for completing moral action (Bebeau, Rest, & Narvaez, 1999; Narvaez, 2005a; Narvaez, Bock, Endicott, & Lies, 2004). Each process is represented by a set of skills (Narvaez et al., 2004; Narvaez et al., 2003). For example, experts in the skill of ethical sensitivity are able to more quickly and accurately read the moral implications of a situation and determine a suitable response. They are better at generating usable solutions due to a greater understanding of the consequences of possible actions. Experts in ethical judgment are more skilled in solving complex

problems and seeing the syntactic structure of a problem quickly and bring with them many schemas for reasoning about possible courses of action. Their information-processing abilities are both complex and efficient. Experts in the skill of ethical focus are able to sustain moral priorities in light of the commitments of a moral self-identity. Experts in the skills of ethical action engage the self-regulation that is necessary to get the ethical job done.

Pedagogy for Cultivating Character Expertise

The IEE model emphasizes two critical features of successful pedagogy: First, it must be constructivist; second, it must attend simultaneously to cultivating expertise on two fronts: conscious, explicit understandings and intuitive, implicit understanding. Integrative Ethical Education adopts the cognitive-mediational view that learning depends on the cognitive activity of students; that learning occurs when incoming information is actively transformed in light of prior knowledge; and that teachers facilitate learning by engaging students in active cognitive processing about content and facilitating self-monitoring understanding (L. M. Anderson, 1989). It assumes that learners are active constructors of meaning, competencies, and skills and that individuals build conceptual frameworks—declarative, procedural, and conditional—in the process of learning to get along with others. When these skills are practiced extensively in multiple contexts, they take on the qualities of tacit, implicit knowledge and the automaticity characteristic of the “unconscious” mind (Hassin, Uleman, & Bargh, 2005; Hogarth, 2001).

A model of instruction that captures these pedagogical goals is coached apprenticeship. A coached apprenticeship model involves using both direct and indirect instruction, mimesis and transformation, a focus on both content and process, tuning both the deliberate conscious mind and the intuitive mind. In an apprenticeship, the guide provides examples and models of skilled behavior and the theoretical explanation for why things are done one way and not another. At the same time, the apprentice is immersed in well-structured environments that cultivate appropriate intuitions (Hogarth, 2001).

Teaching for ethical expertise requires coached apprenticeship and extensive practice in multiple contexts. Integrative Ethical Education offers instructional guidelines for helping children move along a continuum from novice to expert in each ethical content domain that

is studied. To do this, children must experience a type of expert-in-training pedagogy, that fosters appropriate intuitions and deliberative understanding for each skill that they learn. Teachers can set up instruction to help students develop appropriate knowledge by designing lessons according to the following four levels (based on Marshall, 1995). At Level 1 (“Immersion in examples and opportunities”), teachers draw students’ attention to the big picture in a subject area and help them learn to recognize basic patterns. At Level 2 (“Attention to facts and skills”), teachers focus students’ attention on the details and prototypical examples in the domain to build more elaborate concepts. At Level 3 (“Practice procedures”), the teacher provides opportunities for the students to try out many skills and ideas in a domain to build a procedural understanding of how skills are related and best deployed to solve domain-relevant problems. Finally, at Level 4 (“Integrate knowledge and procedures”), students gradually integrate and apply systematically knowledge across many contexts and situations.

Self-Regulation for Sustainability

The role of self-regulation in character development is of long-standing interest. Aristotle emphasized that virtues are developed with extended practice, effort, and guidance from parents, teachers, and mentors until the child is able to self-maintain virtue (Urmson, 1988). Recent research demonstrates that the most successful learners are those who self-monitor their success and alter strategies when necessary. Thus, self-regulation requires sophisticated metacognition. According to a social cognitive view, self-regulation is a cyclical, ever-changing interaction among personal, behavioral, and environmental factors, involving three phases: forethought, performance or volitional control, and self-reflection (Zimmerman, 2000).

Integrative Ethical Education infuses self-regulation on two levels: the teacher level and the student level. For school reforms to be sustainable, educators must take on a self-regulatory orientation for the implementation of character education. This means taking a systematic intentional approach to building a caring ethical school community, facilitating the development of instructional and ethical skills in all members of the school community, including teachers, administrators, and other staff, as members of a comprehensive learning community.

For students to develop and maintain ethical skills, they must increase their metacognitive understanding,

self-monitoring skills, and self-regulation for ethical and academic development. Individuals can be coached to domain-specific self-efficacy and self-regulation (Zimmerman, Bonner, & Kovach, 2002). In the IEE model, teachers continuously draw student attention to the moral issues immanent in classroom life and learning (Narvaez, 2005b). Students are provided guidance and tools to answer one of the central questions of their lives: Who should I be? As McKinnon (1999, p. 42) points out, individuals must “do the work necessary for constructing a character.” The IEE model helps students develop the skills for ethical behavior but requires their active participation in making the decisions that are crucial and relevant for the construction of their own characters. To develop ethical know-how, one must be self-directive; one must take seriously the charge of continually building one’s character. Ethical know-how must be trained holistically, as a type of expertise, at first coached, then increasingly self-directed.

An Implementation of IEE: The Community Voices and Character Education Project

The Community Voices and Character Education Project (CVCE) was an early prototype of the Integrative Ethical Education conceptual framework. The CVCE was a federally funded project implemented in the state of Minnesota from 1998 to 2002.* It was a collaborative effort among the Minnesota Department of Education (called at the time the Department of Children, Families, and Learning), the University of Minnesota, and educators across the state. The focus of the CVCE project was to develop and provide a research-based framework for character education at the middle school level with teacher-friendly guidelines for how to incorporate ethical development into standards-driven instruction. Classroom activity guidebooks were created along with other supportive materials, including teacher-designed lesson plans.

Reflecting both an empowerment model and the historical and legislative emphasis in Minnesota on local

*U.S. Department of Education Office of Educational Research and Improvement Grant # R215V980001. Copies of CVCE materials on CD are available from the Minnesota Department of Education or from the Center for Ethical Education, University of Notre Dame, 154 Institute for Educational Initiatives, Notre Dame, IN 46556; e-mail: cee@nd.edu; downloadable from <http://cee.nd.edu>.

control of curricular decisions, the CVCE project used a “common morality” (Beauchamp & Childress, 1994) approach of presenting research-based principles (top-down) to a local team who adapted them for the local context (bottom-up), formulating a unique intervention. The top-down recommendations included fostering a caring climate conducive to character growth, using a novice-to-expert approach to ethical skill instruction, developing self-regulatory skills in students as they practice ethical skills, and including parents and community members in cultivating character in students. School teams and their leaders were guided in designing a local vision for character education with specific action steps for how to incorporate ethical skill instruction with links to the community. As Elias et al. (2003) pointed out, all program implementations are limited because they must be adapted to local circumstances. “Too often it is assumed,” they write, “that evidence-based programs can be ‘plugged-in’ and then work effectively” (p. 310). Each team developed a unique approach to cultivating character, using schoolwide projects, advisory/homeroom lessons, and/or infusion into academic instruction into some or all subjects. Some teams incorporated existing character interventions (e.g., Lions Quest) into their CVCE intervention. Indeed, the IEE framework provides a comprehensive approach within which existing character education programs can be integrated, extended, and strengthened.

Evaluation of the Community Voices and Character Education Project

In the final year evaluation, only five of eight experimental schools and one control school provided completed pretest-posttest data. The evaluation had several components that correspond to the emphasis of the project (for a more detailed discussion, see C. Anderson, Narvaez, Bock, Endicott, & Lies, 2003; Narvaez, Bock, Endicott, & Lies, 2004).

The primary focus of the project was to design a conceptual framework for character education at the middle school level along with activity books to guide teams of teachers in incorporating character skill development into standards-driven instruction. Both participating and nonparticipating teachers from partner schools thought the framework was valuable. The majority of respondents reported “easy” or “so-so” for the ease of use of the activity books.

We also evaluated the quality of the implementation. Implementation varied across sites in terms of depth

and breadth. Differences in local implementation design, leadership, and stability of the leadership and of the core team, as well as demands on teachers, led to differences in depth and quality of implementation and how many students were influenced. In only two of the five schools was there full implementation of the model. In these schools, all teachers were involved in teaching ethical skills during advisory/homeroom, in their academic instruction, and in schoolwide projects. In these two schools, significant effects were found in student pre/posttests. The other schools addressed a wide number of skills in a limited manner by only a subset of teachers. Other approaches have required the full participation of the school for implementation (e.g., the Child Development Project) so that the student experience is consistent across teachers; as a pilot program emphasizing local control, CVCE did not.

The substantive evaluation addressed effects on students and school climate. Four student measures of climate were used: staff tolerance, student tolerance, student self-report of climate perceptions and attachment to school, and student perception of peer ethical behavior. One or more general measures of each of the four ethical processes were also used. For ethical sensitivity, we used the Child Development Project’s Concern for Others Scale. For ethical judgment, we used a global moral judgment scale. For ethical focus, we used measures of citizenship, community bonding, and ethical identity. For ethical action, we used a measure of moral assertiveness and prosocial responsibility.

Student survey responses were compared with a matched comparison group ($n = 125$) from another school not involved in the project. Across schools, the findings with the ethical development scales were mixed. Most scales indicated nonsignificant improvements over the comparison group, with one exception. Program students reported more sensitivity to intolerance than did control students. The two schools that fully implemented the program emphasized ethical sensitivity. When contrasted with the comparison group, program students in full-implementation schools reported significant gains on ethical sensitivity. Climate was used as a covariate in a MANOVA with school group as factor (full implementation schools, partial implementation schools, comparison school). For climate, effect sizes were moderate for citizenship and community bonding and small for ethical identity. For school group, effect sizes were small for concern for others, community bonding, and ethical identity. These findings

suggest that climate may mediate the majority of effects of ethical skill instruction.

There were three challenges to finding significant differences in pre/post student assessments. First, leadership changes at three schools undermined the test administration in one way or another so that only five sets of usable pre/post data were extant. Second, given the amount of time required for successful interventions to demonstrate an effect, it was deemed a challenge to find significant pre/post differences within 1 year. Third, one of the strengths of the program—local control and local distinctiveness—meant that cross-site comparisons were not possible, insofar as each site’s implementation was not strictly comparable with those at other sites. Thus, for a particular implementation, the numbers tested were small.

These features of CVCE are relevant also to the question of replicability. Replicability typically refers to successful implementation in more than one school. This definition assumes that what is being implemented is identical across sites. This is contrary to the approach taken in the CVCE project. Instead, the emphasis was on local control and local adaptation of the conceptual framework. Replicability did not refer to identical implementation but instead to the replicability of the process and the general features of the model. Based on the lesson plans teachers created in virtually every subject area, CVCE evaluators determined that teachers were able to integrate character skills development into standards-driven academic instruction. Based on the teacher-created lesson plans and the local team and local leader reports, educators were generally able to implement the model with minimal supervision.

The key features of the model were largely followed by most schools. Most teams viewed character as a set of ethical skills derived from four processes. According to the lesson plans teachers devised, most sites did use a novice-to-expert approach to teach character skills. Most sites at least attempted to involve the community in planning and implementation in one way or another, although outcomes were mixed. It is not clear how empowered the students felt as the university Human Subjects Committee did not give permission to interview student participants.

Lessons Learned

The IEE model provides a conceptual framework for character cultivation that guides educators in how to think about what character entails and how to nurture it

in students. The implementation of IEE in the CVCE project was locally controlled, providing maximum flexibility and allowing for adaptations that met local needs and issues (and that are unforeseeable by a curriculum writer). However, the fact that CVCE did not provide a script for teachers made it necessary for teachers to put in time to modify their lessons to incorporate ethical skill development. With minimal training, teacher teams were able to construct multiple units and lessons. Lessons that a teacher modified himself or herself were lessons that he or she would use again and again. This is an advantage. Nevertheless, sometimes modifying lessons can be a daunting first step in character education, especially for inexperienced teachers. Consequently, a year-long scripted curriculum for homeroom/advisory purposes (currently being piloted) could more easily familiarize teachers with the conceptual framework and scaffold understanding of how to apply the model to classroom activities. Maximum flexibility and local control also made it difficult to measure replicable program effects. A scripted approach will make possible a cleaner estimation of replicable program effects.

ISSUES OF IMPLEMENTATION

Our examination of the IEE case study revealed a number of interesting challenges to successful implementation of a character education intervention. In this section, we summarize some of the enduring implementation issues that have emerged in the various character education literatures and from our own experience.

One enduring problem concerns the fidelity of implementation (Laud & Berkowitz, 1999). In the CVCE project, the quality of implementation was related to disparate outcomes. Schools with a broader (across more classrooms and by more teachers) and deeper (more frequent and focused) implementation were more successful, a finding corroborated by other character development programs (see Solomon et al., 2002). This underscores a point made by Elias et al. (2003) that interventions are rarely delivered as planned, even in trials marked by stringent methodological rigor. And even if the program is implemented and delivered as planned, there are few assurances that it will be received by students as intended. As Elias et al. put it, “If children are inattentive, a classroom is chaotic, or the material is not at the right developmental level, ‘delivery’ by instructors may not strongly predict children’s skill acquisition and use”

(pp. 309–310). Thus, in addition to implementation fidelity, one must also attend to factors that limit student exposure to the intervention (Berkowitz & Bier, 2004a).

In their analysis of implementation and sustainability of social-emotional interventions, Elias et al. (2003) note a number of additional obstacles that are highly relevant to character education. For example, implementation fidelity can be threatened by turnover in teachers and program staff. Characteristics of educators and their roles can support or undermine implementation. Not all roles are equally satisfying, level of commitment varies, and tacit knowledge is not communicated to new staff. As the authors put it, “It is not the same thing to create, to deliver, to administer and to continue” an innovative program (p. 314). Working out role differences and supporting new staff is crucial to sustainable programming. Indeed, “success seems to accompany a spirit of continuous improvement and reinvention without excessive divergence from what exists” (p. 314). In addition, although virtually every approach to character education calls for extensive and active collaboration with family and community, the difficulties in forming, effectively utilizing, and sustaining these partnerships are often underestimated.

Elias et al. (2003) summarize a number of factors associated with successful and sustainable program implementation. Such programs (a) have a program coordinator, preferably with appropriate preparation, or a committee, to oversee implementation; (b) involve committed individuals who have a sense of ownership of the program; (c) have continuous formal and informal training; (d) have varied and engaging instructional materials that map onto goals of the school or district; and (e) have buy-in of key educational leaders and the consistent support of critical constituencies. Elias et al. also suggest that a pragmatic, theoretically informed perspective is essential. “Local ecologies,” they write, “will not support an infinite variety of possibilities. What has a chance to work is what fits” (p. 314). What is required, in other words, is a goodness-of-fit between program planning, its objectives and goals, and its flexible implementation “in the spirit of continuous improvement.”

The reference to the local ecology of schools and to obstacles and opportunities that are endemic to complex organizations draws attention to the culture of schools as an arena for character education. The cultivation of a professional learning community within a school is critical to sustainable school reform efforts (Fullan, 1999, 2000). For example, schools that were successful in rais-

ing student achievement and improving school climate had staffs that developed a professional learning community, addressed student work through assessment, and changed their practice to improve results (Newmann & Wehlage, 1995; Pankake & Moller, 2003). Professional learning communities have particular characteristics. They take the time to develop a shared vision and mutually held values that focus on student learning and foster norms for improving practice. Leadership is democratic, shared among teachers and administrators. The entire staff seeks and shares knowledge, skills, and strategies to improve practice. The school structure supports an environment that is collaborative, trusting, positive, and caring. Peers open their classrooms to the feedback and suggestions of others to improve student achievement and promote individual and community growth. We believe that these same practices are critical to sustain a commitment not only to academic achievement but to moral learning as well, and it is welcome to see a commitment to learning communities in a prominent report on high school character education (Lickona & Davidson, 2004).

We suggest that if character education is to be considered an instance of primary prevention then it should possess the features of any well-designed intervention. It should be comprehensive, have multiple components, address multiple assets at different levels of the ecological setting, and be implemented in the early grades and sustained over time. It is now a truism to remark that one-trial or short-term intervention programs have little lasting impact. Moreover, insofar as dispositional coherence is located at the interaction of persons and context, there is little hope for enduring character education that does not attend also to the climate and culture of classrooms and schools. Effective character education requires a pervasive commitment to change the culture of schools as much as to change the behavior of children.

Payton et al. (2000) note a number of specific features of quality social emotional learning programs. These programs (a) articulate a conceptual framework that guides the selection of program and learning objectives; (b) provide professional development instruction to teachers to enable their effective implementation across the regular academic curriculum; and (c) include well-organized and user-friendly lesson plans with clear objectives and learning activities and assessment tools. Moreover, they note that successful programs take steps to improve schoolwide cooperation and school-family and school-community partnerships.

There is a significant literature on the school characteristics that promote academic achievement. Schools with high achievement are orderly and safe; they are respectful and provide students with moral and personal support while expecting them to achieve (Sebring, 1996). Achieving schools have a strong sense of community and high academic standards (strong norms and high expectations for achievement; Bryk, Lee, & Holland, 1993). Interestingly, the characteristics that foster achievement overlap with characteristics that nurture prosocial development. Schools that foster prosocial development have caring climates that nurture a feeling of belonging and competence in students (M. Watson et al., 1997). In other words, there are not two sets of instructional best practice, one for academic achievement and one for character. Both objectives work out of the same playbook. In this sense, effective character education is, indeed, good education. A recent study in Catholic schools using structural equation modeling showed, for example, that climate influenced directly character development. Moreover, character development mediated the effect of climate on academic motivation more so than climate's direct effect on motivation (Mullen, Turner, & Narvaez, 2005).

This suggests, of course, that effective character education ultimately comes down to what teachers do in their classrooms. The extent to which moral and character education is taught explicitly in teacher preparation programs is not clear. It is well known that teachers who have more expertise in both content and pedagogical content knowledge conduct their classes more effectively than do novice teachers (Berliner, 1994a, 1994b; Shulman, 1987; Sternberg & Horvath, 1995). However, if explicit instructional focus on moral content knowledge and pedagogy is limited or absent during preservice teacher training, then one cannot be optimistic that efforts to expand character education will be met with the requisite levels of teacher expertise.

On the other hand, Carr (1991) argued that if teachers fail in their implementation of moral education it is not because they lack knowledge of curriculum theory or lack pedagogical skills. Indeed, he argues that we do our student teachers in education programs "no great favors by proceeding as though education and learning to teach are matters only of the mastery of certain pedagogical skills, knacks or strategies apt for the successful transmission of value-neutral knowledge or information" (p. 11). Rather, teachers fail because the value questions immanent to teaching are not systematically addressed

in their professional formation. Instead, there is "something approaching a conspiracy of silence among teacher educators on this topic" (p. 10). Carr contends that when teacher education programs do not require "sensible reflection upon the moral character of human life and experience, the nature of values and the ethical aspects of the educationalist's role," then the resulting intellectual vacuum leaves teachers vulnerable to faddism; it leaves them ill-prepared to make transparent the immanence and inevitability of fundamental value questions that attend education, teaching, and learning. Sensible reflection might also point to how preservice teachers are taught to frame the moral significance of daily classroom life. Teacher educators might take direction from Jackson, Boostrom, and Hansen (1993), *The Moral Life of Schools*, when thinking about cultivating awareness among preservice teachers of the immanence and inevitability of morality in the classroom. Jackson et al. (1993), for example, pointed out that teachers who maintain ethical classrooms model a strong moral character and expect students to do the same. These teachers point out the moral aspects of subject matter materials and choose materials based on these characteristics. Moreover, in these classrooms moral discussions become part of the classroom flow, occurring spontaneously in and outside of the classroom. In any case, teacher educators need to complete the task of linking best practice with moral character development, a task started by Williams and Schaps (1999).

OPEN QUESTIONS AND FUTURE DIRECTIONS

We have argued that character education requires a defensible psychological understanding of dispositional coherence and of development and a defensible approach to education that conforms to what is known about effective teaching and learning. We proposed a developmental systems perspective as a conceptual framework for character education and reviewed several categories of youth development and prevention programs that show promise as school-based or community-based interventions.

It is an enduring question, however, whether these programs are rightfully considered instances of character education. We made a distinction between character education as a treatment and character education as an outcome. As our review makes clear, there is very little that is distinctive about traditional character education

that warrants it be considered an educational treatment in its own right. Indeed, when advocates point to character education programs that work, these are programs motivated by an entirely different theoretical agenda than one of morality, virtue, or character. Programs that work are associated with positive youth development or social-emotional learning. Developmental science, including developmental psychopathology and the science of prevention, already provide powerful frameworks for understanding risk, resilience, adaptation, and thriving that has little need for the language of character. On the other hand, if character is considered not a treatment but a set of outcomes, then, of course, there is nothing untoward about claiming the findings of developmental interventions as its own. In this case, interventions that are motivated by developmental science, by perspectives on youth development and SEL, for example, provide outcomes that are relevant to a certain understanding of character and give insights about how to prepare youth for the travails and opportunities of adulthood.

Yet we do not want to give up on the idea that character education can be a distinctive educational intervention. Although the literatures on youth development and social-emotional learning provide an attractive vision of adaptation, thriving, and positive adjustment, and although it is tempting for character educators to want to claim these literatures as their own, we think that this vision of successful adulthood is incomplete without a specification of the moral dimensions of selfhood, identity, and community. The metaphors of thriving and flourishing and positive development point mostly toward the notion of what it means to live well. But living well is only half of the challenge. We must not only live well, but live well *the life that is good for one to live*. Discerning the life that is good for one to live is a moral question; it has profound moral dimensions that are not exhausted by avoiding risks and acquiring social-affective competencies.

Certainly, the life that is good for one to live requires avoidance of significant risk behavior, and so character education embraces the science of prevention as a prophylaxis against risks and deficits. Certainly, the life that is good for one to live requires the cultivation of competencies that prepare one for the challenges of adulthood, and so character education embraces positive youth development in its several forms, along with its slogan: Problem-free is not fully prepared. Yet fully prepared is not morally adept. In our view, character education should aim minimally for full preparation of

young people for adulthood, but should not be content with full preparation for living well; it should aim, too, at helping students cope with the ethical dimensions of the *good* life lived well.

The challenge for character education, then, is how to maintain a distinctive voice in educational innovations, psychosocial interventions, and youth programming. An approach to positive youth development that is also an instance of character education would be marked, in our view, by an explicit conceptual framework that embraces a developmental systems orientation while articulating a moral vision of what it means to flourish. This moral vision is ideally a virtue ethic that articulates a positive conception of moral agency as a deeply relational and communitarian achievement that expresses the nature of our self-identity through our lived moral desires.

Another challenge is to exploit the resources of psychological science in framing a defensible notion of moral agency, self-identity, and dispositional coherence. We have made a number of suggestions along the way for a “psychologized” approach to moral character. In our view, social cognitive theories of personality and the cognitive science literatures on expertise provide useful frameworks for understanding the moral dimensions of personality, although other literatures may be exploited with profit as well. We reiterate our conviction that an adequate character education will require robust models of character psychology, characterized by deep integration with multiple psychological frameworks.

Moreover, a developmental systems orientation broadens our perspective on character and character education. There is a tendency, for example, to regard character education as something that takes place in schools as a formal curriculum. Yet, as we have seen, the foundations of emergent morality and of conscience are evident quite early in childhood, and the developmental dynamic and pattern of socialization in early family life is most assuredly a kind of character education that will be of interest to researchers for some time to come. What’s more, a developmental systems perspective bids us to examine the possibilities of dynamic change in character psychology throughout the life course and within the multiple life worlds of the individual beyond family and schooling in areas such as leisure activities and peer relations. Perhaps a life course perspective on character will require additional constructs, such as wisdom (Staudinger & Pasupathi, 2003; R. J. Sternberg, 1998), purpose (Damon, Menon, & Bronk, 2003), personal goals (Emmons, 2002), spirituality and self-

transcendence (Seligman & Csikszentmihalyi, 2000), ecological citizenship (Clayton & Opatow, 2003), and character strengths (Peterson & Seligman, 2004), to capture adequately the complexity of phase-relevant dispositional coherence and human flourishing.

The term “learning environments” is used in many fields, including education, architecture, and psychology. Although definitions vary, most agree that learning environments encompass the learner, the context, and the content of tasks. The concept of learning environments in education has become more prevalent as theories of learning have evolved (Bransford, Brown, & Cocking, 2000; De Corte, Verschaffel, Entwistle, & van Merriënboer, 2003; Jonassen & Land, 2000; Schauble & Glaser, 1996). Recent theories emphasize that understanding results from active construction by the learner.

One type of learning environment, based on cognitive psychology, focuses on helping students accomplish tasks and engage in specific thinking processes. Information-processing theories explore how learners remember information, relate new information to prior knowledge to build schemas that organize ideas, and develop understanding. The breadth and depth of schemas determine whether the learner is able to apply ideas to new problems. Learning environments of this type often stem from research on differences in expert-novice thinking and often provide tutoring and guidance in the use of strategies and thinking processes typical of experts.

A second type of environment is based on ideas about social contexts and practices, focusing on activities,

skills, and discourse used in those contexts. These ideas were discussed by Dewey (1938) and Vygotsky (1978) and more recently by American researchers who have used Vygotsky’s theoretical approach. Environments developed along these lines include tasks that are typical of those used in the disciplines, instructional scaffolding by more knowledgeable others, tool use that supports learning, and development of learning communities that engage in practices representative of the subject area under study. A frequent goal of these learning environments is to create intentional or adaptive learners (e.g., Bereiter & Scardamalia, 1989).

The success of learning environments in achieving their goals depends on the experience and knowledge of learners, the knowledge of the teacher, the design of tasks, and the nature of community that is developed. Consider inquiry as an example. Inquiry is a central learning activity for many subject matter-based learning environments. To promote construction of understanding, teachers help students raise questions, decide on information or experiments needed to answer those questions, collect and interpret the information, and draw conclusions. This type of activity differs from those in more traditional instructional approaches. It changes the role of the teacher from information delivery to scaffolder. That is, it requires that teachers scaffold

activities so that students understand how to think about them as well as gain the procedural knowledge of how to do them. It requires that teachers help students to collaborate and form a community, to take risks, and to recognize that some questions do not have one right answer.

In this chapter, we describe learning environments that reflect the information processing and social cognitive approaches to learning environments. We begin by presenting selection criteria for the learning environments we discuss. In the first section, we present a unifying scheme to characterize programs, describing several learning environments according to the scheme. The purpose is to illustrate the range of learning environments and the similarities and differences in features they contain and what they emphasize. The second section addresses how learning environments are designed, implemented, and refined. We highlight the interplay of theory and practice in this process. The third section discusses what happens and what needs to be considered as learning environments are scaled. It is often the case that learning environments are developed and revised based on experiences in a few classrooms. When more teachers, children, and settings are involved, issues arise that were not initially problematic. These can affect whether learning environments need to be redesigned and whether they are successful. The fourth section contains a summary and conclusions about what we have learned about designing, implementing, and scaling learning environments and offers suggestions for future work.

SELECTION CRITERIA

Four criteria guide our selection of learning environments for our discussion. We primarily focus on classroom learning environments that are theoretically based. We also include some environments designed for use in afterschool programs. Our search for programs was not exhaustive. Our list includes a range of programs that exemplify the characteristics needed to describe learning environments and advance theoretical development and empirical research. The criteria* are:

* An example of a learning environment that is widespread but would not fit these criteria is the JASON project. This widely disseminated program draws on popular topics and creates packages of material for students and teachers, often including technology. But its design is not explicitly based on a learning theory. Other popular programs are designed to provide simulation experiences, such as a model United Nations, simulating

1. *Explicit academic learning goals*: Many learning environments are designed to engage students in interesting activities but have vague academic learning goals. We include only those that have specifically identified and assessed subject matter learning goals. These are likely to be the most informative in considering issues of design, implementation and scaling of learning environments. They also are the most likely to meet the other criteria.
2. *Ambitious scope*: By this we mean a learning environment designed to address academic material in either breadth or depth. Many learning environments in education are aligned with national subject matter standards or frameworks recommended by professional organizations. Programs tied to national standards or frameworks are preferred.
3. *Highly specified and developed materials*: Drawing on descriptions of innovations proposed by D. K. Cohen and Ball (1999), we include learning environments that are highly specified and developed. Highly specified programs have clear theoretical backgrounds, design principles based on research and theory, and guidelines for enactment. Highly developed programs have materials for teachers and students to use, such as student workbooks and readers, assessments, teacher manuals, and professional development materials that exemplify desired enactments. Programs can be highly specified but not highly developed, thereby leaving a considerable opportunity for customization to local contexts, but also running the risk of enactments that stray considerably from the theoretical principles. Similarly, materials can be highly developed but have little theoretical specification, such as commonly used textbooks for teachers and students.
4. *Published research*: Reports on the program and its outcomes are necessary for inclusion. Learning environments that do not include reviewed research may

a meeting of the Organization of American States, or arguing a case in Moot Court. These are what we consider grassroots programs that can serve as useful examples of what to include in learning environments. Often popular and used in many settings, they nevertheless are not designed to link to specific educational standards, have limited scope (even though they consider important topics), are not specifically based on a theory of learning or environment, and, although they provide valuable learning experiences, they vary considerably in the types and rigor of assessment of learning outcomes.

be popular but are not likely to yield theoretical or practical insights necessary to advance knowledge by informing theory, design principles, or practice recommendations.

Table 8.1 lists learning environments that match our selection criteria. This is a purposeful sampling to illustrate the wide range of programs that match. The programs are clustered according to whether they have a disciplinary content focus, knowledge-building emphasis, or an extracurricular learning focus. Each program is accompanied by a brief description and a Web site link. We refer to many of these programs as examples throughout the remaining sections.

FEATURES AND DESCRIPTIONS OF LEARNING ENVIRONMENTS

This section describes selected learning environments based on the four criteria. The programs vary by age of students, subject matter, and goals. Many of the more recently developed learning environments include technology, such as personal computers or Web-based communication tools, either as a primary focus or as an important component. We sample from such programs where there is a strong theory and research base because they are powerful ways to extend learning environments beyond the classroom.

Features of Learning Environments

Table 8.2 (p. 302) presents a framework for examining features of learning environments. We use the features to describe three learning environments that represent both information processing and social cognitive theory. Finally, we present a chart based on the features that characterizes and compares several widely used learning environments. Our point is to illustrate commonality and variety in the design of learning environments. Descriptions of programs in this section contrast environments designed around information-processing approaches and social cognitive approaches to learning.

There are many different ways to describe learning environments. For instance, a tetrahedral model originally developed by Jenkins (1979) and modified by A. L. Brown and colleagues (A. L. Brown, Bransford, Ferrara, & Campione, 1983), presents a framework for examining aspects of learning environments. The Jenkins model, as modified

by A. L. Brown et al., identifies four factors that interact within a learning setting: (1) learning activities, (2) characteristics of the learners, (3) nature of the content to be learned, and (4) the end products or goals of the learning setting. These factors are interdependent: A change in one will influence the impact of others. Another framework, more recently developed by Paavola, Lipponen, and Hakkarainen (2004) examine the models of learning that underlie learning environments. In their approach, they focus on the processes of knowledge creation to explore how learning environments are organized. Quite differently, De Kock, Slegers, and Voeten (2004) examine learning environments around learning goals, teacher and learner roles, and the roles of learners in relation to one another. They consider these to be basic aspects of learning environments that influence student performance and learning. They suggest that these three aspects of the learning environment can provide a classification scheme for designing and evaluating learning environments in secondary education. A framework proposed in *How People Learn* (Bransford, Brown, & Cocking, 2000) provides a set of four design characteristics that can be used to analyze the quality of learning environments. The framework takes into account the degree to which learning environments are knowledge-centered, learner-centered, assessment-centered, and community-centered.

Our framework attempts to provide greater detail about features of learning environments that are important to consider in design and evaluation. Learning environments can be described by the goals, the types of tasks and instructional materials used to reach the goals, the role of the teacher, and how learning is assessed. Technology also may be a central feature. Learning environments encompass different types or combinations of types of social organization. In the design of learning environments, these features are presumed to be interdependent; they work together to affect outcomes. The goals and instantiations of each feature derive from underlying theoretical ideas about learning.

Goals

The goals of learning environments can be academic, social, metacognitive, and developmental; particular learning environments might encompass all four types or only one or two. Academic goals of recently designed classroom-based learning environments tend to focus on standards-based frameworks following recommendations from professional organizations. The National Research Council (NRC; 1996) and the American Association for the Advancement of Science (1993) have disseminated

science standards; the National Council of Teachers of Mathematics (1989, 1991, 2000) has prepared standards for mathematics teaching. Similarly, history standards have been developed by the National Center for History in the Schools (1996) and the National Council for the Social Studies (1994). Although the standards advocated by professional organizations may be consistent with federal No Child Left Behind legislation, the professional standards are guidelines and are not tied specifically to high-stakes assessment. They might be consistent with standards adopted by states and local education authorities, but they are not mandated by local school districts or states. Academic goals focus on learning particular subject matter content. They also entail learning about disciplinary practices and norms such as what constitutes evidence, how conclusions are drawn, how ideas are communicated, how progress in knowledge is made, and how change in knowledge frameworks occur. For instance, student learning about the nature of science might include how science progresses, the role and design of inquiry, and acceptable methods of interpretations.

Goals can also be social, such as the interpersonal goal of learning to work cooperatively. Motivational goals entail improving attitudes and promoting interest, thereby enhancing students' desire to learn and willingness to exert effort to do so. Communicative goals stem from epistemic frameworks of knowledge in disciplines. They focus on accuracy and use of language as it is practiced in the discipline. Within the discipline of history, examples are students who present information in a historically correct manner, using terms and making arguments and explanations as historians would. These communication capabilities can be part of classroom discourse or embedded in artifacts like reports, models, or visual representations.

A third type of goal addresses the promotion of a disposition for thinking and reasoning: mental habits such as persistence and posing questions that support self-directed or self-regulated learning (Costa & Kallick, 2000). Some habits of mind relate to skills in the discipline; others are more global and considered necessary to become a lifelong intentional learner. They can be

TABLE 8.2 Framework for Examining Features of Learning Environments

| Goals | Tasks | Instructional Materials | Social Organization | Teacher | Technology | Assessment |
|---------------------------------|------------------------------|--------------------------------------|-------------------------------------|---------------------------|---|-------------------------|
| <i>Academic</i> | <i>Content</i> | <i>Theoretical Explicitness</i> | <i>Structure</i> | <i>Responsibility</i> | <i>Tools</i> | <i>Types</i> |

metacognitive, such as promoting students' proficiency in the use of learning and self-regulatory strategies. The latter involves planning, monitoring progress, and revising approaches where necessary as well as maintaining concentration. Sometimes habits of mind goals focus on creating adaptive and intentional learners who identify what needs to be learned, are thoughtful and effective in deciding how to accomplish their ends, and use strategies proficiently in the service of their aims (Bereiter & Scardamalia, 1989, 2003).

A fourth type of goal is developmental. Most learning environments are not designed for students of multiple ages. They typically focus on subject matter teaching for one age group, such as late elementary, middle, or high school students. Learning environments attempt to move students forward in terms of their levels of knowledge and in their mirroring of expert thinking, problem solving, and use of discipline-based practice. To do so, they draw on research about learning in the subject areas, student misconceptions, and developmental differences in information processing and use of learning strategies. An example of such an environment is a problem-centered math program for middle school students, *Connected Mathematics*. This program draws from contemporary research on teaching and learning in this subject area, as well as national mathematics standards (Lappan & Phillips, 1998; Lappan, Fey, Fitzgerald, Friel, & Phillips, 2002).

Developers of learning environments are less explicit in identifying social development as part of design principles. Nevertheless, many designs have features that are compatible with what Eccles and Midgley (1989) describe as classroom-based, age-stage environmental fit. Most feature collaboration with others, meaningful problems, active learning, and varying degrees of student responsibility and choice.

Tasks

Tasks are what students do to learn subject matter content and practices. Tasks include the content, the level of complexity of the material to be learned, and the openness of how the task can be accomplished. Learning environments usually feature tasks that are conceptually and procedurally complex. They require students to use learning strategies to remember and organize material and metacognitive strategies to plan a course of action and evaluate results. They often ask students to solve problems or design artifacts with unprescribed routes to solution and with several or even unlimited answers. For

instance, in the science program *Learning by Design* (LBD; Kolodner, Camp, et al., 2003), students learn about force and motion by designing and building miniature vehicles and their propulsion systems. The collection of tasks in a learning environment may include only one discipline or combine several subject areas, such as mathematics and science or history and language arts. They may require students to engage in research to answer questions by doing experiments, conducting surveys in their community, or consulting primary or secondary sources through library or Web-based searches.

The sequence of tasks and topics in a learning environment can vary from tightly specified to very open. The former is likely to be part of programs that highlight the acquisition of well-defined and specific academic content or skills. For instance, skill acquisition models are usually sequential and hierarchical, designed to move learners to higher levels of expertise. The American Association for the Advancement of Science (2001) has published specific strand maps of science concepts and process skills for primary through secondary grades that underlie science programs that match their standards. Similarly, intelligent software programs like Carnegie Learning's *Geometry Tutor* are sequenced so that students learn to solve progressively more difficult problems. On the other hand, the sequence of content, lessons, or experiences may not be as tightly prescribed in some learning environments. Instead, students might explore different topics at different times, such as working on different projects in an online environment for learning, like the *Web-based Integrated Science Environment* (WISE; Linn, Davis, & Bell, 2004).

Tasks can vary in degree of authenticity. Newmann and Wehlage (1993) define authentic tasks as those that mirror tasks found in the discipline to some extent, require transformation of information, and have meaning beyond the classroom. Tasks may reflect real-world experiences of students, such as their community's air quality, or they may involve topics of potential interest with which students have had no direct experience, such as space travel or dinosaurs. They also may be designed to reflect the work of professionals in a discipline. For example, students might develop historical interpretations of reasons for population migration to northern cities during the first half of the twentieth century, or they might mirror how engineers create designs that solve problems of how to better insulate homes or construct tall buildings.

Content and skills to be learned may be contextualized within a problem or question. For instance, students

in LBD are asked to solve design-and-build challenges that involve constructing working devices or models to illustrate science concepts; students in project-based science classrooms are asked to answer such questions as How can good friends make me sick? Similarly, mathematical problem-solving skills are anchored in a videodisc series of more complex adventures of a character named Jasper (Cognition and Technology Group at Vanderbilt, 1997). Tasks also may be designed to reflect disciplinary concepts such as exploring the principles of force and motion or genetics.

Students' artifacts usually are designed to represent their learning. The process of their creation fosters construction of knowledge; for instance, when students create models, they need to decide on what to include, what relationships to illustrate, how to explain reasons for what they have done and what their model shows. In some programs, creation of the artifact is the central feature that drives learning. In LBD, students go through cycles of design as they solve problems; revision of designs should reflect greater understanding of underlying concepts they have studied. Artifacts such as models and designs can be considered open or not predetermined. In contrast, artifacts that demonstrate solution of a math problem can be considered more closed, although there may be various routes to the solution.

Instructional Materials

Materials provided by designers of learning environments range in their level of theoretical explicitness, detail for enactment, and resources provided for teachers and students. Programs chosen for inclusion in this chapter are based on theoretically explicit principles derived from either cognitive or sociocognitive perspectives. These programs are highly specified, but vary in their degree of development. That is, they include a range of examples, materials, and resources for teachers and students to put the ideas into practice.

Most of the programs included are fairly well developed. They usually include professional development in their efforts. The materials provided, however, may vary in how explicitly the principles underlying the program are linked to suggestions for enactment. They also vary in the types of teacher and student material provided to make the program readily usable. Some programs provide curriculum guides with suggestions for enactment and for evaluation along with information about the rationale for the activities and educative materials that help teachers with their own understanding of content

and student learning. Other programs provide suggestions but have many fewer examples of how to enact these suggestions, such as strategies for scaffolding student learning or for building communities of learners. Still others provide reading materials, problems to solve, and suggestions for students to follow when conducting inquiry via information or data gathering. Others also provide software to aid in knowledge construction. When materials are not extensively developed and teachers play a central role in carrying out the learning environment, teachers need to have a greater range and depth of expertise to successfully meet the goals envisioned by designers of the learning environment. This point is discussed more fully in the section on teachers.

Social Organization

A community of practice describes a situation where people are engaged in a collective process of learning that produces common norms, practices, and frameworks for knowledge (Lave & Wenger, 1991; Wenger, 1998). Over time, they develop a common sense of purpose and shared understandings. The communities may have one or several foci. The understandings can involve professional practices such as how problems are framed and solved. The solutions entail processes such as how evidence is collected, what counts as evidence, and how evidence is interpreted or solutions justified. Discourse, how members of a discipline communicate, is another aspect of community that often is emphasized in learning environments. Here students report findings and interpretations in language that mirrors those of the subject area. The discourse emphasizes the difference between everyday language and styles and the more formal ones of the subject matter areas. Language and patterns of social interaction and debate shape meaning making and help students understand how knowledge is built and verified in the discipline (A. L. Brown, Metz, & Campione, 1996; Rogoff, 1995). For instance, in Guided Inquiry supporting Multiple Literacies (GIsML), an approach to science instruction developed by Palincsar and Magnusson (2001; Magnusson & Palincsar, 1995), the learning environment is designed around the notion of community. A tenet of GIsML instruction is that science classrooms are communities that should reflect key elements of the culture of science. In GIsML classrooms, teachers and students engage in a collective process of learning that produces shared understandings of scientific ideas and practices. Science learning involves becoming socialized into the practices of science, such as using the discourse tools of

talking, listening, reading, and writing. Language, then, is considered central and necessary for constructing scientific understanding.

Some learning environments are less formal in their focus on disciplinary practice and discourse. They stress intentional learning that is fostered by developing group knowledge about a topic through asking questions, information gathering, debating, critiquing, and synthesizing. For instance, in A. L. Brown and Campione's (1994, 1998) *Fostering Communities of Learners*, students select a topic of interest, break into cooperative jigsaw groups, and share with peers who have collected other information. Together they synthesize the information and apply the principles derived to solve problems or pursue further questions. Similar interactions are promoted by the Computer-Supported Intentional Learning Environments (CSILE; Scardamalia & Bereiter, 1991). The environment provides a community space that supports collaborative inquiry through information searching and sharing for the purpose of knowledge building. The class explores a common topic and posts information and comments about the information on the multimedia community knowledge space.

Learning environments often are linked to communities that extend beyond the classroom in various ways. Some encourage community participation, such as drawing on "funds of knowledge" (Moll, Amanti, Neff, & Gonzalez, 1992) to bring skills, knowledge, and experiences related to student background to bear on subject matter. Some attempt to bridge in- and out-of-school discourse and ways of knowing (Lee, 2002; Moje, Collazo, Carrillo, & Marx, 2001) by drawing on commonly held beliefs and contrasting these with how experts in the discipline might study and explain a phenomenon. Community engagement is encouraged as students survey communities and present findings to audiences in the community, such as local interest groups and students in other classes or in other schools via Web-based publication. Technology-based learning environments, such as *Kids as Global Scientists* (Songer, 1996) and WISE, often connect students with graduate students or scientists via telecommunication; students share data, ask questions about findings or interpretations, or get feedback on their artifacts. Students often collaborate with other students across school sites to collect, share, and interpret data.

Teacher

Teacher responsibility in learning environments varies with respect to topic selection, task design, and assess-

ment. Some programs have built-in topics and instructional sequences, whereas in others teachers can choose from a list of designated topics and set their own sequence. Some include a combination of both. For instance, in GIsML, teachers use a heuristic to design their own approach to suggested topics. The heuristic conceptualizes instruction in guided inquiry science as a series of cycles of investigation involving engagement, investigation, and reporting. Teachers play a central role in orchestrating instruction by guiding students through cycles at an appropriate pace and ensuring that students develop scientific knowledge and reasoning. WISE provides a library of inquiry projects for which materials, including lesson plans, have been developed. WISE teachers can use the projects as stand-alone science units or integrate them into their existing curricula.

Few, if any, programs leave task design solely to teachers. Some come with intelligent instructional software that provides specific hierarchical tasks and guides student learning, such as *Cognitive Tutors* (Alevan & Koedinger, 2002) and the computer-based reading environment *Literacy Innovation That Speech Technology Enables* (LISTEN; Mostow & Aist, 2001; Mostow & Beck, in press). Other programs, such as *Project Based Science* (PBS), offer comprehensive materials for teachers that include suggested tasks but assume that teachers will adapt them to local conditions. The key is that the adaptations made by teachers are congruent with the underlying principles on which the learning environments are designed.

All programs include assessments for evaluating student understanding. They differ in how much the teacher is encouraged to use classroom-based assessments to inform instruction. Some programs include pretests and posttests. Several programs also encourage teachers to create their own assessments; for instance, they may provide guidelines for how students might create a multimedia presentation to showcase learning. Many programs also encourage evaluation of artifacts and provide rubrics for doing so. Other programs contain built-in assessments that determine whether students can progress to higher-level activities. For instance, in the after-school program *Fifth Dimension* (K. Brown & Cole, 2002; Cole, 1995), children must achieve goals specified on task cards before moving to the next level of activities. Most of the activities use educational software and computer games that emphasize problem-solving and literacy skills across a range of content areas, including math, language arts, social studies, science,

technology, and fine arts. Task cards accompany each activity and help children get started, specify expected achievements, and provide information for obtaining a credential as an expert in the Fifth Dimension. Similarly, students cannot progress in Cognitive Tutors unless they reach a certain degree of proficiency in solving math problems at their current level.

The role of the teacher varies considerably. In some environments, the teacher's position in enacting the learning environment is central to helping students meet their goals. For instance, instructional efforts by the teacher to scaffold student learning, diagnose difficulties, and assess understanding is an important part of making WISE work. In Connected Mathematics, the teacher works closely with students to help them make sense of the problems under study. In contrast, guiding student understanding is less critical in Cognitive Tutors and LISTEN, where the technology provides a high level of guidance and is the major influence on student learning.

The more teachers have responsibility for topic selection and design, the greater the range of competencies they must have to make learning environments work. Subject matter knowledge refers to the understanding of the key ideas, the connection among ideas, disciplinary practices, and the nature of the discipline. Some environments, such as Cognitive Tutors, are based on a careful analysis of learning so that the teacher does not need to have as deep an understanding of subject matter as in a program like CSILE or Fostering Communities of Learners. In the case of knowledge-building programs like CSILE, teachers must be able to select topics, understand key ideas, and assess understanding based on their own expertise.

Curricular knowledge refers to how to design and sequence tasks. Some programs, such as WISE, are designed to supplement the curriculum so that teachers must decide how to best incorporate Web-based inquiry into their existing curricular structure in a manner that enhances what already exists. Other programs, such as PBS, are designed to replace existing units within a curriculum; a teacher needs to determine what the learning environment affords, the new unit's benefits, and whether it fits well with other aspects of the curriculum to determine whether to make a substitution.

Knowledge of students refers to teachers' ability to draw on student prior knowledge and skills, student experiences, and student motivation as the basis for content representation and diagnosis of student understanding. As in the other areas of competence, the more the teacher

is central to content representation—providing examples, activities, evaluations—the greater the degree of knowledge of students the teacher must have.

Pedagogical expertise refers to knowledge of different types of instructional formats: discussion, small group work, or demonstrations and how to carry them out. In learning environments, the pedagogy also includes how to enact these instructional formats and support student learning in a manner that is warranted, given the premises underlying program design. For instance, in Connected Mathematics, teachers need to be able to support group problem solving; in GIsML, teachers need to actively guide students through an inquiry cycle; in WISE, teachers scaffold students' Web searches; in CSILE, the teacher has to understand and carry out the knowledge-building process according to how it is conceptualized by the Knowledge Forum and create a community of learners while doing so.

Technology expertise, including knowledge of how to use and maintain the technology (troubleshooting) and how to use the technology as a learning tool for students, is critical in some learning environments. Those that use highly structured technology programs where the teacher is not central require somewhat less expertise about using the technology as a learning tool, yet still require the teacher to be a skilled troubleshooter. Other technology-based programs, such as WISE, Kids as Global Scientists, BGuILE, and GEODE, require considerable expertise in helping students exploit the benefits of the technology to support thinking.

Technology

Learning environments utilize a variety of technologies for a range of purposes. Participants in many innovative learning environments are actively involved in information gathering, such as searching on the Internet, information sharing by means of e-mail or instant messaging, and using simulations to generate information for further study, data modeling to aid in information assimilation, and information representation tools like visualization software. For example, students interacting with ThinkerTools software (White, 1993) learn about basic principles of physics through direct interaction with simulations of force and motion phenomena. Online learning environments and workspaces, such as WISE and CSILE, provide custom-designed software tools to support students' knowledge building and knowledge integration. These types of environments are often designed to foster collaboration. CSILE provides a communal

database and Web-based communication tools; WISE has interfaces to support collaboration around the technology and via the technology. Other computer-based environments are designed for individual work. Cognitive Tutor software assigns problems to students on an individual basis, monitors students' solution steps, and provides feedback and hints. LISTEN software displays stories on a computer screen and provides individual assistance as children read aloud.

Computer-based environments such as Cognitive Tutors and LISTEN have technology as the core of the learning environment. Although other components may augment the technology in these programs, the technology is the main delivery system for instruction. For instance, in Cognitive Tutors, group problem-solving tasks and discussions are meant to support or reinforce the learning targeted by the instructional software. Whereas some computer-based environments may contain all of the content, others, like CSILE and WISE, help to organize learning by scaffolding individual or group research processes. Still other programs may use a variety of technologies, but these are not the key elements of the environment. In Connected Mathematics, LBD, and Project Based Science, technology tools are intended to leverage learning within the environment. For example, in Project Based Science, technology is utilized to support students as they create artifacts of their learning, such as using handheld computers to create concepts maps.

Assessment

Most learning environments include or recommend several types of assessments to evaluate participants' learning, although some types are more critical than others. Individual and group portfolios, student reports and presentations, and pretests and posttests are characteristic of many programs. In some, the design and evaluation of artifacts is central. In an LBD physical science unit, for instance, students design and build miniature vehicles. As students go through the design process, they move back and forth between cycles of design and redesign as they design, build, and test miniature vehicles that can travel over varied surfaces (Kolodner, Camp, et al., 2003).

Discipline-based programs focus on all or some of the following targets: content knowledge, reasoning skills, and the nature of the discipline. Those that are more general might include content assessments and also dispositions to learning such as intentionality in posing

questions and seeking information to answer those questions. Some programs also assess motivation in terms of student interest, feelings of efficacy, and use of learning strategies.

Program Descriptions

We describe three programs to illustrate variations in how designers emphasize and instantiate features. The descriptions include discussion of features that are central to the learning environment depicted; therefore, not all features are included in an individual program description even though they may operate in the program. For instance, many programs include collaboration among students as they discuss ideas or conduct investigations. However, some programs are specifically designed to foster collaboration, such as Knowledge Forum and Kids as Global Scientists. Similarly, some programs include artifact creation as a critical element in evaluating student learning; others rely on more conventional assessments even though students do produce artifacts such as reports.

Project-Based Science

Project-based learning is an approach that has been popular since Dewey. In the 1980s, TERC (www.terc.edu) developed a project curriculum that incorporated new telecommunication technology. It posed questions about environmental topics like air quality and trash decomposition, and students did experiments, collected data, and shared results with their counterparts in other locations.

More recently, the University of Michigan and the Detroit Public Schools have worked collaboratively to design project-based learning environments tied to social constructivist principles. The projects last from 6 to 8 weeks and are an integral part of the middle school science curriculum; project content is selected to meet national science standards proposed by the American Association for the Advancement of Science (1993) and the NRC (1996), as well as district and state science objectives, which are compatible with national standards.

The essential components of project-based science are that it (a) uses a "driving" question that encompasses science content and activities; (b) results in a series of artifacts, or products, that address the question; (c) allows students to engage in authentic investigations; (d) involves collaboration among students and teachers; and (e) supports knowledge construction through use of

learning technologies (for more detailed description of the components, see Krajcik & Blumenfeld, in press; Singer, Marx, Krajcik, & Chambers, 2000).

Goals. The standards emphasize the need for students to investigate the everyday world. Engaging in inquiry is presumed to help students learn science content and science processes and to experience the academic framework within which scientists work. Student understanding derives from the need for students to plan investigations, collect and analyze data, keep track of the process, and evaluate their findings in light of the aim of the experiment and their own methods. Critical thinking and problem solving are necessary as students interpret data, consider discrepancies between their predictions and findings as well as discrepancies between their findings and the findings of others, and discuss and debate possible reasons why discrepancies exist. These opportunities also help students to understand the nature of science, such as how questions are generated and investigated, what counts as evidence, how scientists interpret and report results, and how ideas are advanced in science.

Improvement in students' ability to use scientific forms of communication is accomplished by highlighting how scientific language, discourses, and writing genres differ from the technical discourses of other content areas and from everyday discourse. Students have opportunities to explain their ideas about scientific phenomena in oral and written form. The experience of inquiry in the service of studying questions relevant to students' lives is assumed to contribute to students' attitudes toward and valuing of science and to influence their decisions to take more science courses.

Tasks. A driving question serves to organize science content and tasks. Sample questions for projects include "What is the quality of air in my community?" (chemistry); "Can good friends make me sick?" (biology); and "Why do I have to wear a helmet when I ride my bike?" (physics). As students pursue solutions to the driving question, they develop meaningful understanding of key scientific concepts.

Good questions are related to the real world and reflect important aspects of students' daily lives. They are selected to be scientifically worthwhile, to contain rich science content that reflects standards, and to be feasible in that students can design and perform investigations in classrooms to answer the question. Questions

also must be broad enough to generate smaller questions that students can raise and address depending on their interests. Although the projects highlight one area of science, to answer the question students might use concepts from different areas. They also employ math and literacy skills as they compute results, graph data, and write reports.

Projects are sequenced within grade levels. A greater level of scaffolding for science processes and for technology use is provided earlier in the year. For example, initial projects might contain benchmark lessons helping students learn to make explanations by stating a claim, citing supporting evidence, and linking the evidence to a conclusion that supports the claim. Supports are faded as students become more proficient in engaging in inquiry and using learning tools. Projects are also sequenced by grade level. Driving questions for each year of middle school are designed to encompass content that is identified by national, state, and/or local standards for that grade. However, teachers might also use projects regardless of sequence, which might be necessary based on circumstances, school calendars, and individual school policy.

In addition to the real-world nature of the driving question, PBS contextualizes learning in several ways. Students experience phenomena by conducting observations and collecting data in their neighborhoods, such as taking measurements of water quality of a nearby stream or collecting indices of air pollution during a neighborhood walk. These activities draw on students' prior knowledge and experience and serve as anchoring events that are referred to throughout the project. For instance, teachers use a driving question board that includes data collected from these activities; they add information relevant to answering the driving question as the project progresses.

Students produce artifacts, or products, that represent their learning. The artifacts reflect emergent states of knowledge and understanding about solutions to the driving question. The artifacts are cognitively complex and are relatively open. For instance, students create models where they must decide on variables to include, relationships among the variables, and explanations for their choices. Students create concept maps to illustrate relationships among key constructs. They prepare presentations that are attended by community members and other teachers and classes. They write books that address the driving question to share with younger students. Because artifacts are concrete and explicit (e.g., a

physical model, report, videotape, or computer program), they can be shared and critiqued. This allows others (students, teachers, parents, and members of the community) to provide feedback and permits learners to reflect on and extend their emergent knowledge and revise their artifacts. The creation and sharing of artifacts makes doing project-based science more like doing real science and mirrors the work of scientists.

Technology. PBS makes extensive use of learning tools (Krajcik, Blumenfeld, Marx, & Soloway, 2000) that are integrated into the curriculum. They are used to support the learning goals of the curriculum, rather than the curriculum's being built to capitalize on the technology's affordances.

Using concepts from learner-centered software design (Quintana et al., 2004; Soloway, Guzdial, & Hay, 1994), each tool has been designed to take into consideration the unique characteristics of novice learners. Such tools have specially designed supports that help students complete inquiry tasks they normally would not be able to complete. For example, Model-It illustrates principles of learner-centered design by representing information in a way that is familiar to learners but also helps to introduce them to more professional or symbolic representations (Jackson, Krajcik, & Soloway, 2000). Students select variables, indicate relationships among them, and then test their models. Similarly, students engage in Web searches using Artemis, a tool designed to help students keep track of what they have found and what is useful. Librarians select Web content to increase the likelihood that middle schoolers will find material relevant to their project and with an eye toward appropriate levels of reading comprehension. To improve access, recent technology includes handheld computers, so that all students can have frequent and immediate access to their own technology tools. These are used in conjunction with desktop computers located in classrooms and computer labs. Software for handhelds allows students to draw representations, share artifacts, store information, and write explanations.

Learning tools expand the range of questions that students can investigate, the types of data and information that can be collected, and the types of data representations that can be displayed to aid interpretation. The tools are used across several curriculum projects and years, so that students become familiar with them and can benefit from repeated use (Krajcik et al., 2000; Wu, Krajcik, & Soloway, 2001). Students can work individu-

ally or collaboratively. When using desktop computers, students usually work collaboratively because of the limited number of machines; handhelds, which are less costly and thereby more plentiful, allow for ubiquitous individual work.

Teacher. The teacher plays a central role in the enactment of PBS. Teachers must have considerable knowledge of the curriculum because they must make adaptations to fit their circumstances in ways that are congruent with underlying principles. Knowledge of the content and of how students learn it is essential because teachers provide crucial benchmark lessons about science content and processes that prepare students for inquiry. Teachers also must be familiar with the technology and be able to capitalize on its potential as a learning tool for students. All of this requires support for student learning; thus, early in the term, teachers do a considerable amount of scaffolding. They model thinking, structure tasks by preparing lists of criteria that students can use to evaluate whether the research questions they choose are valuable and feasible, and distribute charts to help students organize data collection and data analysis. Later, students are expected to be able to carry out procedures or produce artifacts with less help.

Assessment. Assessment of learning in individual projects is based on a combination of student artifacts, project specific pre- and posttest scores, and content interviews with a sample of students. The tests contain both closed and open-ended questions that range from low to high levels of cognitive difficulty. That is, students respond to questions about facts and also to scenarios that ask them to apply their knowledge to a new situation (Marx et al., 2004). Scores on statewide tests are used to determine how students who have participated in PBS curriculum compare with their counterparts who have engaged in other district-supported standard-based science instruction efforts (Geier et al., 2004).

In addition to measures of students' learning, a range of perception and motivation constructs are assessed. Student perceptions of the classroom environment (e.g., real-world nature of the question, opportunities for collaboration, and teachers' press for understanding) and its influence on attitudes toward science and technology and motivation to learn and self-regulation (e.g., use of learning and metacognitive strategies) are explored using a combination of surveys and interviews (Blumenfeld, Soloway, Krajcik, & Marx, 2004).

Instructional Materials. As D. K. Cohen and Ball (1999) recommend, the curricula and materials we designed for PBS are highly specified (the theoretical principles and methods are clearly defined) and developed (materials for teachers and learners are available and usable). The materials, developed collaboratively by science educators, scientists, and classroom teachers, contain extensive information about each lesson in the project along with reading selections, handouts, and worksheets. In addition, educative materials for teachers focus on content and content representation, potential problems with student understanding, and suggestions for management to avoid potential enactment problems (Davis & Krajcik, 2005; Schneider & Krajcik, 2002).

Professional development is tailored to helping teachers enact the curriculum. Instructional technologies support the ongoing development of teachers. Summer institutes and Saturday and late afternoon working sessions make use of data on student learning outcomes, content and pedagogical content concerns, and teacher enactment difficulties (Fishman, Marx, Best, & Tal, 2003). Technology is also used to support teachers and to help them manage their instructional responsibilities. A Web-based teacher support system called Knowledge Networks on the Web (KNOW; www.umich.soe.know.edu) was designed and is used to distribute curriculum materials, illustrate enactment of lessons, share teacher commentary about enactment issues, and display examples of student work. KNOW can be accessed by professional development leaders and by individual teachers who also can query others as they plan enactments.

Web-Based Integrated Science Environment

An example of a virtual community for learning is the Web-based Integrated Science Environment (WISE; <http://wise.Berkeley.edu>). WISE is an online environment for middle and high school that engages students in collaborative inquiry projects, supported by the use of Web resources (Cuthbert, Clark, & Linn, 2002; Linn, Davis, & Bell, 2004; Linn & Slotta, 2000).

Technology. WISE utilizes Web-based technology and the classroom teacher to enable students to engage in sustained investigations around phenomena as a route to deepening students' scientific understanding. Features include a browser-based interface for students, les-

son plans for teachers, and an online library of inquiry projects. The student interface incorporates an inquiry map that guides students in their investigation of a topic. The map provides a level of guidance to enable students to work independently on a project by showing the steps that students need to follow as they work. The software also includes an electronic guidance tool, or an avatar, that provides hints and reminds students of the purpose of the activity. Other custom-designed software tools help students use the Internet to gather and critique evidence, take notes, design approaches, and participate in online discussions with peers and scientists.

Tasks. WISE projects range from several days to several weeks and involve students in investigating scientific phenomena, designing solutions to problems, critiquing scientific ideas, and debating real-world scientific controversies (Linn, Clark, & Slotta, 2003; Slotta, 2004). Typical projects involve students in such diverse activities as investigating the nature and cause of frog deformities, designing a house that is comfortable for desert living, and debating different perspectives on how to control malaria worldwide.

Goals. Academic goals of the program include developing students' conceptual understanding of standards-based science content (NRC, 1996) and promoting scientific, language, and technology literacy skills (Linn & Slotta, 2000). Social and interpersonal goals focus on promoting students' autonomy in learning, helping students to learn from peers, and promoting a positive disposition toward science.

Social Organization. WISE science instruction emphasizes knowledge building within a scientifically oriented classroom community (Linn, Clark, & Slotta, 2003). Students primarily work collaboratively and independently in small groups. Web-based communication tools enable students to connect with peers and scientists to share data, discuss and debate ideas, and report findings. The classroom teacher interacts with groups as they progress through a WISE project, guiding and assisting students when necessary. Students and teacher have a shared purpose of making sense of scientific ideas and practices.

Instructional Materials. The WISE learning environment provides students with an online workspace for working individually or collaboratively through a se-

quence of activities that constitute an inquiry project. The workspace is a browser-based interface that helps students navigate through activity steps by incorporating prompts, such as pop-up windows for note taking, windows that provide hints, and evidence pages that add ideas about the topic of inquiry. Online investigations are further supported by classroom hands-on activities and explorations. For example, in a project called “Plants in Space,” students use the WISE interface and Internet resources to investigate plant life and explore different conditions for growing plants on earth and growing plants in space (Williams & Linn, 2002). They collaboratively create a small hydroponics garden in their classroom and conduct investigations of their plants to analyze factors relevant to plant growth and then use their analyses to consider factors important for plant growth in a space station environment. The project involves students in critiquing Web evidence regarding factors for plant growth, such as soil, water, air, and light; participating in online discussions with peers and scientists; and critiquing additional evidence to determine feasibility of particular plants for growth in a space station environment. Students conduct daily observations on plant growth and development from their own garden as well as local gardens, design and carry out investigations on their plants, and report their recommendations for growing plants in space. The WISE interface provides students with information on plants, as well as additional evidence on conditions on space stations to help raise questions and guide the investigation of ideas about plant growth. WISE software helps students keep track of data, take notes on evidence, and then use evidence to respond to questions and speculate on which plants would be the best option for a space station environment. Student-generated artifacts, such as notes from investigations and presentations, are intended to reinforce literacy skills and showcase learning.

WISE projects are designed to appeal to students’ interests and curiosities, relate to real-world scientific topics, and help students develop scientific inquiry skills. Projects are created collaboratively through partnerships with a wide range of participants from science agencies, professional organizations, museums, schools, and universities. For instance, the “Plants in Space” project partnership included scientists, classroom teachers, science education researchers, and technology specialists (Williams & Linn, 2002). WISE partners work together to design a pilot project, observe its implemen-

tation in classrooms, and then refine the project based on the classroom trials. These design teams follow design principles that draw from a theory of learning as scaffolded knowledge integration (Linn, Davis, & Eylon, 2004). This perspective suggests that cohesive understanding is best promoted when learners are supported in connecting new ideas and perspectives to their ideas about the scientific phenomenon they are investigating (Linn, Davis, & Eylon, 2004). WISE design teams use the scaffolded knowledge integration perspective to create discipline-focused activities and technology features to support student inquiry in WISE projects. In addition, WISE provides an online authoring environment to enable design teams to create and refine diverse curriculum projects that align with WISE design principles and relevant science standards (Linn, Clark, & Slotta, 2003). WISE partnerships have designed and refined an online library of more than 50 inquiry projects (Shear, Bell, & Linn, 2004).

Teacher. WISE provides the classroom teacher with online support that includes a curriculum library of inquiry projects with accompanying lesson plans, descriptions of learning goals, information on likely student prior conceptions, assessments, and links to national science standards. The teacher workspace provides scaffolds to help teachers plan and run WISE projects. Technology features that support teachers include grading tools, classroom management tools, formative assessment tools, and customization tools that enable teachers to tailor projects. The projects are intended to be flexible and adaptive for teachers so that they can easily incorporate them into existing science programs. This flexibility enables teachers to select a project for use as part of a larger unit of study, or use a project as a stand-alone science unit. The role of the teacher, then, is to select relevant projects from the WISE online library and customize them for local classroom use. The teacher’s role also is to facilitate student work through a project. The teacher interacts with small groups of students, assisting them in interpreting Web-gathered information and materials and helping them to link their experiences with scientific concepts (Slotta, 2004).

Assessment. To assess content learning, the teacher has online access to multiple-choice and short-essay subject matter tests. WISE also incorporates opportunities for students to create artifacts and

presentations that can serve as assessments of science content and inquiry skills.

Cognitive Tutors

Researchers at the Pittsburgh Advanced Cognitive Tutor Center have developed computer-based learning environments, called Cognitive Tutors, for high school mathematics classrooms (Alevin & Koedinger, 2002; Anderson, Corbett, Koedinger, & Pelletier, 1995; Corbett, Koedinger, & Hadley, 2001). A Cognitive Tutor program integrates classroom instruction with intelligent instructional software that provides students with individual support for math learning. The program is a full curriculum, composed of classroom learning activities, student text materials, and instructional software.

Goals. The Cognitive Tutor curriculum is aligned with standards for mathematics instruction and curriculum emphasized by the National Council of Teachers of Mathematics (2000). Goals of the program include developing students' math problem-solving abilities and deepening procedural and conceptual knowledge as a means to raise students' mathematics achievement.

Tasks. Cognitive Tutor software assigns problems to students individually, monitors students' solution steps, and provides feedback and hints. The Geometry Cognitive Tutor, for instance, presents students with geometry problems dealing with such concepts as angles, area, and the Pythagorean theorem (Alevin & Koedinger, 2002). The tutor displays error messages in response to mistakes, provides a geometry glossary and on-demand hints, and keeps track of students' mastery of each skill to be learned. The tutor is part of an integrated full-year geometry curriculum called Cognitive Tutor Geometry. In addition to geometry, Cognitive Tutor software and curricula have been developed for high school algebra and integrated mathematics courses.

Tasks presented by the tutor are problems that connect to real-world situations. For instance, the algebra tutor emphasizes algebraic reasoning through such problems as estimating the cost of a car rental, planning profits for shoveling snow, and organizing to sell ads for a school yearbook (Corbett, McLaughlin, Scarpinatto, & Hadley, 2000). Problems involve multiple math concepts and skills and provide extensive skill practice. The tutor provides a problem-solving space consisting of question sets, worksheets in a window, and feedback

that ensures students reach a successful solution (Corbett et al., 2000).

Instructional Materials. The design of Cognitive Tutors is based on principles that draw from adaptive character of thought (ACT-R) theory, which proposes that complex cognition arises from an interaction between declarative knowledge of information and procedural knowledge of how to use information to do various cognitive tasks (Anderson, 1993, 1996; Anderson & Schunn, 2000). A fundamental assumption of ACT-R is that procedural knowledge can be learned only by doing. Tutor software is designed, then, to provide skill practice in a variety of problem-solving contexts so that students can acquire and strengthen their procedural knowledge (Anderson, 1993).

Accompanying the software are instructional materials that help orchestrate whole-class instruction and collaborative problem-solving activities that emphasize real-world situations. The materials include a problem-based textbook for students and a teacher's guide that consists of assignments, assessments, teaching suggestions, and classroom management techniques. The purpose of the textbook and classroom activities is to parallel and extend the development of concepts emphasized in the software.

Technology. The tutor software is specially designed for monitoring individual students' problem solving. Cognitive Tutors are able to monitor students' problem-solving performance and keep track of their mastery of each skill to be learned. To do this, each Cognitive Tutor employs a cognitive model that represents the skills and strategies of students at various levels of competence (Corbett, Koedinger, & Hadley, 2001). The tutor uses the model to analyze an individual student's problem-solving performance. When a student makes an error and cannot produce the correct action, the tutor suggests what action should be taken. The tutors provide tailored practice on math skills until students reach mastery performance levels. Once a student reaches a mastery level of performance in a particular section of a tutor curriculum, the tutor stops presenting new problems. In this way, a student's learning time is spent on strengthening requisite skills for successful problem solving.

Because the tutor is meant to provide suggestions to a student when that student experiences difficulty, the tutor's ability to diagnose student errors and provide use-

ful feedback is crucial. For a tutor to diagnose effectively and give feedback requires that its cognitive model be based on an accurate task analysis. In the design of a tutor, a task analysis is done for each task to develop cognitive models to represent the competencies required to complete each task. The strength of such an analysis is that the cognitive processes engaged in solving a problem are thoroughly mapped. With some degree of certainty, then, the tutor is able to match errors to a family of error types and is thus able to take advantage of prior knowledge and enable careful scaffolding by following students' solution paths through the problem-solving space. For instance, when an error occurs, the tutor initially displays an error message and provides on-demand hints, with multiple levels of hints available for each step of a problem to ensure that the correct path to a solution is followed. Seeing a brief error message, the student is allowed to correct errors without assistance. Multiple hint levels allow the student to succeed with minimum possible assistance. Problems are selected and designed to reflect real-world situations and allow for the practice of specific skills. Multiple representations from the discipline (tables, graphs, symbolic expressions) are built into the software.

Teacher. The Cognitive Tutor curriculum integrates individual tutor use with classroom instruction and collaborative problem-solving practice. Students spend about 40% of classroom time working individually on problems assigned by the tutor and the remaining time engaged in collaborative problem-solving activities and whole-class instruction (Alevan & Koedinger, 2002). The role of the teacher is to facilitate the problem-solving activities and class discussions and circulate and assist students as they work in the tutor environment. To succeed, the teacher needs to have subject matter knowledge, be familiar with tutor software, and be comfortable in facilitating collaborative problem solving.

Assessment. Assessment is an integral part of the Cognitive Tutor curriculum. Cognitive Tutor software includes step-by-step assessments of students' mathematical skills and provides a skill report to identify math skills levels and progress for each student. Assessment tools are also provided in the teacher's materials and include pretests and culminating exams, quizzes (answer keys provided), and rubrics for grading class presentations. Teachers are also encouraged to create

and share their own assessments, consisting of quizzes and tests, on an online teacher community.

Comparing Programs

Table 8.3 compares six programs across the features of learning environments. The table characterizes and allows comparison of several widely used learning environments. Our point is to illustrate commonality and variety in the design of learning environments. The entries in Table 8.3 use language that we have drawn from respective descriptions of the programs. In some instances, programs describe similar features, but use different terms.

Summary

The environments described in this section have academic goals, are theoretically based, wide in scope, and have published research on their effectiveness. The descriptions illustrate that while programs have similar features, they differ in how each translates theory into practice. One difference is in which features are central to a particular learning environment. For instance, technology is the core in many programs; in others it is secondary or not present at all. Another difference is that content might be addressed using problem, project or design based units. Content might be linked to students' daily lives or in issues that are derived from those encountered by scientists, mathematicians, or other experts.

Goals usually focus on understanding of the content and processes of a discipline. Development of expertise is an aim shared by most learning environments, and some programs emphasize intentional learning as a goal. Age related developmental goals are mostly absent, although program features match recommendations for instruction based on developmental needs of late elementary and middle school students. Highly sequenced learning environments are usually based on information processing theory, which emphasizes individual construction of knowledge. To guide knowledge development these environments rely on detailed models of expert and novice thinking. Other environments emphasize social aspects of learning and focus on development of learning communities.

The success of any learning environment depends on the teacher, although the programs vary with respect to teachers' roles. In some programs, much of the burden of instruction is shared with technological tools or materials

TABLE 8.3 Program Comparisons

| Program | Goals | | | |
|--|---|---|---|--|
| | Academic | Social and Interpersonal | Habits of Mind | Developmental |
| Connected Mathematics (Lappan et al., 2002; Lappan & Phillips, 1998; Reys et al., 2003) | Math knowledge, understanding, and skill; math content and process goals aligned with national standards | Mutually supportive learning | Become independent learners; intellectual methods of the discipline | |
| CSILE/Knowledge Forum™ (Bereiter & Scardamalia, 2003; Scardamalia, 2004; Scardamalia & Bereiter, 1994; Scardamalia, Bereiter, & Lamon, 1994) | Knowledge-building skills; deep understanding in different academic domains | Interpersonal skills | Habits of mind for lifelong learning; intentional learners | |
| Fifth Dimension (Cole, 1995; K. Brown & Cole, 2000, 2002; Gallego & Cole, 2000) | Learning through play: Cognitive outcomes include computer literacy, comprehension, and problem-solving skills | Build relationships between children and young adults | Develop autonomy, knowledge, and skills for everyday practices | Extend children's cognitive and social development |
| GenScope™/BioLogica™ (Horwitz & Christie, 2000; Hickey, Kindfield, Horwitz, & Christie, 1999, 2003; Hickey, Wolfe, & Kindfield, 2000; Horwitz, Neumann, & Schwartz, 1996) | Use basic concepts in genetics to reason and solve problems in the domain | | Acquire the habits of mind of professional scientists | |
| GIsML (Hapgood, Magnusson, & Palincsar, 2004; Magnusson & Palincsar, 1995; Palincsar & Magnusson, 2001; Palincsar, Magnusson, Collins, & Cutter, 2001) | Science content understandings; scientific reasoning | Work in a community of learners | Enculturation into scientific community | |
| Kids as Global Scientists/BioKIDS (Huber, Songer, & Lee, 2003; Mistler-Jackson & Songer, 2000; Songer, 1996, in press; Songer, Lee, & Kam, 2002) | Conceptual understanding of standards-based science content; longitudinal development of scientific reasoning skills; technology skills | Positive motivational beliefs toward science | Develop understanding of nature of science | |

| Program | Tasks | | | | |
|------------------------|---|--|---|--|--|
| | Content | Sequence | Authenticity | Contextualization | Artifacts |
| Connected Mathematics | Math problem-solving activities | Sequenced to develop understanding and skills | Real-world, purely mathematical, and whimsical situations | Problem-centered: Math concepts embedded in problems | Represent learning |
| CSILE/Knowledge Forum™ | Knowledge-building workspace to produce and improve ideas | Open sequence: Supports multiple curriculum areas | Tied to interest of classroom community | Self-selected inquiry by students and/or teacher | Contribute to community knowledge |
| Fifth Dimension | Problem-solving and communication activities | Children move through a maze of activities at own pace | Children select activities and level of challenge | Socially oriented | Illustrate how tasks were accomplished |

TABLE 8.3 *Continued*

| Program | Tasks | | | | |
|-----------------------------------|---|--|---|---|--|
| | Content | Sequence | Authenticity | Contextualization | Artifacts |
| GenScope™/ BioLogica™ | Genetics problem-solving activities | Interactive software presents problems and guides learning | Tied to student interest; domain-focused | Framed by the domain: Tasks focus on genetics | Represent students' mental models |
| GIsML | Inquiry science investigations | Cycle of investigation guided by teacher | Real-world science; firsthand and secondhand investigations | Knowledge production in a scientific community | Reflect content knowledge and reasoning skills |
| Kids as Global Scientists/BioKIDS | Inquiry-focused activities | Sequenced to support inquiry readiness and foster science learning | Real-world; discipline-based | Interactive inquiry around science themes | Showcase content and inquiry knowledge acquisition |
| Program | Instructional Materials | | | Resources | |
| | Theoretical Explicitness | Detail for Enacting | | | |
| Connected Mathematics | Drawn from cognitive sciences research: Students develop understandings from direct experience with mathematics | Complete middle school curriculum; comprehensive guides for enactment | | Teachers follow a guidebook; students use unit books | |
| CSILE/Knowledge Forum™ | Principles of knowledge building | Online knowledge-building courses, resources, discussions, and tutorials for teachers | | Online workspace is used by teacher and students; scaffolds and resources for students in workspace | |
| Fifth Dimension | Design principles derive from cultural-historical activity theory; explicit principles for site design | General implementation guidelines for site design and management; core principles frame program design | | Adaptable model: Each site is run by a community and university partnership that develops a unique program based on core principles | |
| GenScope™/ BioLogica™ | Model-based teaching and learning framework: Learners need to construct, elaborate, and revise mental models of biological phenomena | Online demonstration of Web-based lab activities illustrates use for teacher and students; activities can supplement or supplant teacher's course | | Teacher guide and student worksheets; software provides prompts for students as they engage in investigations | |
| GIsML | Sociocultural theory: Learning arises from individual activity and social interaction in the social and cultural world | Teacher learns tenets of GIsML instruction via professional development; unit activities provided | | Teacher's guide for supporting use of student text materials | |
| Kids as Global Scientists/BioKIDS | Constructivist learning theory and learning cycle approach serve as theoretical frame; promoting readiness for inquiry provides explicit guidance in design | Downloadable curriculum to help teachers plan and enact lessons: Includes descriptions of activities, information on using digital resources, annotated student worksheets | | Curriculum binder consisting of teacher guide and student worksheets; handheld software; online database for students and teachers | |

(continued)

TABLE 8.3 *Continued*

| Social Organization | | | |
|-----------------------------------|---|---|--|
| Program | Structure | Communities of Practice | Beyond the Classroom |
| Connected Mathematics | Multiple arrangements: Individual, pairs, small groups, and whole class | Ways of thinking, reasoning, and communicating in mathematics | Home connections: Newsletters and activities for home |
| CSILE/Knowledge Forum™ | Collaborative knowledge work within a multimedia community space | Knowledge-building practices and discourse | Online network of databases for community participation |
| Fifth Dimension | Children pair with adult mentors as coparticipants | Social and discourse practices in a playful activity system | Cross-site activities via communication technologies |
| GenScope™/BioLogica™ | Pairs or individual students engage in activities | Practices of the scientific community; focus on scientific inquiry and reasoning | |
| GIsML | Students work together with guidance and support from teacher | Cultural elements of the scientific community: Scientific values, conventions, norms, beliefs | |
| Kids as Global Scientists/BioKIDS | Students work collaboratively with teacher as guide and facilitator | Inquiry knowledge development in a learning community: Science inquiry reasoning, communication | Online discussions and data sharing with peers at other school sites and with experts; students utilize Internet resources |
| Teacher | | | |
| Program | Responsibility | Centrality | Competencies |
| Connected Mathematics | Enact curriculum units; assign homework; assess student work | Primary position in enacting; work closely with students to make sense of math | Facilitate problem-centered curriculum; pedagogical expertise |
| CSILE/Knowledge Forum™ | Prepare students for knowledge-building work; set expectations; initiate inquiry | Allow for student-directed inquiry; scaffold students in the process of knowledge building | Understand knowledge-building process; technology expertise |
| Fifth Dimension | College-age adults partner with children throughout every activity | Role of teacher and learner is flexibly shared by adults and children; adults guide as much as necessary for children to make progress and have fun | Ability to regulate the quality of interaction around the tasks; maintain role as a capable peer |
| GenScope™/BioLogica™ | Coordinate class and computer activities; assess student progress | Monitor students during computer activities; lead peripheral activities; provide individual assistance to students as needed | Course planning; integrate computer activities with classroom activities; technology expertise |
| GIsML | Determine the initial inquiry; guide and shape students' interactions with materials, ideas, and classmates | Central role in mediating students' interactions: Guide students through the inquiry cycle | Knowledgeable about science content, nature of science, and scientific practices; support students' knowledge building |
| Kids as Global Scientists/BioKIDS | Adapt program for classroom use; guide inquiry activities; assess student work | Key facilitator for learning: Guide students through inquiry phases as they investigate and research | Ability to tailor lessons to support students; science content and technology knowledge |
| Technology | | | |
| Program | Tools | Centrality | Function |
| Connected Mathematics | Graphing calculators; optional computers and third-party commercial software | Students use calculators regularly; computer software activities are optional | Calculators are integrated into the curriculum as a tool for solving problems |
| CSILE/Knowledge Forum™ | Electronic group workspace: Communal database and Web-based communication tools | Workspace is used for note taking, searching, organizing, and sharing information | Scaffold individual or group research process |

TABLE 8.3 *Continued*

| Program | Technology | | |
|-----------------------------------|---|--|--|
| | Tools | Centrality | Function |
| Fifth Dimension | Computers and third-party commercial educational software | Computer software and telecommunications activities are pervasive | Computer-mediated activity that interweaves play and learning |
| GenScope™ / BioLogica™ | Computer-based software learning environment consisting of custom-designed tools for exploring genetics | Technology-supported science learning: Structures and guides learning activities | Provide individual students with a sequence of activities and scaffolds for investigation work |
| GIsML | Technology, such as computers and software, used to leverage learning | Technology used when advantageous to make ideas visible for students | Support the development of conceptual understanding |
| Kids as Global Scientists/BioKIDS | Web-based databases, handheld technology, and the Internet for interactive inquiry | Technology tools and resources utilized in inquiry activities | Scaffold inquiry process for students: Technology used to gather and organize data, analyze data, communicate with peers and experts, and create reports and presentations |
| Program | Assessment | | Targets |
| | Types | | |
| Connected Mathematics | Pencil-and-paper quizzes and unit tests; self-assessments; projects | | Math concepts and skills; disposition toward mathematics; work habits |
| CSILE/Knowledge Forum™ | Individual and group portfolios of research work; reports, multimedia presentations, and demonstrations | | Depth of understanding and ways of thinking in different academic areas |
| Fifth Dimension | Children complete task cards after each activity; progress is noted in a log | | Monitor students' progress through activities |
| GenScope™ / BioLogica™ | Electronic portfolios of students' investigations | | Modeling and explanation of processes and mechanisms of genetics |
| GIsML | Student reports and presentations; written responses in science notebook | | Understanding of science concepts; scientific reasoning and explanation |
| Kids as Global Scientists/BioKIDS | Individual and group generated artifacts and presentations | | Science content knowledge and scientific inquiry abilities |

on the Internet. In others, teachers have the primary role in instruction so that they have considerable responsibility for making instructional choices such as what questions or topics to pursue, how to represent content, and how to adapt the learning environment materials in a manner that is congruent with basic premises but also tailored to specific circumstances. These types of environments require greater teacher knowledge of content and pedagogy and of the principles that guide the design in order for goals to be achieved.

All programs make use of artifacts as reflections of student understanding. Students synthesize and apply concepts through artifact creation and revision. However, program developers also are under pressure from funding agencies and school systems to demonstrate effects on more conventional and widely understood

methods. Most use performance on curriculum specific tests and on high stakes standardized tests as evidence of increased achievement.

The criteria we used narrowed the range of programs included in our descriptions, although even in this limited sample there is considerable variation in how features are designed. Our descriptive framework differentiates specific aspects within each feature and therefore is useful for providing considerable detail about overall program design. Researchers, designers and practitioners can use this detailed information to match their ideas about development of a learning environment with ones that already contain aspects of interest in each feature. Developers then might look across programs to study techniques for instantiating these aspects and making modifications to fit their goals.

DESIGN AND IMPLEMENTATION OF LEARNING ENVIRONMENTS: INTERPLAY OF THEORY AND PRACTICE

In this section, we describe how theory is used to design learning environments, how data are gathered on enactment and student outcomes to shape design revision, and how this cycle helps to inform theory and practice. We begin by examining the role that design principles play in guiding the development process. We then illustrate the process by showing how difficulties in implementation common to many learning environments are addressed via iterative cycles of implementation, evaluation, and revision. Finally, we discuss debates about the merits of design research, which is used extensively in the field of learning environments.

Design Principles

The design and building of learning environments is an iterative process. As illustrated in the previous section, most programs use theory as the basis for design. Developers collect data on enactment and outcomes and revise features that do not work as anticipated. As Ann L. Brown (1992) argued in her groundbreaking paper on design experiments, the idea is that enactment and theory inform each other; consequently, designers generally do not see the innovation as a fixed entity. Through cycles of revision to make features work as intended, they provide valuable information on how theory works in practice and under what circumstances. This information is used to generate design principles for the creation of new learning environments.

Design principles bridge the gap between theory and practice. They are an interpretation of a program's theoretical base and are meant to inform the development of instructional sequences and activities. The initial articulation of design principles is usually tentative, and principles are revisited and strengthened through the iterative design process. They are of central concern to program developers because they provide guidance for the design process by delineating design principles for environments and describing instructional practices that make them work as intended in varying contexts. This more specified level of theoretical analysis is important because the results provide direct guidance for organizing instruction. This is the type of approach Burkhardt and Schoenfeld (2003) argue is necessary for making progress in solving tough educational problems. In this way, the iter-

ative work can lead to stronger connections between theory and classroom practice.

Design principles can take different shape and forms. Some are very general; others are heuristics that inform sequences and activities; and others dictate the prominent features and how they can be instantiated. One example is Edelson's (2001) Learning-for-Use framework, which is drawn from cognitive science principles. The framework is meant to help curriculum designers integrate content and process learning in the design of their own programs. Edelson and colleagues (2001; Edelson, Salierno, Matese, Pitts, & Sherin, 2002) are currently applying this model to the design of technology-supported science learning environments. His framework articulates four principles for design: (1) Learning involves the constructing and modifying of knowledge structures; (2) knowledge construction is a goal-directed process; (3) situations in which knowledge is constructed and used determine its accessibility for future use; and (4) knowledge must be constructed in a usable form before it can be applied. Note that the principles are not detailed enough to spell out every design decision.

In GISML, a more specific heuristic is used for the design and implementation of guided inquiry (Magnusson & Palincsar, 1995). The heuristic is based on a conceptualization of instruction as a series of cycles involving engagement, investigation, and reporting. This heuristic, derived from a sociocultural perspective, is intended to reflect how scientific knowledge production actually occurs in the professional science community. Because inquiry in the scientific community also involves a combination of firsthand investigation of phenomena and secondhand investigation of the work of others, the heuristic also emphasizes these culturally authentic practices. Similarly, LBD design principles provide guidance for how students can learn science content and practices in the context of design-and-build activities. LBD's cognitive constructivist framework emphasizes the role of routines and procedures in helping learners organize and access their knowledge so that they can apply it and relate it to new situations (Kolodner, Gray, et al., 2003).

Another example is the backward design framework of Wiggins and McTighe (1998), which is aimed at creating effective curricula linked to standards. It begins with learning outcomes based on standards that specify what students should know and be able to do. It includes three stages for design: Identify desired results, determine acceptable evidence, and plan learning experiences

and instruction. The design process is based on a broad theory of understanding informed by Dewey (1933), Bloom (1956), Gardner (1991), and others (see Wiggins & McTighe, 1998) and is compatible with a range of instructional approaches.

Design principles are not detailed enough to spell out every design decision; they are midlevel propositions that are not specific enough so that one designer's particular instantiation of the principle can be readily incorporated into a different environment. In fact, many programs derive similar design principles even when their design principles are not explicitly stated. However, it is uncommon for researchers to compare instantiations of the same principle across programs to see which are most effective and under what conditions. Nor is it common for them to compare different ways to instantiate design principles within a program or across programs (Collins, Joseph, & Bielaczyc, 2004). Cobb, Confrey, diSessa, Lehrer, and Schauble (2003) argue that designers can help each other avoid pitfalls by reporting initial designs and doing retrospective analyses to explain how experiences informed final designs. One example is an attempt by Quintana et al. (2004) to create common design principles for technology scaffolds based on a synthesis of other's work in the field. Another is a recent paper by Puntambekar and Hubscher (2005), which reviews and critiques the current state of scaffolding in design. What is needed now is a synthesis across programs that can be part of a framework of design principles. The framework presented in the previous section may prove useful for program designers as they seek to find principles within each area that might inform their own efforts.

Iterative Cycles of Design

We provide examples from our own and others' work on how design and implementation interplay to improve theory. The interplay enables a more well-developed, grounded, and nuanced understanding of constructs, a range of examples of the constructs and their interactions within context, and illustrations of their value for teachers and students. The data collected usually includes some combination of classroom field notes, teacher reports, and video records of instructional interactions, including technology use. In addition, evaluation of learning includes examination of artifacts, student performances, test scores, and interview responses.

We discuss contextualization and design of learning tools as examples of how designs are tested and revised. We also highlight findings about consistent challenges faced by teachers and students that also influence revision and result in more specified design principles.

Contextualization

Theoretically, the principle that learning is situated makes contextualization important for designing learning environments. Contextualization situates student learning by making content concrete and meaningful. It organizes subject matter concepts and skills, helps students draw on prior knowledge, provides a common and continuous reference point for discussion, and motivates learning. Some programs strive for authenticity in how contextualization is achieved. Authenticity, as defined by Newmann and Whelage (1993), involves tasks that are worthwhile and meaningful for learners, supports active constructing of knowledge, and reflects disciplinary practices.

Bransford and his group (Cognition and Technology Group at Vanderbilt, 1997) contextualize through anchoring instruction in a videodisc series called *The Adventures of Jasper Woodbury*. The program materials consist of a series of video-based narrative adventures that pose problems for fifth- through eighth-grade students to solve, such as developing and evaluating a business plan for raising funds for a student-run project. All the information necessary to solve the problem is embedded in the video adventure story. Adventures address such math topics as introductory statistics, geometry, and algebra. The problems are created and sequenced based on a model called the IDEAL problem solver (Bransford & Stein, 1993). The emphasis of *Jasper* is on developing students' mathematical problem-solving, reasoning, and communication skills.

Others, like Learning by Design (LBD), use the design of everyday artifacts to organize instruction around something concrete that students need to build and test. LBD is an approach to science learning that has sixth- through eighth-grade students learn science by engaging in design-and-build challenges (Kolodner, Camp, et al., 2003). The challenges are centered on the design and construction of working devices or models that illustrate science concepts. For example, students learn about force and motion by designing, building, and testing miniature vehicles; they learn about the

human respiratory system by designing artificial lungs and building partial working models; and they learn about erosion by designing and constructing a model erosion management system.

Project-based science is organized around a driving question that is related to students' everyday lives. For instance, students explore ideas about force and motion to answer the question "Why should I wear a helmet when I ride my bike?" In addition, anchoring events such as a film about head injuries or demonstrations are used to illustrate big ideas and are referred to throughout the unit as the focus of discussion as students learn more about phenomena under study. Students also experience the phenomena directly whenever feasible, such as doing an "air walk" to examine signs of pollution in their neighborhood.

Contextualization poses problems for instantiating theory into practice. For instance, there were differences in the effectiveness of driving questions that were selected to contextualize PBS units. Students considered some to be more real-world than others. Those that focused on ecology, such as "What is the quality of air in my community?" were perceived as more relevant than questions focused on physical science, such as "How can we build big things?"

We noted problems in instructional practice in use of the driving question and anchoring events. Because teachers are more familiar with stand-alone activities or lessons, they varied in their use of the driving question to organize and synthesize instruction. Some attempted to use student experiences to contextualize concepts but failed to relate that experience clearly to the idea. Instead, to promote participation, they encouraged long discussions of experiences students shared that often diverted from and did little to help students understand how those experiences related to the point. Moreover, some teachers had difficulty helping students experience phenomena because of local circumstances, rules, or resources. For example, visits to a local river were not permitted by some principals, and some schools were not located close to a body of water.

As a result of these experiences, we experimented with different driving questions, altered contextualization activities, created new professional development material, and revised our curriculum materials. For example, we developed driving question boards for the class to post what they learned after completing each main investigation, activity, and artifact to indicate how it contributed to answering the question. We provided

alternatives to experience the phenomena through video of the teacher visiting a river and through the design of virtual field trips presented on CD ROMs. The cycles taught us how to make contextualization more effective, how to help teachers use contextualization, and how to provide alternative possibilities to aid teachers in tailoring for their own students and settings (for more detail, see Krajcik & Blumenfeld, in press).

Our experiences with contextualization are similar to those of other groups. For instance, the designers of *Jasper* needed to tinker with the use of video and stories to make them meaningful to students and to make the mathematical problem involved clear, rather than clouded by too much extraneous detail. Holbrook and Kolodner (2000) found that although design challenges in LBD were intended to provide the context for learning science concepts and practices, teachers would fail to contextualize instruction. Instead, they often attempted to teach the science first and then introduce the design challenge. Design activities were often more like arts-and-crafts activities as students and teachers focused on constructing working models and neglected to make links to the underlying science concepts (Kolodner, Camp, et al., 2003). In the process of re-designing LBD to work better in middle school science classrooms, the designers consulted with teachers to develop a 3-week introductory unit called a launcher unit comprising a series of short design challenges meant to introduce science, design, and collaboration practices (Holbrook & Kolodner, 2000). To accomplish this, the launcher unit emphasizes the norms for doing science and design independent of the science content. Rather than introduce science and design processes at the same time students learn science content, the principle is to establish a classroom culture first, to better prepare students for learning science from design activities during regular LBD units. Launcher units also reduce the complexity of instruction for teachers so that they can transition more easily into new teaching practices required when using design to contextualize learning (Kolodner, Camp, et al., 2003).

Technology

Many recently designed learning environments rely on technology; in fact, the use of technology tools that scaffold learning constitutes one of their hallmarks. Designers usually find that creating software that is usable in classroom situations requires multiple research cycles. For instance, during early implementation ef-

forts, Cognitive Tutors' designers found that the software required computers with greater computational power than was typically found in schools. They also found that the computer interface was confusing to students, and sometimes the tutors gave inappropriate feedback about student problem-solving attempts (Anderson, Boyle, Corbett, & Lewis, 1990). Continuous refinement via cycles of implementation and evaluation allowed designers to respond to challenges. Developers closed the gap between school computers and tutor software, improved the interface and the tutor's cognitive model, and transformed Cognitive Tutors into a complete mathematics curriculum (Corbett et al., 2001; Koedinger & Anderson, 1998).

A related challenge for design is how to make the technology user-friendly. The cost of learning new software and new uses of technology is often high for students and teachers. First-time use of new technology with students can preoccupy teachers with managing the technology and keep teachers from effectively interacting with students to support learning during technology use. To address this problem, WISE designers developed a mentorship model of professional development (Slotta, 2004). Experienced WISE teachers work with novice teachers in workshops in which videos of WISE master teachers are discussed and social supports such as peer networks and close mentor relationships are provided. Also, because many software applications are tailored for a particular learning environment approach, all the features and affordances contained in any one piece of software may not be used easily across programs.

Another challenge is to create programs that are learner-centered so that the degree of scaffolding can be tailored to students' level of expertise (Quintana et al., 2004; Soloway, Guzdial, & Hay, 1994). In addition, designers need to determine what constitutes effective scaffolding to promote student thoughtfulness. For the most part, each learning environment uses software of specially designed scaffolds to support the learning of novices. Customized scaffolding is provided at the macro level in terms of organization and functionality (notebooks, drawing boards) and at the micro level through prompts. Some learning tools promote inquiry, such as those that ask students to make predictions or provide databases and ways to keep track of information gathered; others aid collaboration via mutual visualization, common notebooks, or group databases; some help with interpretation and modeling. How scaffolds are designed tends to be unique to each program, which means

students must learn to respond to different sources of support each time they encounter new software. Greater attention is being paid to the variations in how scaffolding is designed, and there is interest in identifying more common design features to aid students (Puntambekar & Hubscher, 2005; Quintana et al., 2004).

Project Based Science makes use of several software tools. Students use Model-It to easily build, test, and evaluate qualitative, dynamic models. Students can import the functional relationships they developed into DataViz. Students plan their models by recording ideas and creating objects and factors. Next, they build relationship links between the factors using qualitative and quantitative representations. A graphical view of each relationship is also provided. For data visualization, Model-It provides meters and graphs to view factor values. As students test their models they can change the values of factors and immediately see the effects.

The incorporation of learning supports or scaffolding that addresses the differences between learners and professionals is central to learner-centered design. By guiding the selection of goals and processes, scaffolding enables the learner to achieve goals or accomplish processes that would otherwise be too difficult. Reducing complexity is a common design principle for scaffolding. The software incorporates three types of scaffolding (Jackson et al., 2000). Supportive scaffolding guides learners through steps within phases of inquiry; for example, when constructing a model, students are reminded to make a plan of variables to include before building and testing. Reflective scaffolds support learners' metacognitive activities. For instance, they are prompted to test individual relationships or a sequence of relationships before evaluating the entire model. Functionality in the software supports testing and debugging, allowing students to determine which relationships work and which may need revision. Intrinsic scaffolding supports different levels of user expertise; it makes the simplest level of functionality available to the novice learner, but allows learners to access advanced features as their capability grows.

Wallace and colleagues (Wallace, Kupperman, Krajcik, & Soloway, 2000) used observations of how students search for and make use of information on the Internet to learn how to support students in using online resources. They found that many students do not behave as intentional learners who aim to increase or build knowledge as they search. Instead, students interpret the task of seeking information as one of getting a single

right answer or numerous good hits. Moreover, students' background knowledge about their question often is limited; as a result, they have trouble generating any keywords other than those used in their questions. Failure to create synonyms may also be due to limited appreciation for the significance of keywords or a lack of understanding about how the technology works.

In addition, Wallace et al. (2000) report that students do not have efficient ways to monitor what they have accomplished; they lose their place if the search continues over a period of time, often repeating what they have done before or not making use of the information they have already gathered. Moreover, they have few strategies for reading or evaluating a considerable amount of material online. Perhaps it is because students are used to looking up brief answers in textbooks or other reference sources such as encyclopedias and dictionaries that they may have neither skills nor inclination to critique what they find.

These findings point to some of the areas in which students need support if they are to conduct effective searches, and suggest that a major challenge to using digital information resources is to provide tools that allow students to embed information seeking in a sustained process. Such tools must support both searching for simple answers where students are looking for factual information, and also complex exploration of information when learners are trying to understand a multifaceted problem.

Based on classroom observations of students, Artemis was created to support students as they access and use digital information over the Internet (Wallace et al., 1998). Artemis allows students to accomplish multiple tasks within a single computer environment. This keeps work from becoming fragmented and allows students to return to where they left off in prior sessions. The workspace allows for recording of searches and includes links to actual documents, helping students sustain the information-seeking process over time. One feature, the question folders, supports students in thinking about and organizing the information they find in terms of their query. They also help students to note what other questions or information they might usefully pursue. Students can store links to items they find interesting in question folders and can create multiple folders that reflect different areas of the search or the refinements of an initial question. The folders allow flexibility in storing links and are available across multiple work sessions so that students can

draw on what they have done before. Students can add or delete items or evaluate what they have found to date. Also, past results windows keep a live list of student searches so that they can see how they searched previously and what they have found. This feature is helpful, as observations indicate that students forget which queries they have submitted and consequently repeat the same questions. It also allows students to index what they found and to review their process over time.

There is a broad topics feature that includes a list of topics organized by domain. The topics present a hierarchy of terms that can be browsed or searched as the first step in creating a query. It is intended to help students generate keywords and draw on prior knowledge as well as giving them a view of the structure of the content area they are exploring and providing them with alternative and productive ways to search.

Artemis is connected to the University of Michigan Digital Library, which contains a collection of relevant sites for middle school students (see <http://umdl.soe.umich.edu>). The objective is to alleviate the frustrating problem students often have of getting numerous irrelevant hits when performing an Internet search. Teachers and students also have the ability to critique, comment on, and recommend sites. Reading others' recommendations and their accompanying rationales and contributing their own critiques can help students learn to evaluate information and sites and also increase motivation.

Design changes similar to those made to the software programs described above can be adapted by other developers as they seek to create learning tools that are theoretically based and that work in classrooms.

Teachers and Students

Most developers of learning environments find that their innovations pose predictable enactment challenges for teachers and students. As some of the examples about contextualization and technology illustrate, quite often, the intended program envisioned by designers differs dramatically from what actually unfolds in classrooms. This is almost always the case in early implementations.

A significant challenge, then, for those designing learning environments is to anticipate difficulties and create innovations that will support teachers and students in engaging in new modes of teaching and learning. Designers need to think through how a learning environment can be enacted and sustained in real-world

instructional settings. This process entails making modifications to accommodate to a range of classroom issues. In early implementations of PBS, we found that as teachers tried unfamiliar instructional strategies or new arrangements, the results were often less than ideal; teachers ran out of time and did not relate back to the driving question during lessons, artifacts were left unfinished, and discussions did not facilitate the construction of key ideas (Marx, Blumenfeld, Krajcik, & Soloway, 1997; Singer, Marx, Krajcik, & Chambers, 2000). Time, we learned, is a precious commodity in classrooms; teachers struggle to cover curriculum, address mandated requirements such as testing and test preparation, and incorporate new requirements such as programs on drug awareness or character education. Because time is at a premium, teachers often dropped activities that enabled discussion, reflection, and revision, all of which are essential for knowledge construction. Some teachers proceduralized and simplified artifact development to save time rather than help students to develop, share, and revise their work. Others failed to devote class time for students to compare findings from investigations and consider what varied results meant, an essential component of the inquiry process.

Another difficulty for teachers is the management of groups working on different questions or activities. This challenge is increased when students have difficulty self-regulating and staying on task. The problem is magnified when technology is involved and computer access is limited, so that work time must be organized and coordinated.

Building a community of learners is also problematic. To foster collaboration and create appropriate norms, teachers must help students learn to work together productively, to respect, share, discuss, and critique each other's ideas. This interaction pattern takes time to develop and to carry out. Also, it may not result in "correct" answers, which is troubling to many teachers. When facing challenges of managing complex collaborations, teachers often cut these interactions short and give children the answers.

Teachers also have difficulty scaffolding experiences so that students can take responsibility for learning. They often give students too much independence without adequately modeling thinking processes, structuring the situation, or providing feedback. When students are unsure about what questions to pursue or how to design an investigation to answer questions, teachers simply give students a question and an experiment rather than

let them develop and critique their own design as a route to learning about scientific processes. Mergendoller and colleagues (Mergendoller, Markham, Ravitz, & Larmer, in press) discuss in detail what types of scaffolding are necessary across time as problem-based learning curricula unfold. They stress that scaffolding is the key to management and also to student learning.

These problems led our PBS group to change our initial designs so that our materials provided greater support for teachers and students and could be used effectively across different classroom settings. For example, we shortened projects and focused on essential content, simplified artifacts, and provided alternatives to accomplish tasks when small-group work was too demanding (Krajcik & Blumenfeld, in press). We also included educative materials for teachers in the curriculum packages that contained information about management, content, and difficulty students might have with the content. We included ideas for adaptations and the principles underlying designs, so that teachers might adapt them in a manner congruent with the basic principles underlying the goals (Davis & Krajcik, 2005; Schneider, Krajcik, & Blumenfeld, 2005).

We used what we observed as the basis for discussion during professional development. During these sessions, an important part of the process of making revisions was collaboration among school personnel, teachers, and university researchers. Often, researchers identified a problem and teachers would work on strategies or suggest revisions to solve the problem. For example, we worked on ways to introduce inquiry so that students' early experiences were more highly structured and scaffolded and less complex. At other times, teachers complained about activities that did not work or technology design that was confusing. We worked on ways to introduce modeling technology to separate issues of learning to manage the software from learning what models are. We also worked on strategies to help students understand scientific explanations by creating a rubric for students and teachers and scenarios where students contrasted explanations they might make to a parent to explain the meaning results of an investigation from those a scientist might make. We highlighted scientific language, use of evidence, and ways of interpreting data. We also tried to link our professional development to student and teacher learning (Fishman et al., 2003).

Students. Significant design challenges involve promoting student participation, thoughtfulness, and

motivation. The learning environments described here represent a considerable departure from the type of classroom experience with which students are familiar. These learning environments require greater participation, more personal responsibility for learning, more self-direction, and more self-regulation (Blumenfeld et al., 1991; Blumenfeld, Kempner, & Krajcik, in press). Constructivist approaches require students to be motivated to ask questions, join in discussion, engage in sustained inquiry, and produce and revise artifacts. Not all students are willing to participate at this level; Scardamalia and Bereiter (1991) report unequal amounts of participation in their Computer-Supported Intentional Learning Environments (CSILE). As students built a class database, less able and less assertive students seemed to be somewhat “sidelined” from the action.

Linn (1992) reports that students were often not respectful of each other (e.g., would refuse to share computer keyboards or information), and groups developed status hierarchies and norms consistent with gender stereotypes in her Computer as Learning Partner environment. She found that quality collaboration was difficult to achieve; less dominant students tended to agree with more dominant ones, and students reported a variety of perspectives rather than try to understand the merits of different points of view and come to common understanding. One reason students might not collaborate productively is because they may not know how to do so. Palincsar, Anderson, and David (1993) addressed this problem by designing a program to help students learn scientific argumentation as a way to enhance the quality of dialogue and improve student learning.

Reports of enactment problems from several of the programs attest to the challenge of eliciting thoughtfulness. Linn (1992) notes that students using the Computer as Learning Partner environment experienced difficulties generalizing from laboratory experiments to their everyday experiences and to new material they had not studied. Students tended to continue to respond to questions with their intuitive ideas rather than with the scientific principles integral to the topic under study. Also, there is evidence that students who collaborate via networks need help engaging in substantive conversations (Linn & Songer, 1988). As described earlier, Wallace et al. (2000) found that although students were on task while doing Web searches, the search frequently did not reflect engagement with the subject matter. Scardamalia and Bereiter (1991) also report that

students have trouble generating questions that allow them to explore a topic in depth. They suggest that students’ approaches to learning can be characterized as a “schoolwork module” where, rather than engaging with the material so as to ask significant questions and enhance their knowledge, their aim is to find the right answer and get the work done. As a result, they developed ways to help students evaluate questions and inserted prompts into CSILE, a community knowledge-building software tool, that promoted more thoughtful interaction (Scardamalia & Bereiter, 1991).

Descriptions of middle school students’ first experiences with inquiry in PBS reflect what others report (Krajcik et al., 1998). Students tended to select questions for inquiry quickly, without considering their merits. They did not think through what data would be necessary to answer these questions and often were not systematic in data collection. Only when the teacher asked for rationales for how the questions related to the issues under study did the students begin active discussions.

Issues of participation and thoughtfulness are closely linked to motivation. A fundamental goal of new learning environments is for students to take responsibility for and ownership of their own learning by inquiring, discussing, collecting, synthesizing, analyzing, and interpreting information. For these opportunities to be productive, students must invest considerable mental effort and persist in the search for answers to questions and solutions to problems.

However, whether students will be motivated to do so is not certain. On the one hand, there is reason to assume that students will respond positively to constructivist-based learning environments. Instructional factors that affect motivation include challenging work, opportunities for active learning, emphasis on topics that are perceived as valuable and that have personal or real-world relevance, provision of choice and decision making, use of collaboration, incorporating a variety of instructional techniques, and use of technology (Fredricks, Blumenfeld, & Paris, 2004; Guthrie & Wigfield, 2000). Also, Hickey (1997) argues that practices promoted by constructivist-based curricula are likely to minimize the effects of individual differences in motivation, as students participate in and become members of communities of practice. In fact, standards-based programs that incorporate these features promote positive attitudes (Hickey, Moore, & Pellegrino, 2001; Kahle, Meece, & Scantlebury, 2000). Participation in PBS stems the de-

cline in interest in science typically found during the middle school years (Blumenfeld, Soloway, Krajcik, & Marx, 2004). Case studies of sixth graders by Mistler-Jackson and Songer (2000) suggest that their technology-based inquiry program promoted a high level of motivation and satisfaction.

However, findings from several studies demonstrate that student reactions are not uniformly positive. Individual differences influence how students approach tasks in learning environments. Meyer, Turner, and Spencer (1997) found that fifth- and sixth-grade students differed in their motivation, strategy use, and engagement depending on their disposition to seek or to avoid challenge. They suggest that teachers need to create a climate where task focus, not ability focus, is encouraged, where mistakes are viewed as opportunities for learning, where seeking help is seen as adaptive, and where collaboration to solve problems and use others' expertise is the norm.

Veermanders and Jarvela (2004) showed individual differences in fourth graders' reactions to the Knowledge Forum (CSILE) learning environment. They found that students who reported higher learning goals demonstrated more self-regulation. These students moved beyond thinking about procedures and focused on the key ideas of the inquiry task. Consequently, the teacher responded by scaffolding the content rather than procedures of inquiry learning. In contrast, students whose goals for learning were lower, who wanted to avoid work or look smart rather than understand the material, faced more challenge in mastering the content.

Renninger and her colleagues (Hidi, Renninger, & Krapp, 2004; Renninger & Hidi, 2002) have shown the importance of interest on individual student motivation. Students are likely to engage more deeply and benefit from activities that they perceive to be personally meaningful. They are likely to be more motivated and more self-regulating when they study content in which they are interested. Motivated students are more likely to organize information and relate it to prior knowledge, promoting deeper understanding of content. Krajcik et al. (1998) and Patrick and Middleton (2002) showed that students' behavior during science projects differed depending on individual interest in the project question and on whether the inquiry tasks afforded enough situational interest to sustain engagement. Situational interest can "catch" students. Opportunities for making choices, working with others, and using technology can

trigger a short-term response that may not "hold" over time. Situational interest may eventually lead to more intrinsic interest in the material being explored. However, if investment in understanding does not occur, then ways to hold situational interest need to be incorporated into learning environments so that students will be more likely to engage with the ideas (Renninger, 2000).

Revisions in features of LBD illustrate responses to problems of teachers and students. Kolodner, Camp, et al. (2003) initially found that their instructional program was not specific enough to work in middle school science classrooms. So LBD designers made a number of changes to support teachers and students. They revised the initial focus on design to a redesign approach that emphasizes the role of iteration in refining and developing understanding (Kolodner, Camp, et al., 2003). They accomplished this by sequencing activities to ensure that students were guided through multiple trials of testing and building. Designers also added core activities, called rituals, in which students and teachers repeatedly engage as they progress through LBD cycles (Kolodner, Gray, et al., 2003). The repetition of core activities is meant to help students become familiar with scientific and design practices. Additional changes by designers included adding a student text, providing optional software to support student design activities, and integrating design worksheets, called diary pages, into the design cycle (Kolodner, Camp, et al., 2003; Putambekar & Kolodner, 2005).

As they went through the iterative design and research process, LBD designers drew from other approaches, such as Fostering Communities of Learners (A. L. Brown & Campione, 1994), to better support collaboration (Kolodner, Camp, et al., 2003). By drawing from design principles of other programs, they were able to make their own approach more complete. Similar problems and alternative solutions have been reported by the Cognition and Technology Group at Vanderbilt (Barron et al., 1998).

Merits of Design Research

Research on learning environments incorporates methodological traditions from several related fields. The work is highly interdisciplinary, with research teams drawn from psychology, computer science, education, and cognitive sciences; often, the teams include disciplinary specialists from mathematics, the

sciences, or the social sciences. Over the past decade or two, the new, hybrid field of learning sciences has emerged with which many of the designers and researchers discussed here affiliate. A new journal, the *Journal of the Learning Sciences*, has appeared, and the International Society of the Learning Sciences (www.isls.org) has been organized. Moreover, educational journals (in particular, *Educational Researcher*) have published a lively and spirited debate about the epistemological strengths and weaknesses of research associated with learning environments. This debate has influenced discussions about the broader field of educational research and even the structure and role of colleges of education (Burkhardt & Schoenfeld, 2003). The NRC has published a book presenting the findings of a committee it constituted to contribute to this debate (Shavelson & Towne, 2002). And the newly formed Institute for Educational Sciences in the U.S. Department of Education has contributed through its research standards for funding (www.ed.gov/about/offices/list/ies/index.html) and through the What Works Clearinghouse, a Web-based service (www.whatworks.ed.gov) that evaluates and reports on educational research in support of reform.

The main points of contention in this debate concern a number of fundamental issues. Articles about research on design, which includes learning environments, point to differences with more traditional variable-centered research (see, e.g., the theme issue of *Educational Researcher*, vol. 32, no. 1, 2003, on the role of design in educational research and the special issue of the *Journal of the Learning Sciences*, vol. 13, no. 1, 2004, on design-based research). One point of debate concerns the integrated nature of learning environments. Some (Blumenfeld, Fishman, Krajcik, Marx, & Soloway, 2000) argue that all features (see Table 8.2) are presumed to work together; therefore, when doing research on a learning environment, it may not be possible to unpack contributions of various features. This is a common problem when learning environments are key elements in systemic reform programs (Fishman et al., 2003). By disaggregating the elements, for example, in a factorial experimental design, the value of some variables may be diminished. It might be possible to design large enough experiments for learning environments that have several factors, but the size of such an experiment is likely to be unmanageable.

The problem of losing the essential qualities of learning environments when disaggregating for experimental

studies has contributed, along with other issues, to the concept of design experiments (A. L. Brown, 1992; Collins, 1992) and, more recently, design research (Kelly, 2003). Design research is more akin to engineering, or maybe architecture, than it is to natural science. Simon (1996) distinguishes between natural sciences and sciences of the artificial, or design sciences. The latter include, for example, engineering, computer science, and medicine. When applied to the study of learning, as in research associated with learning environments, design research addresses four challenges (Collins et al., 2004): creating theory that addresses learning in context; studying learning phenomena in real settings rather than in rarified laboratory settings; employing a broader range of learning measures; and linking research findings to formative evaluation. In addressing these issues, Collins et al. point out that design research also has its own challenges: addressing the complexity of real settings and the difficulty of control in such contexts; volumes of data associated with mixed qualitative and quantitative research methods; and comparing findings that emerge from different types of designs.

One of the premises of design experiments is that the intervention is integrated: It works as a whole. The elements are not orthogonal, and changing one element of the system affects all elements. Thus, one cannot decompose the program as if each element were an independent variable in a more conventional experimental design. As a result, usually there is no attempt to separate variables to test their independent and interactive contributions to the instructional program as the basis for making recommendations for practice. In addition, comparison among features across programs is not likely to be attempted because they emphasize different aspects of the theory and are designed for somewhat different purposes. Instead, the research strategy is to modify individual programs based on evaluations and to track whether changes in features affect student learning. The idea is to obtain outcomes that are reliable and replicable for the entire program so that eventually it can be disseminated with minimal support. Therefore, it is unlikely that enough information about the effect of each program's features will be available so that a mix-and-match strategy of selecting and combining effective parts of each based on empirical findings can be used. Also, standardization of features is not likely to occur, because constructivist theory is formulated in a way that does not lead to explicit prescriptions for action. Rather, it encourages adaptation and

modification of program features based on design principles as a way to enact the principles derived from theory. It is interesting to note, however, that recently an attempt has been made to integrate various aspects of these efforts in a learning environment called Schools for Thought (Lamon et al., 1996).

Well-done design research can provide findings that are more contextualized, have more detailed descriptions of learning in real settings, and present nuanced and complex examples of the range of outcomes when students engage in learning environments. But there has been considerable criticism of the failure to compare results of learning environments with results of other educational approaches or to use control groups. More recently there have been reviews of effects across problem-based learning environments (e.g., Gjibels, Dochy, Bossche, & Segers, 2005; Hmelo-Silver, 2004).

Among others, Cook and Payne (2002) have called for more use of experimental methods, including randomization of subjects to conditions, for policy-relevant research in education. The recent NRC book edited by Shavelson and Towne (2002) on scientific research in education raises similar points. One of the crucial points of argument concerns the validity of inferences drawn from design research studies. Without randomization and the use of control groups to which learning environments can be compared, there are many threats to internal validity of the research, thereby weakening the power of causal inferences.

Depending on the unit of analysis and length of time that an intervention might take, it is possible to conduct randomized experiments in real settings (see an early example by Clark et al., 1979). But substantial barriers exist. For example, in our work we engage teachers in long-term professional development in order for them to learn how to do inquiry in urban middle school classrooms. For some teachers, it takes a number of years to gain proficiency in the complexities of the curriculum and the instructional model (Geier, 2005). A number of researchers (e.g., Hawley & Valli, 1999) have argued that teacher support systems ought to be used to help teachers master complex instruction. Based on these arguments, we have collaborated with teachers with whom we have worked in Detroit in the creation of such a teacher support system. As a consequence, teachers act like professionals: They talk to each other, share ideas and challenges, and support each other through difficulties. Moreover, they work in the context of a districtwide systemic reform program, so their collaboration is strongly

supported by district officials who encourage teachers to share their practices with each other. Because it takes about 3 years for some teachers to master the instruction and even longer to gain expertise, it would be impossible and, in the eyes of district officials, counterproductive to isolate teachers from each other. As a consequence, an experiment in this context would most assuredly result in the blending of practices across treatment groups as teachers share their practices, thus confounding treatments and weakening causal inferences.

Problems also are apparent in the definition and enactment of control groups. For example, if designers are serious about integrating technology and capitalizing on the affordances that new technologies provide, then comparing an instructional unit with the technology to one without it would be tantamount to comparing quite different instructional units. Moreover, there may be no way to create truly comparable control groups that do not have technology if, in fact, the technology provides unique affordances. For example, there may be no way to enable students to conduct simulations of complex systems without using the processing power of computers.

There have also been calls for more mixed-method research designs (Johnson & Onwuegbuzie, 2004) to be employed in evaluating outcomes of educational and social innovations that could be applied to research on learning environments. Indeed, Collins and colleague's (2004) approach to design research employs a range of methods, from ethnography to quantitative assessments of learning. The advantages of mixed-methods studies include the broader range of data that can be used to understand the learning environment as it is actually enacted, the impact the learning environment has on students, and the opportunity to use the strengths of one method to balance the weaknesses of another. The weaknesses include greater cost in time and dollars and the need for a broader range of expertise, thus almost necessitating a team of researchers rather than one. Methodological purists might also object to mixing epistemological systems.

SCALING LEARNING ENVIRONMENTS

Once learning environments have been tested in a small number of settings, the challenge is to test their usability in a wide variety of circumstances. Designs for learning environments stem from research on learning, development, and motivation. Initial implementation combines insights from this work with best practices. As

we discussed earlier, initial implementation results in new information about theoretical warrants for design and about teacher practices that make the designs work. Usually in initial development, proof of concept is salient; scaling is not a critical issue.

Scaling of learning environments involves another level of effort and draws on findings from organizational and policy research. This work provides insights into how contexts into which learning environments are scaled impact enactment and success. Thus, designs that work initially may need to be modified to deal with new sites. As a result, design principles for scaling need to be developed as a new round of implementation that includes more sites occurs.

To discuss context issues in scaling, we present ideas about usability reform, problems of scaling of learning environments that use technologies, and research on the role of leadership in scaling. Many of these problems are not unique to scaling of learning environments. Because learning environments include multiple features, they pose special complications; features work together, and change in one feature to accommodate circumstances in different sites may necessitate change in others.

Types of Scaling

One type of scaling involves an increase in the number of users across settings. Work on diffusion of innovations is pertinent here. There are two primary points of view about diffusion. Rogers (2003) and his group view diffusion from the point of view of fixed innovations, examining how organizations take up and use the innovation. Van de Ven and colleagues (Van de Ven, Polley, Garud & Venkataraman, 1999) examine how innovations are modified as they become part of an organization's approach to its work. In this view, innovations that are not sufficiently malleable to be made part of local organizational culture will not succeed. Of course, this raises the problem of how changeable an innovation can be before it ceases to be an innovation. A. L. Brown and Campione (1996) refer to this issue as the problem of lethal mutations.

Scaling involves further tests of theory and practice; as the innovation meets a variety of different circumstances, adaptation is necessary. Warranted adaptations can teach us more about instantiations of features and also about practices that make them work. Features of the learning environments will need to be adapted to

deal with the setting and resources of the schools, variations in the capability of teachers, and the background of the students. A standard rule of scale is this: For an innovation to have staying power, enactors must make it their own.

Generally, as programs go to scale they are first taken up by "early adopters." These teachers are risk takers who are enthusiastic about trying new things and about what the new program can offer. In the second phase of scaling, more adaptation likely will be required, and more of the adaptations will be of the "lethal" type. That is, one can expect teachers to change the innovation to match what they are used to or what their circumstances allow. This change is most likely when the learning environment differs from the "grammar of schooling" (Tyack & Cuban, 1995). The grammar of schooling reflects the day-to-day life of classroom instruction, including the formal curriculum and instructional activities, but also the rhythm and flow of interactions within the classroom and across the school. It also encompasses the unacknowledged but highly practiced assumptions and norms that guide roles and routines in school. Innovations such as learning environments that require considerable knowledge and skill and substantial changes in the teacher role are likely to challenge the grammar of schooling and therefore be subject to more pressure to conform. The problem of lethal mutations resulting from adaptation may be lessened when the learning environment is more self-contained, with teachers as managers rather than key figures in implementation.

A second type of scaling involves increasing numbers of users within a system. When scaling within a system, problems of adding numbers remain the same, but additional issues emerge. One big difference between the two types is that in the former, solutions to problems posed by context can be idiosyncratic. Solutions to problems in systemic scaling involve dealing with district and state policy and management. As numbers of users within the system grows, unique solutions become more difficult to create, and more systemwide solutions are needed. For example, when one teacher needs more computers, the principal might buy a few new ones or might borrow some from another department or the technology laboratory. When many teachers in the school or the system have the same problem, such borrowing or moving of resources will not work. Similarly, when one or two teachers need extended class time for students to conduct an investigation, they might trade periods with

a colleague. When many teachers need extra time, systemic scaling may require new or flexible scheduling.

The success of systemic scaling will be influenced by the gaps between the demands of the innovation and school culture, capability, and policies. If considerable change in practice is required by a learning environment, teacher study groups can provide opportunities for information exchange about strategies and support for experimentation. However, if the culture does not support risk taking, or policy makes study group meetings and common planning times hard to arrange, then such change is less likely. Similarly, if content emphasized on district and state tests differs significantly from the content and learning goals of the learning environment, administrators and teachers are not likely to support the innovation or work for its success. Gomez and colleagues (Gomez, Fishman, & Pea, 1998) suggest “test bed” research as a way to see if a setting has enough of the requisites to take on the innovation. Research on social welfare and community-based programs suggests that interventions work only when there are enough resources (personal, monetary, social) for participants to take up the innovation. For instance, resource issues come into play with afterschool programs such as Fifth Dimension because each site often has its own funding structure and responsibility for budget and space. Sometimes even a successful program will be short-lived due to resource issues.

Adaptation

In addition to knowledge of how environments influence the success of innovations, adaptations necessitated by scaling to new circumstances also provide valuable information about design, theory, and practice of specific features of learning environments. The need for adaptation or tailoring raises questions of malleability and theoretical warrants. That is, in what ways can critical features of a learning environment be enacted differently, yet still remain true to their theoretical foundation?

Culture and Adaptation. The degree of explicitness in instruction is one example of the tension between adaptability and warrants. Among others, Lee (2002), Moje and colleagues (2001), and Ladson-Billings (1995) discuss the need to be explicit when teaching science to children from different cultures. Explicitness involves making very clear how one communicates, thinks, and proceeds in scientific endeavors

while at the same time addressing the students’ cultural ways of explaining phenomena or using evidence. Exploring approaches to explicit instruction that honor children’s cultural backgrounds and scaffolds learning that conforms with premises of constructivist learning environments can help to identify when adaptations are “lethal” and contradict warrants.

Adapting learning environments to make them explicit can mean making thought processes very transparent, such as contrasting how scientists talk with how students talk with friends, or contrasting what counts as evidence in science with what counts as evidence in conversations with your mother (Moje et al., 2004). Adaptation may result in more direct instruction. In a learning environment that assumes children should engage in inquiry to learn content, making the scientific processes explicit might short-circuit children’s exploration of what are good questions or what are reasonable and feasible designs, as teachers tell students questions to ask or procedures to follow. Teachers are likely to be very explicit in response to their concerns that students will generate wrong answers or misconceptions as they explore phenomena or solve problems. However, helping students construct understanding from their inquiry might require explicit instruction, especially when students are inexperienced or not skilled in keeping track of results, interpreting findings, or drawing conclusions. The defining problem is to strike a balance between adaptations that create more explicit instruction in support of thinking and adaptations that convert inquiry to direct instruction with little opportunity for deep thinking. The former can preserve the intent of learning environments to achieve national science education standards; the latter capitulates to the grammar of schooling.

Social organizational features also will need to be adapted to student cultural backgrounds. Learning environments that entail building discourse communities, in which students debate ideas, critique each others’ work, or explore alternative answers to problems, will need to adapt to students whose backgrounds limit questioning of adults, limit argumentation, or foster an orientation to one right answer. Participation structures that vary from those used in the home also will pose problems, especially for younger students (Phillips, 1972). In addition, adaptation will be necessary when the learning environment depends on small-group work and is scaled to places where students come from backgrounds that

differ in status. A variety of instantiations of group work have been developed to deal with problems of dominance in groups by nonminority or wealthy students (E. G. Cohen, Lotan, Scarloss, & Arellano, 1999).

Cultural background of students and school setting also affects whether the driving question and anchors make sense and are appealing. Solving this problem stretches our understanding of theory and practice. Are there some contextualizations that work across populations? Are there others that do not? What characterizes them? Moreover, whereas a premise of inquiry is for students to explore questions of interest, once the learning environment is scaled and needs to be developed to suit many different settings and to address specific learning standards, there are constraints on the variation of questions that can be used.

The pressure to create highly developed but adaptable materials illustrates a major tension in scaling. Teachers may not be prepared to change topics in different classes or each year in response to student interest. Teachers and administrators also will be hesitant to consider driving questions that students initiate that do not lend themselves to content that meets national, state, or district standards. Receptivity to student interests is more feasible when projects are supplementary to the curriculum than when they are the main route to convey material mandated by state and local curriculum frameworks. Moreover, even if teachers are motivated and knowledgeable enough to do so, constant changes limit the learning benefits that accrue to teachers from engaging in multiple enactments of the same curriculum material (Geier et al., 2004). One solution we and others have found is to have students raise questions of interest in the context of a driving question around which the unit is developed. Curriculum materials offer advice on types of questions students are likely to raise and how teachers might proceed. This solution keeps key ideas consistent but gives students input.

Technology and Adaptation. Learning environments that use technology also will face tensions of adaptability as they scale. One problem involves interfaces. Learning environments may spread to sites where other technology is in use. If the interfaces differ dramatically from those already in use, teachers and students will have the extra burden of learning something new and possibly a way of operating that differs dramatically from what they know. Utilization of many different applications in the same or different innovations

creates difficulty and sometimes resistance to use that requires redesign of the technology in a way that still supports learning as envisioned in the original design.

Another problem with technology is accessibility. If the learning environment requires frequent use of technology for individual or small-group use, accessibility and number of machines becomes important. Adaptation will be necessary in situations where technology is limited or where access is restricted. The result may be that alternative forms of learning support will be needed or that different ways of getting the benefits of the technology will have to be found. For example, handheld computers are much less expensive than desktop machines, but they lack some of the power and affordances of desktops. In some cases, access might be improved through a handheld program at the expense of power. The designer of a learning environment then has to choose whether the cost of power is worth the benefits of access. For some activities, such as word processing or collecting scientific data in the field, the cost is worth the benefit. For some, such as modeling complex systems, the affordance of the technology might be lost when less powerful devices are used (Fishman, Marx, Blumenfeld, Krajcik, & Soloway, 2004).

Research on Scaling of Learning Environments

One type of research on scaling of learning environments involves examination of how the innovation is adapted, whether these adaptations are warranted, and how well they work. Here researchers examine enactment and student outcomes to compare different instantiations by teachers. Data include observations, student tests, and interviews. As with design work during development phases, the role of iterative cycles of revision based on student outcomes and field-based data collection are discussed.

Another type of research examines how innovations are adapted to make them usable in systems with varying policies, resources, populations, and capabilities (e.g., Lee & Luykx, 2005). Here the focus is on gaps between existing conditions and the requirements of the innovation. This research shows that when the gaps are large, the innovation is extensive, and considerable change is needed for it to work (e.g., altering a substantial part of a curriculum). Researchers examine how policies are adapted and how the system develops capacity to deal with the demands of the innovation (Fishman et al., 2004; McLaughlin, 1990).

A third type of research involves comparison of outcomes of learning environments with other innovations or with control groups, either in fully randomized trials or in quasi-experimental studies. Arguments for such approaches are based on the need to know the added value of new programs and to draw causal inferences. As we discuss in the section on research, there is considerable debate about how experimental designs might or might not work in the context of schools and school districts. For example, there is the problem of selecting and controlling appropriate comparison groups so that they really do control for the full range of parameters that might affect outcomes.

When used in the real world of schools, innovations are not static. Teachers in control groups hear about interesting innovations and often introduce elements into their own classrooms; the result is that their classes are no longer controls. For example, we were interested in how we might help urban students become more successful at making scientific explanations as they learn in PBS curricula that we designed collaboratively with teachers in Detroit Public Schools through the Center for Learning Technologies in Urban Schools (LeTUS; Marx et al., 2004). We designed a three-group, quasi-experimental study to test our instructional approach. The study was designed to contrast non-LeTUS classrooms with LeTUS classrooms using the explanation instruction and LeTUS classrooms not using the explanation instruction. In the larger LeTUS reform effort, some of the teachers who were enacting the explanation instruction also happened to be peer leaders in the professional development program for other LeTUS teachers. Unknown to us, they incorporated the explanation instruction into their professional development activities, thereby changing the nature of one of the comparison groups. The other LeTUS teachers who were not supposed to be enacting the explanation strategies had been exposed to them during professional development. In effect, the teachers were acting professionally; they had reason to think that what they were doing in their classrooms would be useful in other district classrooms, so they made it available to their colleagues.

Critics of randomized experiments also argue that the numerous innovations that exist in most schools also make it impossible to do clean comparisons. For example, outcomes from innovations in the area of science might be influenced by new literacy or math programs that improve student skills and abilities to benefit from the science learning environments. In the

high-stakes environment of American public education we are currently experiencing, no school principal who wants to keep his or her job would be willing to leave known achievement problems unaddressed because one of the departments, say, the science department, is engaged in an experiment studying a learning environment. If the principal knows that there is a literacy problem in the school, he or she is going to bring resources to bear on that problem. If the principal is successful and the literacy problem begins to be solved, it is likely that it will affect the students who are in the science department's learning environment study. Most likely, the researchers conducting the learning environment study will not even know about the changes in the school's literacy program. They will proceed with inferences about the value of their program without knowing the threats to validity that the other activities in the school pose.

Professional Development

Scaling also requires professional development to help teachers enact the innovation in a warranted manner and realize the intended goals of learning environments. A significant problem for designers as they scale is the amount of time it takes teachers to become proficient in implementing learning environments. In our experience, initial attempts to change from a didactic model of instruction to a more constructivist approach rendered teachers novices once more. As they tried unfamiliar instructional strategies or new arrangements for which their practical or event knowledge was limited, the results were choppy; teachers ran out of time, left activities unfinished, and did not respond to or return to student suggestions or questions. Also, attempts to deal with one feature inevitably entailed problems with other features. That is, teachers not only had difficulty with individual features of PBS, they had difficulty orchestrating among them (Marx et al., 1997).

At the end of the first year of their work in PBS, each teacher's practices represented a profile of enactment, with some features instantiated in a manner more congruent with the premises underlying the innovation than others. Overall, teacher progress was not linear; they moved back and forth between new and old ideas and practices. Generally, as Shulman (1987) suggests, development was "dialectic." Teachers advanced and retreated as they confronted dilemmas and attempted to meet challenges posed by the new

approaches to teaching for understanding. In fact, it took almost 3 years for teachers to grasp the ideas underlying PBS and to become proficient enactors of the innovation.

Obviously, the process of change to promote student construction and understanding is difficult. It is essential that we find ways to assist teachers so that they are willing to try new approaches and persist in their attempts. Supporting teachers as they collaborate, enact, and reflect is time-consuming, labor-intensive, and expensive. Professional development is time-consuming, labor-intensive, and expensive as well. As typically practiced, it requires all participants to be in the same place. Scaling provides challenges in that teachers may be in many different geographical locations and require different types of help. Harnessing the potential of the new technologies is one promising route to make professional development more effective and efficient (Fishman et al., 2004; Hunter, 1992; Lampert & Ball, 1990; Roup, Gal, Drayton, & Pfister, 1992).

Virtual learning environments are now being designed as a vehicle for professional development for teachers. Web-based learning environments are one way to develop communities that help teachers understand premises, develop new knowledge of content and pedagogy, discuss and solve problems, and view video of teaching strategies that aid enactment of the innovation. Interactive technologies make it possible to illustrate new instructional possibilities, to enhance understanding of premises underlying interventions, to demonstrate challenges of enacting the new approaches and strategies for meeting them, and to illustrate a range of practices congruent with the innovation. It also can extend the benefits of face-to-face meetings via telecommunication.

An example of an online community is The Math Forum, a group of individuals who use computers and the Internet to interact and build knowledge about mathematics and mathematics teaching and learning (Renninger & Shumar, 2002; www.mathforum.org). The Math Forum supports a network of relationships around the exchange of resources supporting teachers, students, researchers, parents, and others who have an interest in mathematics and mathematics education. This online community includes Math Forum staff, whose primary role is to provide interactive services that foster discussion, support the creating and sharing of resources, and encourage collaboration on problem posing and problem solving (Renninger & Shumar, 2002). Services include Web-based discussion areas

and ask-an-expert services for teachers and students, interactive projects and math challenges for students in grades 3 through 12, math-related Web resources, an online mathematics library, and an area for teachers to exchange math units and lessons for use across all grade levels, from preschool to college.

The interactive nature of The Math Forum serves as the basis for community building and sustained community participation. Participants interact around the services and resources within an open community that is designed to promote communication between Math Forum staff and participants, as well as among participants. The Math Forum is structured to invite participation and sustain it by providing opportunities for participants to pose questions, receive support tailored to their needs, and contribute to the site. Students, for instance, are invited to work online with a Math Forum “mentor” who provides individual feedback on students’ problem-solving efforts. Teachers are invited to participate in online discussions with other educators, pose questions about mathematics and mathematics instruction directly to a Math Forum staff member, and contribute their own ideas to the Forum community. The Math Forum site does not specify what teachers should do; rather, the site makes available services and resources for teachers to explore and make use of for their own professional needs (Renninger & Shumar, 2002).

Another example is Knowledge Networks on the Web (KNOW), developed by Fishman and colleagues (Fishman, 2003). In contrast to The Math Forum, this tool is curriculum-specific; it is designed to support teachers as they enact PBS. It contains clips of teacher enactment of lessons, teacher commentary on what they did and what they might change, and information about content, management, and student learning. In addition, teachers can send questions to others who have recently enacted the same lessons or to senior staff. KNOW is developed so that it can be used as a platform for other learning environments to use with teachers as they scale. That is, developers can customize videotape clips, comments, and information for their own innovation.

CONCLUSIONS

The information in this chapter has implications for design, research, and policy. We discuss how the material reviewed can inform future work in each of these areas.

Design

Three critical issues in design need to be addressed in future work on learning environments. These include the need to specify more clearly the design of features of learning environments, the design of environments for different subject areas and populations, and the creation of usable designs.

Features

Although effective design for all elements of learning environments is challenging, three features illustrate difficulties. First, technology is a central part of many learning environments, yet teachers are not likely to effectively help students use technology as learning tools if the cost of learning how to use the technology is high in terms of time and effort. The technology needs to be easy for teachers and students to use or its benefits will not be realized. In addition, further work is needed on how to design technology to encourage students' deep cognitive engagement. There are enough technology tools in use that it is time to consolidate knowledge and create design principles. Recent efforts on how to build common scaffolds are an example of what is necessary. A recently published special issue of the *Journal of the Learning Sciences* devoted to scaffolding highlights our improved understanding of the effects of scaffolding in complex learning environments (Davis & Miyake, 2004). What we do know is that these principles must address both teacher and student needs.

Addressing infrastructure issues is critical in design for technology. Problems of access, maintenance, and support need to be addressed if technology is to function as envisioned. When sufficient technology is not available in the classroom, when teachers do not have necessary software, or when computers are not configured properly and maintained frequently, instructional time cannot be effectively used. Relying on teachers to carry out these tasks as different classes in different subject areas use computers during the day is not feasible. Attention to these issues is even more important as an innovation scales.

Another design challenge is how to effectively reach beyond classrooms to involve communities. Designers have attempted to create conditions for community involvement, including telecommunications with experts or with other students, working with community groups, and drawing on community knowledge. There are problems to be solved for each of these strategies. We have

not yet found ways to optimize the effect of community building to enrich students' learning experiences.

Assessment for designers, assessments for teacher use, and assessments for policymakers need further development. Assessments used by designers to evaluate the effectiveness of learning environments vary considerably from scoring artifacts, using posttests or gain scores, to employing standardized tests that are also of interest to policymakers. Each of these types of assessments varies in how closely it is aligned to goals of the learning environment. The tension between assessing whether learning goals have been met and using policy-oriented assessments such as state or nationally standardized tests that are not aligned with program goals is an old but enduring problem. Moreover, traditional forms of assessment do not usually address other important goals of learning environments such as better understanding of the nature of the disciplines or developing new dispositions toward learning. To complicate matters, assessments that provide information to designers or policymakers are not likely to be very useful to teachers who need to judge learning as it unfolds in the day-to-day enactment of learning environments in their classrooms. Classroom assessments should include a range of artifacts: models, reports, presentations, visual representations, and problem solutions. Designers need to build these into their programs along with scoring rubrics for teachers so that each is aligned tightly with the goals of the learning environment. Moreover, there are continuing challenges in the design of authentic assessments for classroom use that are feasible and economical of time and resources.

Subject Areas and Populations

Another set of issues the field must address is to develop design principles across subject areas and populations of learners. Robust learning environments exist in all subject areas, and others are being tested and refined. There is a continuing need to design new environments that cover a range of important subject matter content and skills. Continuing development will allow the field to address the questions regarding whether design principles are general or vary by discipline. One way to answer these questions is to apply design principles used to create existing environments in one discipline to different subject areas.

We also need to create learning environments that address learners of different ages. A goal should be to establish design principles that take account of

developmental needs, interests, and capacities. Developmental literature provides considerable information for designers to make educated guesses about how to tailor environments for different ages. This information needs to be put in practice and tested empirically to determine what specific components of designs are important so that environments work for learners of different ages.

A related point is the need to address issues of diversity and individual differences. For the most part, designers have not been specific about how different types of learners respond to and benefit from their programs and what design principles work. Although there are some general guidelines about the importance of attending to student culture in instruction and in addressing community characteristics, there is little work on variations in design of learning environments that consider adaptations required to meet the needs of diverse groups of learners. In light of the growing diversity in our classrooms, developing and testing design principles to support students from different backgrounds is essential. Similarly, we need to examine how learning environments can be created or adapted for inclusiveness of special needs learners. There is evidence that such environments can help address diversity because they offer a variety of instructional techniques, activities, technology tools, and different ways for students to participate. Some learning environments emphasize different ways for students to demonstrate knowledge through creation of artifacts such as models, designs, visual representations, and oral presentations. This variety allows students to use modalities that draw on their strengths.

Usability

We need to consider how to design learning environments for different contexts to determine how design principles can reflect conditional variation. This variation might include availability of resources such as technology and equipment, scheduling, and the nature of communities that schools serve. Differences might influence how learning is best contextualized, what community knowledge can be drawn on, and what sources of support are available.

There is a need to anticipate predictable challenges of enactment to make learning environments usable. To make learning environments work, designers need to have a deep understanding about the reality of classrooms and schools. All learning environments create

common challenges in addition to unique ones associated with context, yet design principles are not always clear about how to adapt as these challenges are confronted. The recent trend toward working closely with groups of teachers during the design and revision phases is a step in the right direction. Collaborations allow incorporation of the craft knowledge of teachers about what skills are necessary for teachers and students and help identify potential difficulties in enactment. Such collaborations enrich designs and make them more feasible for actual classroom use, and they show the need for careful and long-term collaborations to create robust learning environments that have the potential to scale up.

Another issue in designing learning environments is how to build in adaptability. Design groups report that teachers, pressed for time and worried about content coverage, do not always make effective modifications that are warranted. Many teachers are likely to eliminate or truncate opportunities for construction of understanding that are the hallmark of learning environments. Designers might include principles for modification along with examples of enactments that are faithful to the intent of the innovation and that are explicit about why this is the case. Online environments for teachers are an especially useful way to address this problem. A significant tension for designers is how to make designs responsive to the many issues that might arise while at the same time not straying far from basic principles underlying the design of the learning environment. Essentially, designers face a balancing act or trade-off in creating models that are fixed or creating models that are adaptable but specified and developed enough that they can minimize fatal mutations.

Problems of enactment also call for creating learning environments for teachers, not just students. Attention to teacher understanding is critical so that their modifications are congruent with the basic premises of the learning environment. Learning environments vary in the centrality of the teacher's role. As teacher centrality increases, the problem of how to design professional development to build teacher capability becomes more critical. Recent efforts point to some promising approaches, but they have not been compared in terms of the key features that need to be incorporated, nor is there a robust empirical literature on the effectiveness of teacher professional development. As the number of teachers using a learning environment increases, designers also have to consider how to build system capacity so

that growing teacher knowledge and skill can be used to help inform others.

Research

A critical question for consideration is this: Has the research and development community working on learning environments matured sufficiently to enable us to make stronger causal inferences about the efficacy of designing learning environments of the type discussed here? We argue that there are enough learning environments at sufficient levels of sophistication and maturity that have been through cycles of design and proven their efficacy that we can start doing more causal studies to evaluate impact as compared with other types of instruction. We are at a point where more comprehensive and systematic research is possible and necessary to compare different designs and to provide evidence allowing the field to make causal attributions of effectiveness. A step in this direction may be to draw from the framework for examining learning environments presented in Table 8.2 as well as the program comparisons presented in Table 8.3.

For such a program of research to have value for developers and policymakers, we also need to identify a range of dependent variables that are consistent with the intent of the designers and that are calibrated against important outcomes such as state and national standards. Some programs stress content knowledge, others skills, others dispositions toward learning, and others the nature of the discipline. Because programs differ in their desired outcomes, learning environments are not easily contrasted, nor are comparison groups easily defined.

Longitudinal research is essential to determine the enduring benefits of participating in learning environments. What learning, social, and economic benefits accrue over time? Are students more likely to show higher achievement, stay in school and earn high school diplomas, and continue selecting courses in subjects where they have participated in such programs? Do the skills and dispositions toward learning transfer to other areas of learning and continue to improve with the degree of participation in learning environments? Moreover, are the benefits associated with participating in learning environments equally distributed across different types of students, or are there interactions between student background characteristics and participation?

With respect to teachers, there is ample evidence that learning environments pose significant instructional challenges (Windschitl, 2002). Although there are sev-

eral ways professional development is undertaken, there is general agreement that these efforts should focus on enacting the learning environment, rather than improving general teaching skills or attitudes. Teachers need help with content and with the specifics of the pedagogical features of learning environments, such as managing multiple activities, building collaborative communities, using technology as a learning tool, and assessing student understanding.

Little is known about how teachers change over time and the factors that support or inhibit teacher learning and their growing instructional competence. There is some evidence that it takes about 3 years for teachers to learn to use learning environments productively in their instruction. However, studies have not systematically determined whether teachers continue to improve, whether there are individual differences in their learning trajectories, and whether new approaches and instructional skills transfer to teaching for which theoretically designed and developed learning environments are not available.

The learning environments research community needs to create a consensus about the way research on these environments should proceed. Recently published special issues of the *Journal of the Learning Sciences* (Barab, 2004) and *Educational Researcher* (Kelly, 2003) have started to address differences of opinion and build systematic methodological principles that can create a more rigorous approach to design and to determining effectiveness of learning environments.

Finally, most of the research and development we describe here on learning environments is based on an underlying theory of learning. Designers have learned a great deal about how to instantiate theory into practice. They have enriched theory by grounding it conceptually and contextually. They have demonstrated how models of learners, goals, settings, and instruction work together and how each needs to be addressed. It is time to consider the implications of design for learning theory. Design principles developed from this experience are what might be called midlevel theory. That is, they are statements about what needs to be considered in creating a learning environment. We also need critical analyses and reviews of how the findings affirm or disconfirm underlying learning theories.

These environments provide the context for interdisciplinary research. They combine learning, motivation, development, subject matter, and culture and discourse. Combining insights from each field can be used to

improve design principles, because each field has explicit assumptions about its own topics and implicit assumptions about the topics of others. Drawing on the knowledge and strength of each field can help make the design stronger and more explicit. This diverse expertise can be used to improve designs. For instance, learning theorists often assume that creating interest and increasing participation in activities will result in greater cognitive engagement. Motivation researchers find that such situational interests does not necessarily translate into willingness to invest effort in using the types of strategies necessary to construct deep level understanding of content. Similarly, motivation researchers pay less attention to subject matter instruction. When insights from both fields are combined, they are likely to result in better understanding and instantiation of theory into practice.

Policy

Without question, one of the primary goals of designers of learning environments is to have them used by learners. There are certainly questions of theory and research, just described, but ultimately, the goal of this work is to improve learning and other valued educational goals. Schools and other institutions focused on children exist in a social and political matrix in which public and private policies have great impact. To achieve their goals of widespread use of their intellectual efforts, designers and their colleagues must attend to the policy environments for success. To influence policy, designers of learning environments need to attend to issues of scale. They must show that the program can work in many places and retain effectiveness as numbers of participants grow. This requires that adaptability, changeability, sustainability, and achievability are realized in design. These characteristics also require support from policymakers. They are not ensured by good design alone. The importance of issues that arise in scaling will depend on whether the decision maker is at the building, district, or state level.

For adaptability, designers have to consider local conditions. The original design might be highly tailored to circumstances. To scale, designers will need to build in ways to modify aspects of the design to meet a variety of circumstances. As we discussed, these circumstances might differ in the languages and cultures students bring with them to school, different types of individual needs, and different ages. They might include diverse community values, a range of political expressions, and differ-

ent state, district, or building policies. They might include variations in curricular objectives or different high-stakes assessments.

Policymakers can have a huge impact on the quality of enactment of learning environments through a range of actions, from recruitment and retention policies for teachers to resource allocation decisions for infrastructure and operations and sustained professional development that addresses classroom enactment. Policies are key to support adaptability for programs so they can stay true to the basic principles underlying their design. Programs that are based on adaptability to local conditions, including variable classroom situations within a district or school, may be challenged to survive in an increasingly standardized climate where the goal of achieving higher scores on standardized tests dominates. In a very real sense, the learning environment literature that we discuss here constitutes a source of innovation—new ideas in pursuit of values ends—that exists in a fragile ecosystem of, on the one hand, research and development, and on the other, the rough-and-tumble of federal, state, and local policies.

Innovations are not static. It takes time for an innovation to take hold and mature as it is adapted to new circumstances. Consequently, using very early summary evaluations in making decisions to continue the effort can over- or underestimate the impact. To be effective, the enactment of learning environments in schools over time requires a stable staff; recent evidence suggests that the longer teachers enact a learning environment, the greater their contribution to student learning. This kind of stability is very hard to achieve with the enormously high turnover rates in teaching and the loss of a high percentage of teachers early in their careers as they leave for different careers, for personal reasons, or because of inadequate or even hostile working conditions.

For learning environments to be sustainable, designers need to be sure that they align with objectives and disciplinary frameworks of district, state, and national standards. Decision makers need to attend to alignment of policy with the needs of the learning environments they adopt. This alignment needs to occur at multiple levels of administration, from space, time, and resources at the building level to attention to teacher professional development, resource allocation, and objectives at high levels.

The goals of learning environments cannot be achieved without alignment with learning objectives and without alignment of policy and practice that support the

innovation. This alignment is what makes possible attaining outcomes such as improved achievement. The alignment should be focused on building dimensions of school capacity, such as teacher capability, knowledge at the building and district level of what is required, and leadership to meet those requirements. Moreover, judging if the goals are achieved depends on choosing assessments that are aligned with curricular goals and with policy needs. Whether the learning environment is deemed successful may differ on whether the criteria used are gain scores on content area tests, raw scores on standardized tests, or pass rates on high-stakes assessments. But policies regarding alignment need to conform with and contribute to the policy environment of high pass rates on high-stakes tests. School leaders working in an era of adequate yearly progress defined by federal legislation ignore high-stakes assessments at their peril. If learning environments that are used in schools do not contribute a response to the very real imperative of federal policy, then administrators are not likely to support their adoption. The ultimate question in schools may be: Does the learning environment contribute to or detract from teachers' ability to increase test performance? For designers, the challenge is to meet these goals while at the same time addressing other important goals.

Conclusion

During the past 10 to 15 years, many exciting learning environments have been designed and implemented in and out of school. These environments represent new approaches to learning. Some are focused on individual learning based on information-processing theory that promotes more expert performance and ways of thinking. Analysis of task requirements and thinking of experts are the basis for these environments. Others stress that learning is situated and social. More knowledgeable individuals, such as teachers, scaffold experiences of learners so that they can accomplish tasks they could not complete on their own. Both approaches use tools to facilitate learning.

As a result of these learning environments, students have been exposed to new ways of learning: solving meaningful problems, working with others, using technology, creating artifacts. They have gained knowledge and skills, appreciation for disciplinary practices, and new dispositions to learning. Designing, enacting, and scaling these types of learning environments is difficult for all involved—researchers, teachers, and students. In

this chapter, we highlight the premises and problems and point to what we have learned and what we still need to know. Most important, we argue that these challenges and ways to address them inform both theory and practice. It is true that enacting these environments is challenging, yet the challenges should not be a deterrent to adoption. The environments described represent ambitious pedagogy and strive for ambitious outcomes. As we think about creating the learner, worker, and citizen of tomorrow, we also need to think about how we envision the next generation of schools. These types of environments offer the promise of creating adaptive learners, effective information users, collaborative workers, and citizens who understand how knowledge is generated in different disciplines. For all the challenges, well-designed learning environments offer considerable promise in attaining these goals.

Case Example

Thalia was a clever 2-year-old when her baby sister was born. She had a large vocabulary and could express all her thoughts. Her parents praised her verbal skills but chided her stubbornness with respect to toilet training. On the day her baby sister was born, Thalia was sitting in the kitchen waiting for her favorite television program to start when her grandmother said, "You are a big girl now, Thalia, and I would be very happy if you let me help you to get rid of your Pampers. I am sure you agree that walking around in wet Pampers is such a nuisance." Thalia simply said that she was afraid to sit

on the toilet. A few minutes later, the phone rang and Grandma told her that she had a baby sister and that they had to leave for the hospital immediately. Thalia threw a temper tantrum; she did not want a baby sister and did not want to go to the hospital; she only wanted to watch her program.

On their way to the hospital, Thalia was silent. She realized that her baby sister would be her big rival from now on, and this premonition was confirmed when they entered the hospital room and all eyes were on Jenny. Thalia tried several times to get her parents' attention, then gave up and silently slipped away. Grandma found

her in the bathroom and asked her why she left the room. Thalia replied, “I hate Jenny.” She refused to go back to the room and started sobbing: “I do not know what to do about it.” Grandma understood; she took her in her arms and said, “Tell you what, you come back with me and ask your daddy to lift you up to have a close look at Jenny. Then you tickle him the way he likes it and tell him you love him very much. How is that?” Thalia still sulked but did as Grandma suggested. Her father cuddled her and said, “You are my big girl, Thalia.”

On their way home, Thalia was quiet for a while, then—out of the blue—she announced, “Grandma, I am a big girl now and only babies wear Pampers. Will you teach me to use the bathroom? I know it will be difficult, but I will do my very best. And, Grandma, can you do it real fast?”

At home, Grandma began to lead Thalia through a series of toilet-training activities that, on the surface, might look familiar to anybody who has helped a child use the bathroom. However, there were a number of significant and purposeful differences. Grandma first explained that she had taught a lot of children to use the bathroom and that all these children felt confident that they could do it her way. Next she explained that children might want to use the toilet seat in a different direction than adults do, because they need to have a firm grip on something for support, for example, the toilet paper holder. They went through the successive motions together. “First, you observe what the best sitting direction is and which object you can use for support. Can you tell me what this could be, Thalia? Yes, the toilet paper holder would be a good choice. Then you lower your pants, and when you have a firm grip on the toilet paper holder, you lower your body on the toilet seat. When you’re finished, you pull yourself up and use some paper to clean up. Finally, you flush the toilet and pull up your pants.” Thalia repeated in her own words what she did while performing the successive actions. Then she went through the successive motions herself while Grandma pretended to clean the bathroom.

Grandma laughed when she heard Thalia say to herself, “Hold your hands firmly on the toilet paper holder for support.” She remembered that one of her teachers had stated that Vygotsky was the first to describe how young children use private speech as a way to develop internal control of their thoughts, feelings, and actions. Then she heard Thalia scream and discovered that she was hanging halfway between the wall and the toilet seat. While Grandma was helping the child to find her

balance, Thalia said, “Grandma, I tried to tear off some toilet paper but I lost my balance. I still cannot do it alone but I will try again later.”

In the next few days, Grandma encouraged the training process by giving appropriate feedback and emotional support. Thalia reflected on her actions and asked several questions, such as, “Grandma, what will happen if there is no toilet paper holder to hang on to? What can I do if the toilet seat is too high to sit on? Can we practice in another bathroom?” By the time her mother and baby sister came home from the hospital, Thalia had become a competent user of the bathroom, who was independent of the adult who had instructed her.

Thalia’s case provides a real-world context for this chapter. I selected this true story because I was impressed by the self-regulation strategies that a 2-year-old could use to pursue her own goals. Thalia formed a mental representation of the hospital situation. She observed that her parents were focused on Jenny and that they neglected her. She interpreted her parents’ behavior as a signal that they loved Jenny more than her. She wanted to do something to change the situation for the better but felt helpless.

Thalia has a goal and she is aware that she does not have a plan of action to pursue this goal. Hence, Thalia provides us with evidence that she searched her memory for a strategy that she had used in the past that would be appropriate in the present context. Winne and Perry (2000) have referred to this type of knowledge as “conditional knowledge,” or if-then chains that link conditions to cognitive operations. This knowledge is necessary to produce new cognitions or behavior products.

Why is self-regulation an important construct, and what might the reader find in this review? In longitudinal classroom studies, my colleagues and I have examined the relative contribution of high school students’ work habits and their perception of situational cues on the intensity of reported effort after completing mathematics homework. We found (e.g., Boekaerts, 2002c) that the intensity of effort was predicted by the students’ learning style (i.e., the type of learning strategies they preferentially used in a domain), their volition style (i.e., whether they had access to volition strategies that promote taking initiative, persisting, and disengaging from ruminating thoughts), and their appraisal of the actual homework task. Our results showed that, after controlling for work habits, the self-regulation of effort in relation to mathematics homework is uniquely deter-

mined by students' perception of the task characteristics and their phenomenological experience. We found that perceived difficulty predicted the investment of effort negatively, and perceived task value predicted it positively. I think that these and similar results have shed light on the whys of students' self-regulation of motivation and effort and that these results are important for the design of new studies and for the promotion of self-regulation in the classroom.

In the first section of this chapter I argue that laypeople and researchers still have a hazy sense of what self-regulation entails. I highlight recent conceptualizations and empirical findings related to the self-regulation of motivation and effort, documenting why we cannot comprehend children's and adolescents' engagement and persistence in the classroom unless we understand how they steer and direct their behavior in the direction of valued goals and away from undesired goals. Accordingly, I propose to look at engagement and disengagement patterns from a self-regulation perspective. I supply examples from recent research, including my own research program, to illustrate how we have translated our theorizing about self-regulation of motivation and effort into research designs and into practice (guided principles for intervention), but also how practice led back into theory. In the final section, I offer some principles for research and practice and also point to some unresolved issues.

SELF-REGULATION IN THE CLASSROOM

Self-regulation is a construct that has been around for quite a while. As early as 1978, Vygotsky argued that young children are capable of regulating their own learning and can be most deliberate, involved, and committed to steering and directing their own actions. In the past 2 decades, educational psychologists have systematically explored the various ways that children and adolescents use self-regulatory strategies as a means to develop internal control of their thoughts and actions during the learning process. Numerous research studies have described the critical and complex relationships that exist between various aspects of self-regulation and achievement. What is self-regulation and which aspects of self-regulation have been studied extensively?

Recent theories of self-regulation locate the sources of individual functioning neither in static personality

traits (e.g., hardiness or conscientiousness) nor in environmental constraints and affordances, but in across-episode patterns of self-regulation. Boekaerts, Maes, and Karoly (2005) defined self-regulation as a multi-level, multicomponent process that targets affect, cognitions, and actions, as well as features of the environment for modulation in the service of one's goals. Given this definition, the key self-regulation processes are goal-related and include goal establishment, making an action plan, goal striving, and goal revision (Austin & Vancouver, 1996). In the classroom, the most salient goals that students need to establish, plan, strive for, and revise are *learning and achievement goals*.

A scan of the literature on self-regulation in the classroom reveals that educational psychologists proposed several evolving models of classroom self-regulation (for a review, see Boekaerts & Corno, 2005; Boekaerts, Pintrich, & Zeidner, 2000; Perry, 2002; Schunk & Zimmerman, 1998; Winne, 1995). Each of the models emphasized slightly different aspects of self-regulation, yet all share some basic assumptions. All investigators assume that students who are capable of steering and directing their own learning process are engaged actively and constructively in a process of meaning generation, adapting at the same time their thoughts, feelings, and actions to steer and direct the learning process.

Despite this agreement, most educational psychologists involved in self-regulation research in the classroom have adopted a specific focus on self-regulation; they concentrate on the learning and achievement goals that students pursue in the classroom, thus narrowing the scope of students' ability to self-regulate through a deliberate focus on the cognitive aspects of self-regulation that are necessary and sufficient to steer and direct the learning process. The advantage of such a clear and deliberate focus on the regulation of the *learning* process itself is that these self-regulation models have been firmly grounded in domain-specific theories of competence development.

Detailed information is now available on the regulation strategies that successful students use in different subject matter areas, such as on how children become competent text processors (Pressley, 1995), composition writers (Scardamalia & Bereiter, 1985), and problem solvers in science and mathematics (De Corte, Verschaffel, & Op 't Eynde, 2000). The basic assumption of most self-regulation models that focus on the regulation of the learning process is that students cannot steer and

direct their own learning unless the conditions for self-regulation are present. What are these conditions? An answer provided by educational psychologists who primarily focused on the learning process is that students need to have ready access to a large repertoire of cognitive and learning strategies, awareness of these strategies, and knowledge of the contexts in which these strategies will be effective (Hattie, Biggs, & Purdie, 1996). Investigators who took the students' motivation as their focal point of interest give a different answer. These researchers argued that students need to have ready access to a large repertoire of motivation and volition strategies, awareness of these strategies, and knowledge of the contexts in which these strategies will be effective (Boekaerts & Corno, 2005; Paris & Paris, 2001; Wolters & Rosenthal, 2000). In the next two sections, I briefly review studies that documented these complementary viewpoints.

Self-Regulation Is Metacognitively Governed

Winne (1996, p. 327) defined self-regulated learning as a "metacognitively governed behavior wherein learners adaptively regulate their use of cognitive tactics and strategies in tasks." Winne and Hadwin (1998) further argued that self-regulated learning consists of four interdependent and recursive phases: defining the task, goal setting and planning, enacting the plan, and adapting one's approach and strategies when a desired goal or outcome has not been met. Winne's work followed the tradition of Flavell (1979), who had made a clear distinction between cognition and metacognition (cognition about cognition). In the 1970s and 1980s, the work of two developmental psychologists, Flavell (1979) and Brown (1978) was influential as a way of studying the development of students' capabilities over time. Both theorists highlighted the construct of metacognition and defined it as students' knowledge about cognitive processes (e.g., study skills, cognitive and learning strategies) and their self-awareness of a knowledge base in which information is stored about which cognitive strategies are useful and effective to reach specific learning goals. Since then, numerous studies have shown that access to a coherent metacognitive knowledge base as well as the ability to use this knowledge base to reflect on one's learning and regulation processes are essential preconditions for the regulation of learning (P. A. Alexander, 2003; Pressley, 1995; Winne, 1995). The conclusion reached by three independent meta-analyses of learning skill interventions (Haller, Child, &

Walberg, 1988; Hattie et al., 1996; Rosenshine, Meister, & Chapman, 1996) was that promotion of a high degree of metacognitive awareness is a crucial feature of effective learning skill training.

Although not all of the research mentioned in this section has been categorized in the literature under the heading of "metacognition," these scholars all assume that self-awareness of and access to metacognitive knowledge directs learning (e.g., monitoring difficulty level, a feeling of knowing) and forms the basis for task analysis and determining task demands. Hence, self-regulating one's learning is best defined as an executive process that makes use of the available metacognitive knowledge and consists of a combination of metacognitive strategies by which students orient on the task at hand, plan and implement their actions, monitor and evaluate their choice of strategies, and remedy ineffective strategies (De Corte et al., 2000; Pressley, 1995).

Worldwide, children have profited from these insights and their applications. Teachers and school consultants have been informed on how to design intervention programs that target the development of cognitive and metacognitive strategies that form a prerequisite for self-regulated learning in everyday classroom activities. For example, De Corte et al. developed an intervention for the development of cognitive and metacognitive strategies in mathematics for primary school children and showed that students who learned to use these strategies were more competent problem solvers than students receiving traditional instruction. Similar results were reported with different age groups and in relation to different school subjects (for a review, see Boekaerts & Corno, 2005). Furthermore, worked examples of different self-regulation strategies have found their way into textbooks and homework assignments, and new instruction methods have been designed to improve children's cognitive and metacognitive strategies. An excellent example is the highly successful reciprocal teaching program designed by Palincsar and Brown (1984), in which teachers model comprehension and integration strategies, such as analyzing the text, asking questions, giving clarifications, summarizing, paraphrasing, and predicting.

Self-Regulation Is Consequential in Nature and Affectively Charged

Let us now turn to those researchers who provided an alternative answer to the question What are the conditions for self-regulation to occur? Motivation researchers

pointed out that many students have the capacity to use their metacognitive knowledge and (meta)cognitive strategies to direct their own learning, but they lack the motivation and volition to apply this knowledge when learning in a new domain.

Classroom life is complex; biological, developmental, contextual, and individual difference constraints interfere with or support students' self-regulation (Pintrich, 2000). There may be many reasons why students do not feel the need to invest time and effort in the selection of those cognitive and learning strategies that are most appropriate in a given learning context. Skill does not automatically create will; accordingly, students' appraisal of the learning conditions and their access to motivation and volitional strategies needs to be brought to the foreground to gain better insight into the self-regulation process as it occurs in real time (e.g., Boekaerts, 1997, 2002a; Corno, 2001; Pintrich, 2000; Randi & Corno, 2000; Rheinberg, Vollmeyer, & Rollett, 2000; Volet, 1997; Wigfield, Eccles, & Rodriguez, 1998; Zimmerman, 2000).

How do students choose the tasks and activities that they engage in? When are they willing to heighten their cognitive and behavioral engagement? Why do students lower effort during goal pursuit? Why do they quit certain learning activities more frequently than others? These and related questions are important to researchers, teachers, and anybody who is involved in student learning. Educational psychology abounds with terms that refer to motivated behavior in the classroom, including (school, intellectual, emotional, behavioral, and cognitive) engagement, effort (management, allocation, regulation), and persistence. Robust bodies of literature address each of these constructs. Reviewing this literature is a substantial task, but it is not my intention to duplicate excellent reviews, such as those by Corno and Mandinach (2004) and Fredricks, Blumenfeld, and Paris (2004). Instead, I want to draw attention to the lack of consensus on definitional components of motivation, interest, and effort regulation. In my opinion, we cannot comprehend children's and adolescents' engagement and disengagement patterns in the classroom unless we understand how they steer and direct their behavior in the direction of valued goals and away from undesired goals, especially when they are faced with obstacles, breakdowns, and setbacks. Boekaerts and Corno (2005) pointed out that, at present, the phenomenology of self-regulation strategies is heterogeneous, involving diverse types of patterns of self-regulation with different purposes, learning trajectories, and suscepti-

bility to intervention. What is needed is a comprehensive theory in which self-regulation is conceptualized as a systems construct and the different purposes that self-regulation serves are clearly defined, operationalized, and integrated.

DIFFERENT PURPOSES OF SELF-REGULATION: TOP-DOWN, BOTTOM-UP, AND VOLITION-DRIVEN SELF-REGULATION

In this section, I explain how the different purposes of self-regulation are conceptualized in my dual processing self-regulation model (see Boekaerts, 1993; Boekaerts & Niemivirta, 2000).

Top-Down or Higher-Order Goal-Driven Self-Regulation

I begin with a short introduction to my dual processing model of self-regulation as it is currently conceived. This model was first introduced in 1992 but was elaborated and extended over the years as theory building in self-regulation progressed and empirical studies shed light on the phenomena described in the model. The dual processing model of self-regulation that I developed together with my colleagues used insights from social psychology (Kuhl, 1985; Leventhal, 1980) to describe two goal priorities that students strive for in the context of the classroom, namely, achieving gains in their resources (e.g., extending their domain-specific knowledge bases, improving cognitive strategy use, increasing competence) and keeping their well-being within reasonable bounds (e.g., feeling safe, secure, happy, satisfied). Students try to achieve a balance between these two goal priorities by straddling the divide between the so-called mastery or growth pathway (e.g., striving for mastery goals; see broken lines in Figure 9.1) and the well-being pathway (e.g., striving for security; see dotted lines in Figure 9.1).

It is assumed that students who are invited to participate in a learning activity use three sources of information to form a mental representation of the task-in-context and to appraise it: (1) current perceptions of the task and the physical, social, and instructional context within which it is embedded; (2) activated domain-specific knowledge and (meta)cognitive strategies related to the task; and (3) motivational beliefs, including domain-specific capacity, interest, and effort beliefs. Task and self-appraisals hold a central position in

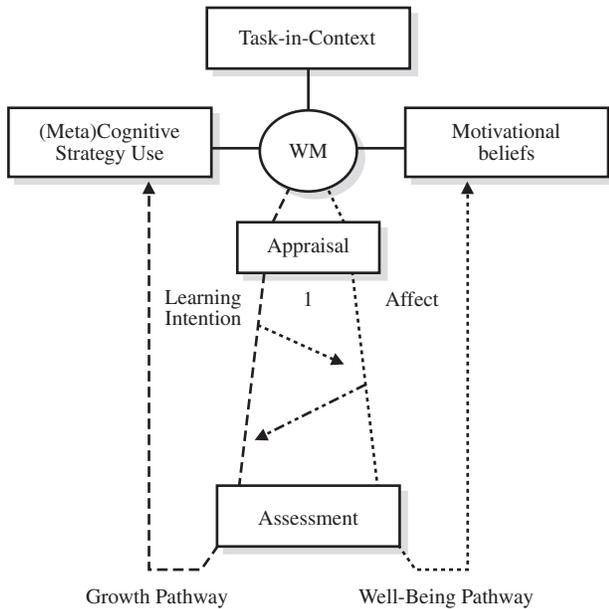

Figure 9.1 Dual processing self-regulation model depicting the different purposes of self-regulation: top-down self-regulation (---), bottom-up self-regulation (- - -), and volition-driven self-regulation (- - - - -).

the model. It is assumed that students are ready to start activity in the growth pathway when a learning opportunity, and the tasks or activities within it, is congruent with their salient personal goals or when they were successful in bringing the learning task in line with the core guiding principles of their goal system. In the latter case, they have adopted the learning goal, meaning that they have formed a learning intention, and start activity in the growth pathway. Hence, favorable task appraisals lead to self-driven self-regulation, meaning that students steer and direct the flow of energy from the top down. *Top-down self-regulation* implies that students' own values, interests, and higher-order goals, which are located at the apex of their goal hierarchy, drive their goal pursuit. At such a point, students' learning intention is firmly in place and they engage actively in the learning process (they start crossing the Rubicon; see later discussion for an explanation).

Bottom-Up or Cue-Driven Self-Regulation

As Kuhl and Fuhrman (1998) pointed out, good intentions may not be put into use and result in goal accomplishment. Many obstacles might occur en route to the learning goal, and students need access to specific self-regulation strategies to overcome these obstacles. For

example, environmental cues may signal to students that the learning environment is not safe. At such a point, students will start exploring the environment for further cues or quit the situation, rather than devoting attention and energy to the learning task itself. In other words, when children or adolescents detect cues that signal threat to psychological well-being, they will redirect their attention to the threat, thus drawing attention and processing capacity away from the learning task. This shift in focus is visualized in Figure 9.1 by the dotted line, marked 1, that runs from the growth pathway to the well-being pathway. In such instances, students are engaged in self-appraisal rather than task appraisal and bring different questions to bear on the situation, such as: Can any harm or loss of face come to me? Will I look stupid if I do this? or Is this a cool thing to do? My argument is that at some earlier point in time, a linkage has been created between specific environmental cues and the child's safety goals, and that activation of this linkage triggers negative emotions, experienced as turbulence, disturbance, or a discrepancy in the affect system (see also Covington, 2004; Pekrun, Goetz, Titz, & Perry, 2002).

The point being made here is that perception of specific environmental cues (task-in-context) may create a mismatch with the students' current learning intention and trigger cue-driven or *bottom-up forms of self-regulation* with the purpose of preventing threat, harm, or loss. Hence, unfavorable task appraisals prompt students to steer and direct the flow of energy bottom-up; cues in the environment and the anticipated negative consequences they call forth drive the students' goal pursuit. Boekaerts (1999) and Boekaerts and Corno (2005) described the purpose of this form of self-regulation as engaging in activities that maintain or restore the equilibrium in the well-being system. Several researchers have referred to this form of self-regulation as "coping" (Boekaerts, 1993, 1999; Frydenberg, 1999). Three basic forms of coping have been discerned: emotion-focused coping (e.g., crying, shouting, self-blame, denial, distraction, avoidance, delay), problem-focused coping (e.g., search for information, active and instrumental behavior, soliciting social support, mindful problem solving), and reappraisal of the situation (making a new mental representation of the stressor). Stress researchers emphasized that use of the different coping strategies critically depends on the students' appraisal of the situation and their awareness of and access to coping strategies that are effective to

restore their well-being in a given context. Note that this definition recognizes the criticality of metacognitive or conditional knowledge for effective coping, even though the term metacognition is totally alien in this field of study. By the same token, educational psychologists have not borrowed any insights from research on coping. Yet, the distinction that coping researchers have made between the different ways that children and adolescents deal with obstacles, setbacks, failures, and breakdowns is highly relevant for the self-regulation processes in the classroom.

Volition-Driven Self-Regulation

Accordingly, Boekaerts and colleagues (Boekaerts, 1993, 1999; Boekaerts & Corno, 2005) blended constructs and research findings from both these fields and proposed that students use two types of self-regulation strategies when environmental cues trigger emotions and a shift to the well-being pathway. At such a point in time, students may use their regulation strategies to explore the extent of the threat, loss, or harm to well-being in order to restore well-being to a reasonable level as fast as possible. However, they may also use their regulation strategies to target obstacles and setbacks for modulation in the service of the *learning* goal. Hence, the dual processing model of self-regulation assumes that students have two alternatives when obstacles arise. They may want to address the noted discrepancy in the well-being system urgently (i.e., emotion-focused coping) and stay on the well-being pathway. Alternatively, they may want to reroute their activities toward growth goals when environmental cues have triggered activity in the well-being pathway. This rerouting is visualized in Figure 9.1 by the path marked 2 that runs from the well-being pathway to the growth pathway.

The former way to target one's cognitions, feelings, and actions is relabeled *bottom-up self-regulation* to contrast it to top-down self-regulation (here a contrast is made between value-driven and interest-driven self-regulation versus cue-driven and emotion-driven self-regulation). The latter way of targeting one's cognitions, feelings, and actions is renamed *volition-driven self-regulation* because it refers to the effort students invest to stay on, or get back on, the growth path despite detected obstacles (here the contrast is between value-driven and interest-driven self-regulation versus volition-driven self-regulation). It might help to conceptualize volitional strategies as the switching track

of a railway system. By turning all lights to red in the affective system, students can continue with the learning activity; they stay on the growth pathway by blocking or attenuating activity in the well-being pathway temporarily.

It is important to realize that students who are on the growth pathway have direct access to motivation strategies that inject value and interest into the task or activity. Next, I provide a brief overview of theories, models, and research findings that underscore this statement.

SELF-REGULATION OF MOTIVATION

Thalia's case illustrates that self-regulation in a natural environment is consequential in nature and affectively charged. Learning experiences that occur in a natural context are often self-initiated or occur spontaneously. Another characteristic of natural environments is that learning is cumulative and socially situated. Thalia's example shows that a specific event (her baby sister is born) and her interpretation of that event *motivates* her to self-regulate her actions to develop a skill that she had considered difficult and redundant till that moment. What explains her motivation to acquire the new skill and her persistence despite setbacks?

One of the basic assumptions of my dual processing self-regulation model is that favorable task appraisals lead to value-driven or interest-driven self-regulation, meaning that the flow of energy fueling the learning process is coming from students' higher-order goals, based on their values, needs, and interests. In other words, learning acquisition is energized and directed from the top down. Several theorists made a clear distinction between goal-directed behavior where the meaning and value comes from the self and goal-directed behavior where individuals pursue goals that are valued by others, either because they cannot avoid these goals or because they are prepared to endorse them. (Kuhl & Fuhrman, 1998 preferred to label this form of regulation "self-control" to contrast it to true forms of self-regulation.) Clearly, many goals that individuals pursue in real-life classroom situations are located in between goals that are truly valued by the self and imposed goals. Nevertheless, the distinction between self-regulation and self-control is crucial because there is emerging evidence that the self-regulatory processes that steer and direct individuals' behavior toward these two different types of goals are distinctive (e.g., Grolnick & Ryan, 1987; Kehr,

Bless, & Rosenstiel, 1999; Kuhl & Fuhrman, 1998; Reeve, 2002; R. M. Ryan & Deci, 2002). I will take up this point again later in the discussion, but first I refer to two major forms of the self-regulation of motivation, namely, experiencing need satisfaction and attaching value to a task or activity.

Top-Down Self-Regulation: Experiencing Need Satisfaction

Deci and Ryan (1985) and R. M. Ryan and Deci (2002) placed the origin of people's motivation in three basic psychological needs: the need for competence, autonomy, and social relatedness. Anticipation of fulfillment of these basic psychological needs forms the basis for intrinsic motivation and autonomous self-regulation. These researchers predicted and found that when the learning conditions support a person's basic psychological needs, he or she will experience need satisfaction and show active and constructive engagement as well as positive emotions. By contrast, when the learning conditions frustrate one of the basic psychological needs, individuals will anticipate negative consequences and experience negative emotions. Thalia feels the need for social relatedness. She wants to relate to her parents and maintain the close bonds that she had with them prior to her sister's arrival. To keep their attention and love, she wants to impress them by showing that she can use the bathroom on her own. Anticipation of their positive reactions has created the need for competence; she wants to master a skill that she had not valued before. She also feels a need for autonomy; she wants to practice the new skill—not because her parents think she should not wet her pants but because she has decided that this skill is important for her.

This example illustrates that very young children can represent an immediate and urgent need mentally. It also shows that it is important that the environment facilitate the fulfillment of a given set of needs. The presence of her grandmother, who can help her focus on her needs by creating a succession of successful learning experiences, sets the scene for the development of effective self-regulation (e.g., “Grandma, what will happen if there is no toilet paper holder to hang on to? Can we practice somewhere else?”).

My main point is that optimal conditions for the development of self-regulation can be created when children are given the chance to pursue goals that they

themselves find personally relevant and are invited to develop their self-regulation skills by selecting their own tasks and activities, taking initiative, showing active engagement, and making their own decisions. Numerous studies have shown that satisfaction of the three basic psychological needs promotes well-being and positive functioning in individuals of all ages, whereas frustration of those needs creates ill-being (Kasser & Ryan, 1993, 1996; A. M. Ryan, 2000). Hence, information about the fulfillment of children's basic psychological needs will provide a basis for researchers, teachers, and school consultants to learn which aspects of the environment are supportive of children's active engagement and which are antagonistic to engagement and effort.

Fulfillment of Psychological Needs in a Classroom Context

There are a number of reasons why learning activities that foster self-regulation may be harder to realize in a classroom context than in a natural learning environment. Teachers often set learning goals for their students that are specified in the curriculum, and they create several successive learning episodes in which students are invited (read: coerced, coaxed) to show goal-directed behavior. Unfortunately, most teacher-provided learning opportunities do not automatically create a felt need, implying that students are not intrinsically motivated to acquire the new skill and that their behavior will not be guided by autonomous self-regulation.

Ryan and Deci (2002) gave the need for autonomy a primary role in the self-regulation process and described different types of motivation along a continuum of self-regulation. On the left end of the continuum they located controlled behavioral regulation; it occurs when a child feels coerced to attain a goal (e.g., “My parents would feel upset if I did not do my homework”). Autonomous self-regulation is located at the other extreme of the self-regulation continuum; it occurs when individuals choose the goal themselves because they feel a psychological need (e.g., “I want to solve this problem because I want to find out why this strategy did not work”). There is abundant evidence that when individuals feel ownership of their goals—either because they inherently enjoy the activity or because it fits with their values or higher-order goals—they devote more time, show greater concentration, and process information deeper (Grolnick & Ryan, 1987), experience flow (Csikzentmihalyi, 1990), and persist longer (R. M. Ryan

& Connell, 1989). Conversely, when individuals feel coerced to achieve a goal—either because they believe that external contingencies are the cause of their behavior (external regulation) or because they would feel guilty or anxious if they did not pursue the goal (introjected regulation)—they score lower on these outcomes. Lemos (2002) provided evidence that pressure to comply with goals of others hinders the personalization of goals and leads to overcontrolled, rigid behavior or undercontrolled behavior governed by one's urges (e.g., aggressive behavior).

In line with the theoretical assumptions of Ryan and Deci (2002), researchers and teachers expect that students' behavior will be guided from the top down by their own learning or mastery goals, yet they forget that most learning tasks that students have to complete in the classroom are not self-chosen and might frustrate the students' need for autonomy. Strong evidence supports the need for autonomy hypothesis in elementary school children. Children who work in classrooms where the teacher supports their need for autonomy (i.e., where teachers offer choices and create opportunities for decision making) work more strategically and persist longer when they meet obstacles (Nolen, 2003; Perry, 1998; J. C. Turner, 1995). However, no such strong effects were found in junior high school (Midgley & Feldlaufer, 1987). Eccles et al. (1993) explained these findings by reference to the large amount of teacher control, as well as the strong emphasis on rules and regulations, in junior high school. Interestingly, Kendall (1992) compared children from a Montessori school, where one of the main features is that students are given the opportunity to pursue their own goals by selecting tasks and activities that they value, with children from a traditional school. The Montessori children showed higher levels of initiative, autonomy, and self-regulation. Hence, it is important to have a closer look at how instructional methods interact with students' need for autonomy.

Nolen's (2003) recent classroom studies illustrated the autonomy hypothesis quite convincingly in ongoing classroom interaction. She studied second and third graders' states of mind in relation to writing and reading classes and found that these states of mind were dependent on the teacher's skills in setting up these classes. Nolen described how, in some classrooms, the teacher presented writing assignments as opportunities for creative self-expression and a way to share ideas. In those classrooms, children considered writing exercises

as a game. The wording they chose to describe their activities in class showed that they felt fully volitional in their actions and considered the classroom environment as supporting their autonomy. Examples of such utterances were: "You get to write about your own life" and "You get to make up your own stories." These statements contrasted to utterances recorded in classrooms where the teacher exerted more control over topics and style of writing assignments and assigned writing exercises primarily for evaluation purposes. The students in these classrooms viewed improving their writing skills as something done for school: "We had to copy all the words" and "You are supposed to write about your own ideas." Nolen concluded that the development of interest in reading and writing is influenced by the way students characterize reading and writing activity: as a job to be done for school, or as a way to share ideas and be entertained. It is important to note that feeling coerced or controlled does not reside exclusively in the environment. It can also be a state of mind that is triggered when being confronted with a domain by thinking about external rules and constraints that apply in that domain (R. M. Ryan, 1982).

Top-Down Self-Regulation: Attaching Value and Experiencing Interest

In the previous section, the emphasis was on the students' psychological needs and how need fulfillment fuels top-down self-regulation. In this section, I want to illustrate that the flow of energy might also come from the students' values and interest.

Attaching Positive Value to Tasks and Activities

Hickey and McCaslin (2001) argued that when learning is viewed as intrinsic sense making, engagement in the learning process occurs quite naturally. These theorists argued that engagement in learning is a function of prior experiences, learning, and understanding how the context interacts with the learning process. If students do not have a favorable expectation that they will be able to make sense of a learning task and its context, hardly any learning will occur. These assumptions underlie expectancy value theory, which assumes that individuals are motivated to perform tasks and actions that they value and perceive as manageable.

Eccles and her colleagues (Eccles, 1987; Eccles & Wigfield, 2002; Wigfield & Eccles, 1992) developed

and tested the expectancy value model in relation to the choices students make in achievement situations. One of the basic assumptions of the model is that all choices come at a cost: If you choose to solve one problem, read one text, or enroll for a particular course, it often means that you eliminate other options. Therefore, the relative *value* that students attach to each alternative and their perceived probability of success on the task are key elements in their decision-making process. Eccles and her colleagues identified four components of task value: intrinsic value (How much will I enjoy doing the task?), utility value (Is this task instrumental for attaining current or future goals?), attainment value (How important is it for me to do well on the task?), and cost (What will I lose or give up by doing the task?).

Eccles and colleagues also studied how students' competence beliefs influence the value they attach to a task or activity, and vice versa. In line with Bandura's (1997) self-efficacy theory, Eccles and Wigfield (2002) reported that changes in students' competence beliefs over a semester predicted changes in their value component, rather than the other way around. Wigfield (1994) pointed out the interesting developmental trend that young children's values and competence beliefs seem to start out relatively independent, but, over time, they might attach more value to achievement tasks that they can complete successfully and less value to activities that they find difficult. In fact, Wigfield et al. (1998) showed that at some point in time, values and competence-related beliefs become positively linked, thus ensuring that the individual maintains a positive sense of self. Accordingly, Eccles and Wigfield assumed that the positive affect that is experienced when one can successfully complete a task becomes attached to these activities and is triggered on later occasions. By the same token, negative affect may become attached to tasks and activities that one cannot perform well.

It is important to note that several of the value constructs that Eccles and her colleagues identified have been studied under different labels. For example, there is an extensive body of research on instrumentality, which is akin to utility value (e.g., Husman & Lens, 1999), and intrinsic value has been studied under different headings, most specifically under the heading of intrinsic motivation and interest (Hidi & Harackiewicz, 2001; Krapp & Lewalter, 2001; Renninger, 1990). Note further that self-efficacy and expectancy beliefs have long been identified as crucial in self-regulation and that the beneficial effect of self-efficacy on student interest and en-

gagement has been well documented at all ages (Bandura, 1997; Pintrich, 2000; Zimmerman, 2000).

Experiencing Interest

Sansone and Harackiewicz (1996) drew attention to the fact that theorists who focused on intrinsic motivation also considered expectancies and goal valuation processes as crucial components of their models, yet assigned specific meaning to these constructs. They also acknowledge that there are two aspects of outcome-derived motivation (expectancy and value) and that these two aspects work multiplicatively (students needs both aspects to regulate their motivation effectively). Sansone and Harackiewicz argued convincingly that it is important to make an explicit distinction between purpose goals and target goals. The former type of goal provides a reason for performing a task or activity (What am I trying to achieve and why?). For example, Thalia wants to learn to use the bathroom in order to impress her parents. The latter type of goal provides more concrete guidelines as to which steps should be taken at a specific point in time. Thalia wants to know what objects she can use for support in order not to lose her balance. In other words, Thalia derives motivation from activated knowledge about the purpose of her activities and she realizes that she needs to have access to concrete scripts (behavioral sequences) to keep her motivation alive.

Sansone and Harackiewicz (1996) proposed that motivation to reach the goal is also derived from the activity itself. In line with the extensive body of literature on interest (Ainley, Hidi, & Berndorff, 2002; Krapp, 2003) they described the positive phenomenological experience of intrinsic interest. Students feel like doing a task or activity when they are cognitively and affectively absorbed in a task and show high task involvement. Sansone and Harackiewicz predicted and found that individuals' phenomenological experience while working toward their goals exerts a greater influence on their willingness to engage actively in the activity than the initial motivation based on purpose and target goals. Applying these insights to Thalia's case means that outcome-derived motivation may be necessary and sufficient to draw Thalia into the toilet-training activity, but process-derived motivation is necessary to maintain performance over time. If Thalia does not have problematic affective experiences during goal pursuit, she will feel good about the training sessions and will be willing to invest time and effort to reach the goal.

The importance of students' phenomenological experiences while working toward the attainment of academic learning goals, particularly their emergent interest, in facilitating and maintaining performance in educational settings has been the object of investigation of interest researchers. For example, Ainley et al. (2002) showed that the nature of a task may have a major impact on students' phenomenological experiences and their engagement in the task. They reported several studies that showed the effect of emergent interest on students' continued engagement. These researchers found that students who were given a choice between two learning activities (e.g., which problem to solve, which topic to read or to write a composition about) activated stored information about the type of learning activity. The level of their reported interest in the topic, triggered by the teacher's brief description of the content of the learning activity, predicted the students' choice of activity and initiated engagement with the activity. Unfortunately, students discontinued the activity when they did not feel good about the task any longer, that is, when the learning experience did not live up to their interest expectation.

Interest researchers have also shown that students do not develop an interest in a study area or course unless they are invited to participate in learning situations that catch and hold their interest. Interest theory (Hidi & Harackiewicz, 2001; Krapp, 2003; Renninger, 1998, 2000) makes a distinction between situational interest and individual interest. The former develops during concrete interactions between the person and the object of (potential) interest, whereas the latter form of interest refers to a relatively stable tendency to engage in interaction with an object of interest. Krapp outlined how an object, topic, or activity that is introduced to a person evolves from an interesting situational event to a longer-lasting individual interest. He describes the growth of an individual interest out of a situational interest as a multistage process and considers attention and curiosity essential prerequisites for a longer-lasting interest to develop. The learner's attention should be caught and held long enough to allow experimentation and exploration; keeping the momentum going after the initial attention given to the object of interest is essential to proceed from situational interest to a stabilized interest stage that produces deep learning. A well-developed interest in a domain of study is reflected in a highly differentiated knowledge domain and many connections to other related domains.

Translating Value and Interest into an Intention to Learn

Researchers and teachers expect students to be interested in a multitude of topics, courses, instructional methods, and learning environments. They realize that when students have developed an individual interest in a domain, this ensures that they show a high readiness to acquire new information and to enlarge their competencies in that domain. However, students do not show longer-lasting interests with all school subjects, and it is essential that teachers support their students' meaning-, value-, and interest-generation processes.

Crossing the Rubicon

Heckhausen and Kuhl (1985) argued that for learning goals to be pursued, students' motivation in a domain has to be transformed into an *intention* to engage actively and constructively in concrete learning activities. These researchers also argued that intentions to act—even those that are self-intentional—might be abandoned later on because individuals do not invest enough effort in maintaining their intentions and protecting them from competing action tendencies. In other words, students may have established a goal and translated it into an intention to act in the goal-setting stage but give up on the goal in the goal-striving stage. The Rubicon model proposed by Heckhausen and Kuhl and later elaborated by Gollwitzer (1990, 1999) describes the link between the goal-setting and goal-striving stages as a path connecting two sides of a river representing commitment. Goal-setting processes precede commitment. These processes refer to the individuals' conscious and preconscious attempts to transform a motivational state into an intention to act. In the goal-setting stage, students make decisions about the targets, focus, expectancies, and type of engagement that they will commit themselves to. They may raise several "what, how, and why" questions before they begin to cross the Rubicon, such as "What is in it for me? How can I make this task more fun? Why is this skill important?" It is evident that it is much easier for students to commit themselves to a learning goal while crossing the Rubicon when (a) they value the activity; (b) they experience a positive experiential state, characterized by joy, excitement, a feeling of competence and interest in the activity; and/or (c) the environmental conditions catch their interest and hold it long enough for the activity or task to be completed.

Motivation Regulation Strategies. Several researchers have described the motivation regulation strategies that students use spontaneously or can learn to use to enhance their motivation in the goal-setting stage. Sansone and colleagues (e.g., Sansone & Smith, 2000) described a variety of avenues by which students may purposely enhance their interest and hold it during the pursuit of relatively uninteresting but important activities. One of these motivation strategies is self-consequating. This motivation strategy refers to students' attempts to anticipate the extrinsic consequences for their engagement or lack of engagement (Purdie & Hattie, 1996). An example of a self-consequating strategy that students use was provided by one of the teachers in our Partnership Program. One of her students said, "I prefer to use paraphrasing a paragraph in my own words as a memory strategy, but you give preference to writing down your own comprehension questions and answering them. I guess you will check whether we are studying your way, so I better start practicing this comprehension question technique." Evidence that students use self-consequating motivation strategies was found in children of different ages and different cultures (see Wolters & Rosenthal, 2000).

A second type of motivation strategy described in the literature is environmental control (Xu, 2004). This motivation strategy refers to students' skill at arranging their surroundings in such a way that it is easier to complete the task without interruption (e.g., switching off the television before starting homework). A third type of motivation regulation strategy is interest or value enhancement (Boekaerts, 2002b; Sansone & Harackiewicz, 1996). This refers to students' ability to make a task more enjoyable or more situationally interesting to complete. For example, students may vary their seating position when doing their homework, facing the door when they do their math homework and facing the map of Great Britain with photographs of the school trip to England while doing their language homework.

Goal-Striving Processes. When students arrive on the other side of the river, their learning intention is firmly in place and a volitional state of mind takes over. Gollwitzer (1999) referred to this state as an implementation mind-set. As the goal-striving process begins, the focus is on the best way to implement the goal, meaning that the necessary learning strategies are set in motion and that students need to have ready access to volitional

strategies to protect their intention from competing action tendencies. I will come back to the volitional strategies that students use in the goal-striving stage in the next part of the chapter.

Summary

The main conclusion that can be drawn on the basis of the reviewed literature on the self-regulation of motivation is that students who act on their felt needs, values, and longer-lasting interests self-regulate their motivation for learning automatically; their self-regulation is *primed* by their higher-order goals. In contrast, students, who do not attach value to an action or are not interested in a topic are not motivated to engage in the learning activity. These students have two main options. Their first option is to deliberately target their own cognitions, feelings, and actions in order to infuse value into the current learning task. I briefly described motivation strategies that students use to infuse value in learning tasks, and I referred to the interest-enhancing strategies that they use during the pursuit of relatively uninteresting but important activities. The second option is that they change the learning situation in such a way that it is brought in line with their own values, interests, and needs. For example, they can ask the teacher whether they are allowed to refocus their composition or their paper on a related issue that they are more interested in. Both these options refer to *nonprimed* decision making and thus may require conscious effort on the part of the student.

Bargh and Gollwitzer (1994) made an explicit distinction between deliberate self-regulation efforts and self-regulation that seems to take place with little thinking or effort on the part of the individual. They showed, for example, that performing a well-learned skill or an inherently interesting activity is initiated and maintained by processes that occur beneath the level of conscious awareness. In the next section, I focus on the role of conscious effort in the learning process, addressing volitional forms of self-regulation.

Self-Regulation of Effort

It is actually strange that we do not have a comprehensive theory of effort regulation that can guide interventions in the classroom, despite the well-established value of the construct for understanding student behavior.

ior and the practical applications it might engender. Reasons for the unpopularity of effort research might be traced to only a few factors. There is no evidence that effort is a cognitive construct, a common metric to measure effort is missing, and our models of self-regulated learning are not well equipped to study effort as it reveals itself in real time.

What Is Effort?

A first question that should be raised is What is effort? Is it a cognitive construct, or is it the emergent result of a constellation of properties of the learning task? If the latter is the case, what are the properties from which effort emerges? For example, do students take stock only of the time spent doing a task, or do they also take account of the number of (in)correct responses that they have generated so far? How do students conceptualize an effortless and an effortful accomplishment, and what are their ideas about hard work? To date, these questions remain largely unanswered. In my opinion, researchers have not capitalized on the potential of effort for theory building and practice.

There are several problems with the definitions, operationalizations, and assessment instruments that have been used in relation to this construct. The definitions vary, and it is not at all clear how the different constructs that are used in the literature, such as (emotional, cognitive, and behavioral forms of) engagement, effort investment, effort allocation, persistence, and perseverance, are related to self-regulation. For example, in their review on school engagement, Fredricks et al. (2004) defined effort as an aspect of behavioral engagement. Clearly, effort should be defined in relation to engagement, but its characteristic features should be operationalized in such a way that it adds to the explanatory power of the larger system of self-regulation.

Developmental psychologist Bloom and colleagues (e.g., Bloom & Beckwith, 1989; Bloom & Turner, 2001) argued that, from a developmental perspective, engagement is distinct from effort. They explained that engagement provides the motivation (energy) and directedness for development and effort ensures that this process goes forward. Children who are already engaged in a learning activity may—consciously or unconsciously—increase or decrease their level of engagement by investing more energy or time in the activity. The former decision refers to the *intensity* of effort and the latter to the *duration* of effort (persis-

tence). Bloom and Turner further explained that engagement and effort are two opposing principles that operate with an essential tension between them. In line with Kuhn's (1977) theorizing about theory emergence, these researchers hypothesized that developmental change in a domain is not simply quantitative or cumulative. For example, children do not become more proficient in understanding and expressing verbal messages by adding up words and sentences.

Bloom and Turner (2001) showed that very young children (13 to 24 months) want to talk about the things that interest them. However, toddlers often find that they cannot accommodate new experiences because their language skills are insufficient. At such a point, they use emotional expression to get their message across, such as pointing, shouting, hitting, and crying. These researchers showed that developmental change in language acquisition is the result of *effort* invested in experiencing and working through a succession of tensions between the old (e.g., what the child already can express in one-word sentences and emotional expressions) and the new (using syntax). Bloom's theorizing can also explain Thalia's behavior. She knew that it would be hard to acquire the going-alone-to-the-bathroom skill in a short period of time, but she was prepared to go through a succession of tensions to acquire it. Bloom and Turner's (2001) explanation can also be extended to include learning new skills in formal learning contexts, as I illustrate later in the discussion.

In educational psychology, researchers have adopted a multidimensional view of effort. For example, Weinert, Schrader, and Helmke (1989) have separated qualitative effort from quantitative effort, and Salomon and Perkins (1989) separated mindful effort from mindless effort. Weinert et al. distinguished between time spent (quantitative effort) and the type of cognitive strategies used (qualitative effort) and found that these different types of effort affected mathematics performance differentially in 10- to 12-year-old students. They found that students who had high scores on indices of mathematics ability (measured as either scores on the pretest or their self-concept of mathematics ability at the start of the study) spent high qualitative effort, and this in turn had a positive effect on their math achievement measured 2 years later. In contrast, students who scored low on indices of mathematics ability at the start of the study spent more quantitative effort, and this led to more anxiety, and in turn,

to low math achievement. Notably, all students invested effort, but not every type of effort produced learning.

What Assessment Instruments Have Been Used?

A second question concerns the validity of the assessment instruments that are used to measure quantitative and qualitative effort. Researchers have tried to measure effort quantitatively by using various indices of mental effort and processing load. Some researchers measured the number and duration of responses required to solve a problem, others measured students' time on task, and still others used physiological measures to assess ongoing mental activity (for a review, see Eisenberger, 1992). Kahnman (1973) argued that the total energy that can be exerted at any point in time is limited. Accordingly, it was proposed that dual task performance or multitasking increases processing load relative to single task performance. To the extent that these concurrent activities require attention and tap into the same pool of resources, they compete for processing capacity and tend to interfere with one another (Bloom & Turner, 2001; Case, 1992). This explains why low-achieving, less knowledgeable, or less skilled students often experience a *feeling of difficulty* and report having to invest high levels of effort into a task. I come back to this issue later.

How sound are the instruments we use to measure the effort that students invest in the classroom? Most researchers have used self-report instruments. Open-ended self-report measures ask respondents to tell in their own words how much effort they invested in a task, their homework, or exam preparation. Content analyses of the responses allow the researcher to quantify the level of effort reported by students who worked on the same task. An issue that complicates measurement when using narratives is that students may report effort in an unspecified way and there is no way of comparing their reported effort. Consider a teacher's or researcher's problem in interpreting the narrative of two students: Sarah says, "I spent the whole weekend preparing for this exam and I am totally exhausted. I really need a break." Howard says, "I studied real hard during the weekend and did my best to understand all the material." Judging from what these students reported, they each invested considerable time in exam preparation, but do these statements necessarily imply that the quality of the invested effort was high?

Self-report questionnaires of the Likert variety may give the impression that the assessment of effort is less problematic; they consist of a series of items that re-

quire respondents to reflect on the effort expended and then indicate on 4-, 5-, or 7-point Likert scales what level of effort fits their perception of the energy invested in a task or activity (e.g., "I invested *little* effort, *some* effort, *considerable* effort, and *great* effort"). The alternatives provided in most scales seem straightforward and easy to use, and they are rarely questioned psychometrically. Yet, one should ask what the exact meaning of the alternatives is for each respondent. What does "little effort" mean? Is it really less than "some effort"? How wide is the gap between "some effort" and "considerable effort"? Are students aware of the amount of effort they have invested? What metric do they use to communicate to others what the level of invested effort was? Kruger, Wirtz, Van Boven, and Altermatt (2004) found that individuals use an effort heuristic to judge the quality of a performance. Students seem to believe that the more (alleged) time somebody had invested in his or her performance, the better the product is. These researchers also found that the influence of students' perceived effort on their judgment of "quality" was bigger when the ambiguity of the outcome was high.

An issue that further complicates matters is that effort investment is not a linear process; for example, Howard and Sarah might have set themselves a rather general study goal and allocated effort quasi-automatically on Saturday morning, but they may have specified the goal further and revised their level of effort as the weekend progressed. For instance, Sarah's narrative informed us that, initially, she was satisfied with getting a B with reasonable effort. Feedback regarding time needed to work through the material indicated to Sarah that she could easily get an A if she strained herself a little more and did all the provided exercises as well. The favorable time feedback triggered a new aspiration level, prompting Sarah to add some effort that she might not normally have invested. In contrast, Howard started off with an A aspiration, working really hard on Saturday but scaling back on Sunday when he realized that it was next to impossible to cover all the study material and do all the exercises before Monday morning.

My argument is that these students may have started out with a specific idea of how much effort they were going to invest, changing the intensity and duration of their effort depending on certain characteristics of the task or the learning process. In other words, it is difficult to capture the dynamic quality of effort regulation during the goal-striving process. What is needed is a measurement instrument that can register the changing

levels of effort over time. To do that we need to establish an idiographic metric (Austin & Vancouver, 1996) that students can use to register and report on their changing effort levels during the different stages of exam preparation, goal pursuit, or a course. Idiographic measures facilitate within-person comparisons across time and subject matter areas but are problematic for comparisons across individuals. Future research on effort should address two dynamic aspects of the self-regulation of effort: how effort is allocated initially, and how it is maintained during the goal-striving stage.

CURRENT KNOWLEDGE ABOUT STUDENTS' EFFORT

In this section, I summarize what is currently known about students' effort beliefs and how these beliefs may influence increases and decreases in effort.

Students' Theory of Effort

Developmental psychologists have examined students' theory of effort. For example, Dweck (2003) deduced from her longitudinal research that to engage actively and constructively in a domain and overcome obstacles, children need to have access to a *coherent* network of beliefs, a meaning system in which they can integrate emerging new ideas and inject them with motivational value. An increasing body of knowledge endorses this view. In the early years of schooling, children seem to draw on isolated pieces of knowledge to interpret learning tasks and activities. Several researchers (e.g., Dweck, 1991, 1998; Nicholls, 1984; Paris, Byrnes, & Alison, 2001) showed that young children have fragmentary ideas about what good work is and what it takes to achieve it. They do not differentiate between ability and effort, believing that everybody who puts in effort will perform well.

Paris et al. (2001) clarified that children's theory of effort develops gradually over the middle childhood years; they unmasked the unrealistic belief that persistence, good work habits, and good conduct are sufficient to succeed in school, independent of ability. By the age of 10, children have developed ideas about their ability, and they begin to understand that ability is an internal quality that can predict their outcomes (Stipek & Daniels, 1990). They have also come to realize that putting in effort cannot compensate for low ability. An interesting finding reported by Dweck and her colleagues

was that, in the early school years, children may realize that they have not done well on a task and certainly performed worse than their peers. However, these unfavorable beliefs neither decreased interest nor elicited avoidance behavior, as they do in older children (Butler, 1992). Dweck (2003) argued that the reason why unfavorable experiences do not systematically affect actions in this age group is that their emerging ideas about ability and effort are not yet integrated into a coherent meaning system and have, as such, not yet gained consistent motivational value.

Dweck and her colleagues (e.g., Cain & Dweck, 1995) were also able to demonstrate that, between the ages of 10 and 12 years, children seem to have access to a theory of intelligence that reflects either an incremental view of intelligence or an entity view. A well-established line of research links the two theories of intelligence to goal orientation; the incremental view of intelligence is consistently linked to task orientation, whereas the entity view is linked to performance orientation (Pintrich, 2003). Blackwell, Dweck, and Trzemeski (2002) found that at about the transition to middle school (12 to 13 years), children's ideas about ability and effort come together in a network of motivational beliefs around their theory of intelligence and begin to show their impact on the goals they want to achieve and their academic behavior. Based on her longitudinal studies with freshmen in junior high school, Dweck (2003) outlined how children build their motivational meaning system around their theory of intelligence: Children who have built their meaning system around an incremental conception of intelligence focus on improvement and attainment. They view effort as instrumental to improvement and as a sign of involvement and commitment. These children have no problem admitting that they invested effort, even when their performance is (still) poor or when the teacher gives unfavorable feedback on their performance. They interpret errors and setbacks as a signal that more time (duration) and energy (intensity) is needed to increase competence; thus, persisting in the face of hardship, strategizing, and asking for help when necessary comes naturally (J. C. Turner & Meyer, 1999).

Conditional Knowledge Is Necessary for the Self-Regulation of Effort

In one of our own studies (Boekaerts, Otten, & Voeten, 2003), we found that students' activated effort and

ability beliefs led them to refrain from seeking control through effort in some domains at the benefit of gaining control in other domains. We asked freshmen in junior high school to indicate how much time they spent preparing for three regular end-of-term exams: history, mathematics, and text processing in their native language. We also examined their attribution processes of the exam results. Students seldom used effort as an explanation for failure in any of the school subjects studied, but they used it as the dominant factor to explain success in history (average preparation time = 120 minutes), in combination with level of difficulty in mathematics (average preparation time = 60 minutes), and not at all in relation to text processing (preparation time = 10 minutes). Based on these results, Boekaerts et al. suggested that students' willingness to invest time and effort in the acquisition of new skills is determined to a large extent by precoded information about subject matter-specific task demands and about their perceived capacity to meet these demands. This knowledge is akin to the metacognitive knowledge that I have discussed previously and is propaedeutic for the self-regulation of effort in a domain.

From the current research on effort and persistence it is gradually becoming clear that the best predictor of students' self-regulation of effort is conditional knowledge. Kuhl and Kraska (1989) showed that the knowledge that elementary school children had about the obstacles they might encounter during goal pursuit and the way to deal with these obstacles effectively predicted the intensity of their effort. In a similar vein, Efklides, Papadaki, Papantoniou, and Kiosseoglou (1999) reported that high school students who lacked metacognitive knowledge to interpret strategy failure in a specific domain could not decide whether or not it was worthwhile to invest further effort. These investigators showed that students who can act on their feelings of difficulty regulate their actions more effectively. In other words, knowing what effort entails in relation to different tasks and when it is needed is conditional to students' self-regulation of effort. Students also need to be aware of the strategies that are effective to increase or decrease effort, and they need knowledge of the contexts in which these strategies will be effective. The tendency to increase effort when needed and to maintain it despite distracters and obstacles refers to students' volitional competence. Volition is one of the most crucial factors of self-regulation; it is the main topic in our next section.

Promoting Volitional Strategies in the Service of Attaining Learning Goals

Many studies have examined how cues in the learning environment interact with students' felt needs to increase or decrease their active engagement (e.g., Connell, 1990; Skinner & Belmont, 1993); some researchers focused explicitly on how instruction strategies and task characteristics promote or inhibit participation and persistence. It is clear that many common educational practices actually reduce students' intrinsic interest in academic learning (Corno & Randi, 1999; McCombs & Pope, 1994). Educational practices that decrease students' sense making, particularly in disadvantaged students, include a focus on evaluations and grading, normative and relative grading, creating competition between students, public announcements of grades, retention, and acceptance of dropping out. Hickey and McCaslin (2001) argued that engagement in learning is enhanced when obstacles to intrinsic sense making are removed and intrinsic sense making is provoked. Over the years, several suggestions have been formulated for teachers to promote intrinsic sense making and persistence in the classroom. Before I look more closely at these suggestions, I try to answer the question What are volitional strategies?

Development of Volitional Competence

Volitional strategies are aspects of self-management; they refer to persistence, perseverance, and buckling down to work. Corno (1994) defined these strategies as students' tendency to maintain focus and effort toward their goals despite potential distractions. When do students need volitional strategies in the classroom? Many students experience difficulty getting started on an assignment or homework task. They may also get distracted while working on an assignment, for example, when they meet with obstacles or are sidetracked by competing goals (e.g., a telephone call, a program that starts on television, or a noise in the street). Corno reported that weaker students experience difficulty in implementing what she called "good work habits" that protect their intentions, particularly when difficult work must be completed. She argued that these students would benefit from instructions in good work habits. She listed several good work habits, including how to set goals and subgoals, how to prioritize goals, how to organize one's work, how to make a time schedule, how

to stick to that schedule, how to determine the time needed to do various assignments, and how to monitor time spent.

Are there specific situations in which students need volitional strategies? Boekaerts (2002a) and Corno (2001) formulated a number of hypothetical situations in which students need to control their learning environment. Examples are situations where there is a lot of noise in the classroom or where students would prefer to work on another task or with another person. There are also situations where students show a lot of anxiety, anger, irritation, or frustration that obstructs or interferes with their intention to take actions. Indeed, some learning situations may be tedious and boring, requiring a lot of willpower to stay focused on task. Other learning situations are complex and taxing and students might realize that they will meet many obstacles and will have to invest a great deal of effort to finish the assignment. I come back to the phenomenological experience of felt difficulty later in this section.

There are also a great number of learning situations that pose problems to students' intention to stay on track because competing goals catch their interest or concern. Hijzen, Boekaerts, and Vedder (2004) described social learning situations, where students in the group show various forms of low effort, such as preferring to chat instead of working with their peers, taking advantage of other students' work, skip meetings, and, generally, being unreliable about following up on work arrangements (see also Dowson & McInerney, 2001; Wentzel, 1991a, 1991b).

A question raised by educational psychologists as teachers alike is this: Are volitional strategies trainable? Kuhl and his colleagues (Kuhl, 1985, 2000; Kuhl & Fuhrman, 1998; Kuhl & Kraska, 1989) convinced educational psychologists that they are. In fact, volitional strategies develop from early childhood well into adolescence. What is needed for children to develop these strategies is a growing awareness of their own functioning, including their cognitive, motivational, and affective functioning. Kuhl and Kraska illustrated that socialization practices impact the development of volitional strategies in the home, in the peer group, and at school. Xu (2004) emphasized the importance of parents and teachers supporting and actively coaching children to develop willpower. How can teachers assist students in developing their willpower? Kuhl and his colleagues (see, e.g., Kuhl, 2000) proposed that the best way to train volitional strategies is in an "interactive partnership,"

where pairs of individuals work together and constructively react to each other's attempts at self-regulation, highlighting those aspects of goal pursuit that still pose problems for sustained effort. Several educational psychologists (Boekaerts, 1997, 1999; Boekaerts & Simons, 1995; Corno, 1994, 2001, 2004; Lemos, 2002; Perry, 1998; Xu, 2004; Xu & Corno, 1999) provided guidelines for teachers to enhance students' volitional strategies. A recommendation given to teachers and parents is to model volitional strategies and to discuss their effectiveness with students. In the next section, I take a closer look at the contextual factors that promote the self-regulation of effort.

Contextual Factors Impede or Promote Self-Regulation of Effort

Vygotsky (1978) described how adults can help young children to promote intrinsic sense making by helping them to form and retrieve mental images of an action plan (see my example of Thalia). Zimmerman (1998, 2000) reported the beneficial effects of parents, peers, and teachers who modeled self-regulation skills and encouraged children of all ages to copy their behavior. Zimmerman, Bandura, and Martinez-Pons (1992) described in detail how parents can function as explicit and implicit role models when they want their children to acquire a new competency. There is ample evidence that observational learning has a positive effect on children's and adolescents' learning as well as on their persistence when a task proves to be difficult. Adolescents who observed peer models persist on a difficult task showed increased self-efficacy, persisted longer on similar tasks, and improved their problem-solving skills (Martinez-Pons, 1996; Schunk & Zimmerman, 1998).

Students Need to Pick Up Environmental Cues

Increasingly, researchers advise teachers to interact with their students on the work floor, inviting them to monitor their actions and reflect on their attempts to self-regulate their effort while they work. Boekaerts (2002b) and Boekaerts and Simons (1995) described the monitoring instructions that teachers could give their students to build conditional knowledge about the intensity and duration of effort that is required to complete different types of assignments and about effective ways to see that the effort is maintained when the task becomes boring or difficult. Such monitoring instructions, as well as the recording of the volitional

strategies that were undertaken, will make students aware of the situations where volitional strategies are in order and the environmental cues that will tell them whether they have to maintain effort or can discontinue it. Consider the following:

Case Example

Anne Marie is a 16-year-old who wants to become a language teacher. She is well aware that it takes effort to acquire a foreign language at a native speaker level. Her attempts at self-regulation inform her mother that she is willing to invest all the effort it takes to reach her goal. For example, when her mother asked her how much time she still needed to finish her homework, she replied, “I will go on practicing until I can read this French text flawlessly. I will first isolate all the words that I have difficulty with and practice them. Then, I will underline them in the text so that I can see them come up in the corner of my eye while reading.”

This example shows that Anne Marie has set herself a purpose and a target goal. These goals allow her to follow the scripts she has specified beforehand, picking up cues in relation to her progress. Oettingen, Honig, and Gollwitzer (2000) and Corno (2004) showed that when such scripts have been put firmly in place before students need to use them in action, they can easily be activated at the time of use, thus acting as conditional knowledge.

Scripts to Deal with Distracters

Corno (1994) emphasized the key role of environmental cues, particularly *distracters*, in triggering the use of volitional strategies. She advised teachers to have their students draw up a list of possible distracters when studying and categorize them as to where and when they occur. She further suggested that teachers make an inventory of how their students deal with these distracters, comparing the volitional strategies they use and asking students to evaluate how well they worked. This procedure allows teachers to discuss the volitional strategies that their students have marked as “effective” and “ineffective” with the whole class and ask the students to explain why they thought these strategies were (in)effective to deal with a particular distracter. For example, Anne Marie told the class that she had dealt successfully with a distracter in the library. She said, “When I realized that I could not find the necessary resource material for my paper in the library because

other students pressured me to hurry up and vacate the computer, I told them that they would have to wait much longer if they kept bothering me. They took the hint and went for coffee.” Students might even model effective ways to deal with distracters while role-playing these strategies. As a follow-up on Anne Marie’s statement, they could practice effective ways to tell students to stop bullying their peers.

In my own intervention program with students in vocational education, I found that teachers who invite their students regularly to note down effective volitional strategies create a classroom environment where students enjoy discussing their own functioning in the classroom. One of the teachers even asked her students to write their effective volitional strategies on a poster and illustrate them with visual cues. This nicely decorated poster was put up on the wall in the classroom and students enjoyed adding new volitional strategies to the list. At a certain point, the teacher invited her students to consult the poster and pick out one or more volitional strategies that they thought appropriate in the situation they found themselves in. In this way, she coached them to build their conditional knowledge of the type of volitional strategies that are effective in specific contexts, using the information displayed on the poster. After a while, the students called the poster “Tommy” and recommended that their peers spontaneously “Ask Tommy” when one of them expressed doubts as to what to do in a difficult situation.

How Do Contextual Factors Interact with Self-Regulation?

Several intervention programs are currently being set up with students of different ages, and promising results have been reported. I will not describe these ongoing intervention programs. The interested reader is referred to Boekaerts and Corno (2005) and to the special issue on volitional strategies in *a special issue of Teacher College Record* (Corno, 2004). I do make one exception, because I want to draw the reader’s attention to a group of researchers who started to use a wide variety of recording techniques to study *in detail* (a) the self-regulation strategies that students of various age groups actually use to achieve their learning goals and (b) how contextual factors interact with students’ attempts at self-regulation (e.g., Perry & Vandekamp, 2000; Stipek et al., 1998; J. C. Turner & Meyer, 1999). The recording techniques that this group of researchers used included

observations, interviews, stimulated recall, recording students' motivation strategies as they work, self-reports, traces of mental events and processes, and keeping diaries.

Various aspects of the classroom environment seem to contribute to the emergence of self-regulatory skills, such as the types of assignments that the children had to work on, whether or not they had a choice, the type of instructions that were provided, the quality of the student-teacher interactions, and the type of assessment and evaluation procedures that were used. In one of these studies, Perry and her colleagues (Perry, 1998; Perry, Vandekamp, Mercer, & Nordby, 2002) showed that second- and third-grade students engaged constructively in complex writing activities provided their teachers used ongoing assessment, challenging them to make progress without threatening their self-efficacy. All the students who worked with teachers who coached their self-regulation skills demonstrated high self-regulation; they tried to manage all aspects of the writing process independently and flexibly. These students monitored their writing progress in productive ways and self-assessed their performance. Interestingly, when these students met with obstacles, they sought social support from their peers and teachers, and—remarkably—even the low-achieving students in these classrooms showed high self-efficacy for learning and did not avoid challenging tasks.

Second and third graders who had traditional teachers showed different behavior; they avoided challenging tasks and depended on their teachers for feedback and assessment. In fact, these students demonstrated various forms of bottom-up self-regulation, including hiding their work, reducing effort, avoiding different forms of external regulation, and procrastination. What have we learned from this and related studies about effective ways to promote students' volitional strategies? The variety of recording techniques used in these studies allows researchers to pinpoint those instructional techniques that foster intrinsic sense making and top-down self-regulation and contrast them to instructional techniques that promote various forms of bottom-up self-regulation and impede the self-regulation of effort. This information is of high theoretical and practical importance and can be used to design intervention programs to help teachers promote the self-regulation of motivation and effort in their students.

In the previous pages, I have concentrated on the volitional strategies that students need when they en-

counter distracters that draw their attention away from the task at hand. I have also discussed some techniques that teachers might use to help their students buckle down to work. There is also another category of situations that calls for the self-regulation of effort, namely, learning situations where students meet with obstacles en route to the goal. These situations are the next focus of attention.

Interpreting the Phenomenological Experience of Felt Difficulty

Why are some students successful in overcoming obstacles and difficulties to ensure the attainment of academic goals and other students are not? Perhaps one of the greatest barriers to students' volitional control is that they do not have easy access to volitional strategies when they encounter obstacles en route to the goal. These students need external regulation and a great deal of scaffolding to finish the task, mainly because they do not know how to deal with the phenomenological experience of "felt difficulty." Experiencing a feeling of difficulty during goal pursuit may imply several things. It may simply mean that students have met with obstacles of some sort that they had not anticipated and that they need to find their way around them. It may also imply that they are aware that they do not have ready access to cognitive and metacognitive strategies to go around the obstacle and that this awareness causes worries, low expectations, and self-doubt (see also Covington, 2004). My argument is that obstacles en route to the goal and the concomitant feeling of difficulty act for some students as a signal that more effort is temporarily needed to self-regulate the learning process (see also Zimmerman, 2000). In others, a feeling of difficulty may elicit negative emotions, thereby forcing students to change their appraisal of the task and of the self in relation to the task.

I have suggested elsewhere (e.g., Boekaerts, 1999) that students who are willing to increase the intensity and duration of effort when they meet with obstacles have a good chance of remaining on the growth pathway. In contrast, students who experience negative emotions when breakdowns or setbacks occur may tend to conclude prematurely that they are unable to reroute activity from the well-being pathway to the growth pathway because their phenomenological experience inhibits them from dealing with the obstacles in an effective way. They want to attend promptly to an immediate and urgent need to restore their well-being by disengaging

temporarily or permanently from the task. These students may come back to the task later on, but in a smaller way (e.g., by scaling down). Redefining the effort that is needed to perform a task or activity can be seen in Figure 9.1 by following the dotted line connecting the growth pathway with the well-being pathway (marked 1) in combination with the line (marked 2) that leads the student back to the growth pathway.

Clearly, insight into the cognitions and feelings that students experience when they meet with obstacles, setbacks, breakdowns, and strategy failures is essential to help them self-regulate their effort when they meet with obstacles. Several researchers described what actually happens when individuals experience a feeling of difficulty during goal pursuit (e.g., P. A. Alexander, Graham, & Harris, 1998; Carver & Scheier, 1981, 1998, 2000; Efklides et al., 1999; Winne, 1995). These accounts can roughly be subdivided into affectively charged insights and metacognitively oriented insights. I discuss each in turn.

Experience of Difficulty: Low Confidence and Doubt

Two social psychologists Carver and Scheier (1981) theorized that effort reflects both the presence of a goal and awareness of how one is doing relative to standards. For example, Anne Marie told her mother that she would keep practicing till she could read the text flawlessly. Hence, she set herself a high standard, implying that she had a clear purpose and expectancy as well as a ready script to attain the goal. As argued previously, expectancies have a profound influence on motivation, whatever their source. Individuals generate expectancies about the outcome of their actions as they work, and these expectancies (confidence or doubt) influence the effort they are prepared to invest. Individuals who have experienced obstacles in relation to an activity (domain) in the past may interrupt their efforts periodically to assess in a more thoughtful way than occurs while acting the likelihood of a successful outcome. This assessment presumably depends to a large extent on their prior learning history in relation to the activity, on their knowledge about the reasons why these obstacles occur, and on their anticipation of the additional resources they might need to overcome the problem.

Carver and Scheier (1998) showed that college students invest effort and renew effort investment provided

expectancies for a successful outcome are sufficiently favorable. If doubts are strong enough, individuals are inclined to disengage from further effort and even from the goal itself. Disengagement may take the form of overt or covert avoidance behavior. Examples of the former type of avoidance are various forms of giving up, such as quitting the situation, dropping a course, and redirecting one's actions. Illustrations of covert avoidance are daydreaming, wishful thinking, and denying the importance of a goal. Note that these are examples of what I previously labeled emotion-focused coping or bottom-up self-regulation.

Wrosch, Scheier, Carver, and Schultz (2003) maintained that disengagement requires a person to withdraw not only effort but also commitment from unattainable goals. They showed that disengagement can be beneficial to well-being and is most adaptive if the person engages in other meaningful activities. The "scaling back" phenomenon described by Carver and Scheier (1998) and illustrated in Howard's example is a form of partial disengagement. When scaling back, students have in fact given up on the initial goal (e.g., an A grade) while simultaneously substituting it with a more manageable goal. Scaling back is a way to stay in the situation in a meaningful way, even though in a smaller way than originally planned. Students who scale back perceive progress toward an important goal and experience positive affect and confidence, two important ingredients of effortful accomplishment.

An interesting question is this: What makes an individual decide that investing more effort (persistence) is to no avail and that he or she needs to reduce effort, delay, or give up? Several researchers referred to a point in time when an individual considers effort as fruitless and stops trying. They conceptualized this discontinuity between engagement effort and giving up as a perceived shift in difficulty level (e.g., Efklides et al., 1999) or as perceived loss of control (Schwarzer, Jerusalem, & Stiksrud, 1984). Based on insights from their own research, Carver and Scheier (2000) reconceptualized the point of discontinuity as a *region* of discontinuity. This region marks the range of tasks where task demands are close to the individual's limits of performance. In this region, there is a greater variability in observed patterns of engagement effort. Carver and Scheier posited that a person might enter this region from two different directions, leading to different predictions. Individuals who starts out confident but meet many obstacles on their

way to the goal will continue to invest effort, even if situational cues imply less and less basis for confidence. By contrast, individuals who enter the region of discontinuity from the low confidence direction but perceive environmental cues indicating otherwise will continue with little effort, even when situational cues imply more and more basis for confidence. Note that Thalia entered the region of discontinuity from the high confidence direction and continued to invest effort even when she met with obstacles (e.g., when she lost her balance).

Experience of Difficulty: Taxing Processing Demands

Winne (1995) provided a metacognitively oriented insight of what happens when students experience a feeling of difficulty. He explained that students who are still novices in a domain make relatively more errors than competent learners, mainly because the newly acquired knowledge has not been proceduralized yet. For example, in mathematics, students may regress to number crunching when they have difficulty detecting the key words in a word problem that inform them what type of algorithm they have to apply. A request often made to these students is that they have to monitor cues that prevent errors from occurring. However, the monitoring processes that are relevant in the new domain may not have automated yet, meaning that the monitoring process heavily taxes the students' limited attentional resources and working memory capacity. Two social psychologists, Kanfer and Ackerman (1989), neatly showed that fewer cognitive resources are needed to run a proceduralized skill than to perform multiple accesses of propositions strung together in a declaratively encoded rule. They explained that once the transformation from declarative knowledge to proceduralized skills has taken place, which occurred in their experiment around the seventh trial, individuals were able to shift their cognitive resources from the learning process per se (i.e., proceduralizing the new skill) to the regulation of the learning process.

These and similar experiments show that the performance of novices will be disrupted by increasing processing demands, simply because novices have a fragmentary, poorly integrated domain of knowledge and do not yet perform many subprocesses on automatic pilot. P. A. Alexander et al. (1998) shed some light on this issue. They described the multiple stages of exper-

tise development in a domain and reported that students from different types and levels of education proceed through three successive stages of skill development: acclimation, competence, and expertise/proficiency. During the acclimation stage, individuals have limited and quite fragmented knowledge of the domain, and they basically use shallow information processing. During the competence stage, students' domain knowledge becomes more coherent, and they start building up knowledge about the obstacles that might occur during task performance and about various ways to deal with obstacles (metacognitive or conditional knowledge). In the proficiency stage, individuals express personal interest in a domain and have access to a rich and principled knowledge base in which a large repertoire of (meta)cognitive strategies is stored as well as metacognitive knowledge about the context in which these strategies are effective. A great deal of information is currently available about how experts in a domain self-regulate the acquisition of new knowledge by selecting, combining, and coordinating cognitive and metacognitive strategies in functions of their reading and writing goals and the perceived contextual cues (e.g., P. A. Alexander, 2003; Pressley, 1995). Zimmerman (1998) listed the volitional strategies that experts in different disciplines (i.e., students, writers, athletes, musicians) use to stay on track. Csikszentmihalyi (1990) described the all-engrossing task engagement of proficient learners. Like experts, proficient learners experience flow, which is characterized by positive affect and a feeling of being lost in time. This timeless experience might explain why expert learners have recollection of an *effortless* performance (i.e., they report low effort despite high-quality deep-level processing).

In contrast to these experts, novices may have recollections of effortful performance despite poor results. Alexander, Graham, and Harris (1998) characterized *effortful* processors as students who perform adequately in the early years of schooling, in part because they are goal-directed and are prepared to expend high levels of strategic effort in the pursuit of understanding or commendable performance, even despite limited topic knowledge and when facing obstacles. These students are aware that they need to invest a lot of effort in their schoolwork and are willing to do so, provided the teacher provides a great deal of scaffolding. Nevertheless, effortful processors seem to have difficulty building a rich and coherent knowledge base in which declarative, procedural, and

conditional knowledge about a domain are well integrated. They also lack standards against which to monitor their effort investment. This raises the following question: When and why are students willing to invest effort in their schoolwork?

PROMOTING STUDENTS' WILLINGNESS TO INVEST EFFORT INTO SCHOOL WORK

In the previous three sections, I have reviewed the literature on the self-regulation of motivation, interest, and effort. It should be evident from this review that students' theory of effort, particularly the knowledge they have about the type of distracters and obstacles that may occur during a task or activity and how to deal with distracters and obstacles, is crucial to move the learning and self-regulation process forward. Based on the insights provided in the literature, I have formulated my own working definition of the self-regulation of effort in the classroom. It refers to the extension of mental and physical energy over time toward the achievement of a learning goal based on one's motivation meaning system and one's perception of the demand-capacity ratio. In my way of thinking, self-regulation of effort implies students':

- Awareness that a discrepancy may exist between their current goal state and the desired goal state
- Willingness to work through a series of tensions to reach the desired outcomes
- Willingness to interrupt their action plan when distracters or obstacles occur
- Willingness to reflect on the whys of distraction and strategy failure and on possible ways of dealing with perceived obstacles and with the emotions they trigger
- Willingness to select from their repertoire those strategies that ensure progress in competence development in the present context

This working definition illustrates what is presently known about the self-regulation of effort. It allows researchers and teachers to concentrate on specific aspects of the self-regulation of effort. Next, I provide an example from my own research program to illustrate some issues that were raised in the previous sections. The study that I report on illustrates how difficult it is to measure and interpret effort in the classroom. I want to show how theory about the self-regulation of effort led into practice and how practice led back into theory.

How Taxing Are Processing Demands in the Classroom?

Payne and colleagues (Payne, Bettman, Coupey, & Johnson, 1992) defined effort involved in the decision-making process in terms of the mental operations required to come to an accurate decision, including reading, analyzing, and making comparisons. The effort a decision maker has to invest is considered the "cost," and the accuracy of his or her response is considered the "benefit" of a decision-making process. These researchers argued that individuals adjust their processing mode flexibly to maximize benefits and minimize costs during decision making. Cost-benefit trade-offs account for many findings in the decision-making literature but have also found their way into stress research, work psychology, and educational psychology (e.g., Eisenberger, 1992).

In educational psychology, several researchers attempted to define and operationalize the mental operations and the processing load involved in various learning tasks. For example, Entwistle (1988) sorted text-processing strategies into two main classes: surface-level and deep-level processing. He showed that students who dominantly process information in a text by reading, skipping unfamiliar words, rereading, and memorizing use a shallow processing mode, whereas students who supplement and enrich these processing activities by structuring the information read and critically relating ideas and arguments expressed in the text to their own experiences use a deep processing mode. Entwistle assumed that deep-level processing requires more mental effort than surface-level processing.

In one of our own studies, we borrowed the cost-benefit construct from Payne and his colleagues and the surface-level and deep-level processing distinction from Entwistle and his colleagues. The question that we set ourselves was this: Do students adjust their processing strategies flexibly in order to maximize benefits and minimize costs while learning? I next briefly describe this study and then illustrate that several competing conclusions could be drawn for practice on the basis of the obtained results.

Training in the Use of Deep-Level Processing Strategies

During a 6-month training program, teachers explained to students in vocational school (between 15 and 18 years old) the benefits of deep-level processing strate-

gies for text comprehension and trained them to enrich their processing activities by structuring information read and critically relating ideas and arguments expressed in a text to their own experiences (see Boekaerts & Minnaert, 2003; Rozendaal, Minnaert, & Boekaerts, 2003). Our hypothesis was that after such a training program, motivated students would show an increase in reported deep-level processing strategies and a decrease in surface-level processing strategies. We expected that students low on motivation would go on using surface-level strategies. In addition, we predicted that anxiety (operationalized as performance and test anxiety) increases the use of surface-level processing and decreases deep-level processing. The anxiety hypothesis was confirmed, but motivation was positively associated with both types of processing. We also learned from these data that surface- and deep-level processing are not the opposite ends of a continuum, as assumed in the literature, but two distinct processing modes. Inspection of our data and interviews with students and teachers revealed that some students use both processing modes, others rely on a dominant mode, and still others are low on both processing modes. At that point in the data analysis, we went back to the drawing board and theorized that students cannot select cognitive strategies flexibly unless they have easy access to both processing modes; that is, they have a *choice* of strategy use.

Accordingly, Rozendaal et al. (2003) split up the available data set into four groups: students who dominantly used surface-level processing (SLP; 10%), deep-level processing (DLP; 20%), used both DLP and SLP (50%), and used neither DLP nor SLP (10%). We then estimated the relationships between motivation, anxiety, and the two processing modes for each group separately. We found that motivation and anxiety had a different effect on the processing modes in the respective groups. Motivated students tended to make use of their *preferred* processing mode(s), and anxiety was inversely related to the use of deep-level strategies. Does that mean that anxious students put more confidence in their preferential processing strategies, or rather that they tend to shy away from using the "more demanding" deep-level processing strategies, when they perceive the learning task (environment) as anxiety-provoking? Observations and interviews with students and teachers suggested that anxiety and lack of confidence played a key role in the selection of a processing mode. However, alternative explanations were also given for the phenomenon that students relapsed to surface-level processing

after the training period. Indeed, several theoretical perspectives have something to say on this issue and in the following I formulate some testable hypotheses about students' self-regulation of effort.

Willingness to Pay the Cost for the Anticipated Benefits?

It is important to realize that all students in our study, whether they used deep- or surface-level processing strategies or a combination of both, are self-regulating their effort, using their own theory of effort. To advise the teachers in the program how to coach their students' self-regulation of effort, it is essential to gain insight into the underlying mechanism, especially in the groups that do not use the new strategies consistently. What do modern theorists have to say about the mechanism that underlies the increase and decrease of effort?

Willingness to Work through a Series of Tensions

Developmental psychologist Carol Dweck (2003) shed some light on this issue. She and her colleagues gave children between 3½ and 5 years old the choice of continuing with puzzles that they had already solved before or trying new ones. Thirty-seven percent of the children opted to redo the puzzles they had already successfully completed. The main reason they gave the researchers was that they enjoyed doing these puzzles. By contrast, children who opted for the new puzzles said that they wanted to find out whether they could do a harder one. Interestingly, the children who opted for the new puzzles made significantly fewer negative statements about themselves and their puzzle-solving skills than the children who elected to continue with the puzzles for which they already had the necessary strategies. It is easy to imagine that for these children, familiar activities created less uncertainty and the impression of lower cost.

In line with Bloom and Turner's (2001) model of developmental change in language acquisition, I assume that the children who opted to do the familiar puzzles objected to investing *effort* in experiencing and working through a succession of tensions between the old (e.g., the puzzles they already can solve) and the new. Based on Dweck's and Bloom's findings, I suggest that the driving force for acquiring deep-level processing strategies reflects the essential tension between students' current engagement experiences (i.e., using surface-level processing) and their perception of the effort needed to master and feel comfortable with deep-level processing

strategies. This essential tension might have occurred only in those students who were *aware* that the teacher invited them to learn how to accommodate experiences that they could not accommodate yet but considered relevant. In other words, a hypothesis that could be tested in further studies is that students are willing to invest effort in learning to process a text using deep-level processing strategies *only* if they truly believe that they cannot achieve the same result by using already familiar processing strategies (i.e., surface-level processing strategies) and are prepared to work through a succession of tensions to master the new skill and tolerate the anxiety it produces (i.e., pay the cost).

My dual processing self-regulation model specifies the role of negative emotions, such as anxiety, in the self-regulation process. Debilitating thoughts and the concomitant negative affect create an internal context for the task or activity and change the task and self-appraisals. I have explained previously that the infusion of negative affect into task appraisals alters the students' perceptions of the task and triggers bottom-up self-regulation, which may block or attenuate all forms of volitional control to stay on the growth pathway. Kuhl (2000) described the characteristic ways that individuals who tend to experience negative affect when they meet with obstacles dwell on anticipated difficulties. Their processing capacity is overtaxed by questions such as "What if I will not finish reading the text in time?" or "What if there are too many words that I will not understand?" Boekaerts and Corno (2005) argued that students' skill in blocking these ruminations as well as the negative emotions that trigger them (i.e., switch these lights to red) will help students to reroute from the well-being pathway to the growth pathway.

Substituting a "Feeling Unconfident" State with a "Feeling Confident" State

A second explanation for the phenomenon we observed in vocational school relates to what Carver and Scheier (1998) referred to as the phenomenological experience of "feeling confident" about the task. Recall that these investigators found a greater variability in observed patterns of effort in the region of discontinuity, that is, in the range of tasks where task demands are close to the individual's limits of performance. Students who stuck to surface-level processing despite the training they received might have entered this region from the low confidence direction. This would imply that they continue

to use little effort, even when they perceive environmental cues that indicate that the task is not so difficult. The "scaling back" phenomenon described by Carver and Scheier (1998) might also apply here. The students who fell back on surface-level processing may have given up on the initial goal (i.e., process the text using deep-level processing strategies) while simultaneously substituting it with a more manageable goal (i.e., use the more familiar surface-level strategies).

As argued previously, scaling back is a way to stay in the situation in a meaningful way, even though in a smaller way than originally planned. Students who keep using the familiar surface strategies perceive progress toward an important goal and experience positive affect and confidence, two important ingredients of the self-regulation of motivation. Achieving this positive phenomenological state may, in their opinion, be a far greater benefit than the alleged processing benefits the teacher mentioned.

Novices Rely Heavily on Surface-Level Processing to Extend Their Domain Knowledge

A third explanation of the observed phenomenon relates to the students' appraisal that the tasks are too taxing. As illustrated previously, different streams of information are present in the students' working memory. On the one hand, there is information about the qualities and outputs of their *learning process* in progress. For example, students may think, "I do not understand what I am reading. What does this new heading mean?" On the other hand, there is information about various aspects of the *self-regulation of the learning process* in progress, including information about the monitoring processes (e.g., "There are so many new words and I do not know whether we have to look them up or read on and see whether we can grasp the meaning of the text without consulting a dictionary," or "We have to relate what we read to personal experiences. But I do not know anything about this text"). There is also information about the *self-regulation of motivation* in working memory (e.g., "I get the feeling that this text is too complicated for me to read. It is also so boring. I don't feel like continuing. Why am I doing this?").

All these why, where, how, when questions tax students' limited processing capacity while reading the text. They might react to this information overload by simply slipping back to what they normally do when processing a text, namely, reading, rereading, skipping un-

familiar words, rehearsing, and memorizing. P. A. Alexander et al.'s (1998) model of stages of developing expertise predicts that only those students who are in the competence or proficiency stage will use deep-level processing strategies consistently. These researchers showed that students who are still in the acclimation stage rely on surface-level processing strategies rather than deep-level processing strategies to extend their knowledge base and make it more coherent. Most students in our sample who relapsed to SLP might have had limited, fragmentary knowledge about the content of the texts they had to read and of the conditions in which deep-level strategies are superior to surface strategies. This lack of prior knowledge would categorize them as novices in the domain, and such categorization quasi-automatically implies that they make use of SLP rather than DLP (P. A. Alexander et al., 1998). In other words, what we had expected from these students was unwarranted, given their present competence level. I will add yet another explanation for low effort in the classroom that I have not mentioned previously, namely, effort minimalization due to conflicting goals.

Effort Minimalization Due to Conflicting Goals

Corno (2004) explained that students who have worked for a long time under unfavorable classroom conditions are likely to show unproductive work habits. I have previously referred to this phenomenon as low effort due to the perception of suboptimal conditions for learning, and I used Nolen's (2003) recent studies as an illustration of this principle. I believe it is essential to distinguish effort reduction due to suboptimal conditions from low effort due to conflicting goals. I prefer to refer to the latter phenomenon with the term *effort minimalization*.

As mentioned previously, modern students have much more on their mind than doing homework and preparing for quizzes and exams. Teacher-set assignments have to compete for limited resources with other activities, such as sports, dancing, going out with friends, and surfing the Internet. To the extent that preparation time and follow-up activities required for school fit into their overfull agenda, students are willing to invest the required effort in school tasks. Remarkably, Western teachers complain about their students' low effort for their academic studies, and students complain about their teachers' lack of insight into their overall task load. Why these conflicting views? I think that teachers assess benefits and costs

of homework tasks in terms of their instrumentality for future performance in school and beyond. In other words, teachers and researchers have a long-term time perspective, which often contrasts sharply with their students' short-term time perspective.

A study conducted in Leiden (Du Bois-Reymond & Metselaar, 2001) described the phenomenon of the "calculating student." These researchers found that high school students want to get the most out of the system (a certificate) as well as having a "fun" school time with the least effort. If they calculate well, they can have it both ways. They realize that if they miscalculate the resources they have to invest (attention, time, and effort), they have to bear the costs. The peer group and even their parents provide information, help, and support in this important matter. To straddle the divide between surviving in a school system on which they have no influence and enjoying autonomy and emancipation outside school they allocate resources by using modern media (mobile telephone, e-mail, fax, and the Internet) and their social network to share the work load and reduce time spent on homework and preparing for tests and exams. Valuable information about negotiation strategies that work with specific teachers is also exchanged. Du Bois-Reymond and Metselaar (2001) emphasized that modern students are aware of their personal and social assets (e.g., their social status, their parents' influence, their competence and energy, their skills to earn money to pay for their consumer needs), and they negotiate with teachers about how much effort is required for homework and to pass the exams (for further discussion, see Boekaerts, 2003a).

Is the work style described here an example of effort reduction due to suboptimal conditions, and if so, does it rely on the same underlying principles? I do not think it is. I speculate that the effort reduction observed in calculating students is not due to lack of value and interest in the task or to high perceived demand-capacity ratio. Rather, this type of effort regulation depends on societal factors that impact student behavior through peer-group influence (Rydell Altermatt & Pomerantz, 2003). Elliott and Hufton (2002) defended the view that societal changes have a powerful effect on students' perception of work rates and workload. For example, students' conception of hard work may undergo changes when it is common practice in schools that students have a part-time job to pay for their consumer needs (Steinberg & Sanford, 1991).

Summary

What I wanted to illustrate in this section is that different conclusions for practice could be drawn on the basis of our results. Due to a poor conceptualization of the mental load construct in relation to text processing, an inadequate assessment of students' self-regulation of effort, and a total neglect of the different stages of competence development in a domain, we were not able to identify the mechanisms that underlie the relapse to surface-level processing strategies observed in some of our students after the training period. However, we learned that modern theorists have a great deal to say about this phenomenon. We now have a better idea of why students do not make use of newly acquired processing strategies. One reason is that they judge these strategies as "benefits" but are not able to pay the cost for these benefits. Another reason is that they are not willing to pay the extra cost. Our results and the discussions that followed with teachers and fellow researchers helped me to conceptualize where effort is located in the self-regulation system and to formulate new hypotheses.

Where Is Effort Located within the Self-Regulation Process?

I explained previously that in my dual processing model, a distinction is made between two parallel pathways. Activity in the growth pathway is energized by top-down processing, and activity in the well-being pathway by bottom-up processing. At several points in the discussion, I have argued that students who have easy access to volitional strategies and are prepared to use them could stay on the mastery pathway and reroute activity from the well-being pathway to the growth pathway. I would like to suggest at this point that the underlying mechanism responsible for changes in the level of effort coincides with volition-driven self-regulation. More concretely, I have conceptualized volitional strategies as a switching track between the growth pathway and the well-being pathway. Is there evidence that students' conscious or unconscious decisions to increase or decrease effort during the learning process are located in the self-regulation system at the level of volitional strategies?

Student reports confirm that using volitional strategies to stay on the growth pathway or get off the well-being pathway comes at a cost. Students view volition-driven self-regulation to support top-down self-

regulation as effortful. Likewise, they report that recovering from emotions and redirecting attention to the learning task is effortful. J. E. Turner and Schallert (2001) illustrated that students who are on the well-being pathway can move into the growth direction if they (re)appraise the goal as instrumental and call upon volitional strategies to prevent unproductive rumination about shame and manage resources in the task. Preliminary evidence also comes from recent studies reported in social psychology by Baumeister and his colleagues. Baumeister (2003) reasoned that using willpower to resist temptation or to control emotional reactions costs energy that needs to be restored. They asked participants to complete a geometrical puzzle that was in fact unsolvable and measured the time participants persisted on the puzzle. However, before starting the puzzle, these participants, who had skipped a meal, were tempted with freshly baked cookies and chocolates. Half the participants were instructed to resist the temptation and instead eat radishes. Interestingly, those who resisted the treats tended to give up faster on the puzzle than either the participants who had not been tempted or those who had been allowed to eat the sweets. It seems that the effort needed to resist temptation interacted with the effort needed to persist on the task. A similar pattern emerged in a second experiment, in which individuals were requested to focus on their emotional responses as they viewed an upsetting video and either had to suppress or amplify them. Baumeister and Eppes (2005) found that participants who had to focus on their emotions and control them tended to give up faster on a successive handgrip-squeezing task than those who did not have to control their emotions. These researchers suggested that the self-regulation strategies that are needed to resist temptation or control emotions interfere with active engagement and persistence on a task (i.e., with the self-regulation of effort) unless the spent energy is restored.

Obviously, these results need to be taken to the classroom. Researchers need to study what types of volitional strategies students use when they are recovering from emotions and find it difficult to redirect their attention to the learning process.

CULTURAL DIFFERENCES IN THE SELF-REGULATION OF MOTIVATION AND EFFORT

In the 1970s and 1980s, investing effort into a task was considered akin to task engagement and was measured as

students' time-on-task (e.g., Fischer & Berliner, 1985). Researchers discovered that classrooms differ considerably in the time their students engage in academic learning, and that students who spent more time off-task scored considerably lower on standardized tests than students who were actively engaged in completing exercises. In the 1970s and early 1980s, students in typical classrooms paid attention to what they had to do about 70% of the time. This finding made headline news when the results of cross-cultural research in mathematics (e.g., Stevenson, Lee, & Stigler, 1986) revealed that Asian students show higher school achievement than U.S. students. Comparing the classroom behavior of students in Japan, Taiwan, and the United States and interviewing teachers and parents, Stevenson and colleagues had found that 65% of U.S. fifth graders' school days are devoted to academic activities, compared with 90% for Asian students. Asian teachers seemed to manage their classrooms differently, leading to more time-on-task. Moreover, attitudes of Asian parents and teachers toward learning and effort differed from those of their Western peers; they fostered a learning orientation that reassured students that effort and persistence are necessary and sufficient ingredients of the learning process. A prominent line of investigation in cross-cultural psychology clarified that divergent motivational practices exist between East and West. Markus and Kitayama (1991) and Kitayama and Markus (1999) reviewed the literature, showing that in Western countries, the key words describing students' motivational beliefs are *self-efficacy*, *self-esteem*, and attribution of success and failure to *ability*. Self-criticism is not encouraged and weaknesses are played down. As I have explained elsewhere (Boekaerts, 1998, 2003b), such a conceptualization of learning and achievement implies that Western students focus on their strengths and are motivated to invest effort only if they view success as being within easy reach. By contrast, Asian students have a fixed social role and want to fulfill that role to perfection. It is their responsibility to adjust to the context of the school and improve their academic and social skills. The key words that describe Asian students' motivational beliefs are attribution to *effort*, *living up to one's role expectations*, and *self-discipline*.

A number of recent cross-country and cross-cultural studies (R. Alexander, 2000; Elliott & Hufton, 2002; Larson & Verma, 1999) shed some light on cultural and societal influences that affect students' perception of task engagement, effort, and hard work. For example, R.

Alexander reported that student classroom engagement varies across different countries, and that students' understanding of the nature of authority and autonomy influenced their academic engagement to a considerable extent. He noted that students' academic engagement was lower in countries where they were allowed more freedom of action. Beaton et al.'s (1996) study confirmed yet again that Asian students (here: students from Korea and Japan), though ranking among the very best in mathematics and science in international comparative studies, have a relative low self-concept of ability compared with German students, but that they hold a firm belief that effort is necessary and sufficient to achieve in these subject areas.

Elliott and Hufton (2002) also reported consistent cross-cultural differences in effort beliefs. They found that Western students (here: students from the United States and the United Kingdom) put a greater emphasis on the instrumentality of effort for academic success than students in the Russian Federation (St. Petersburg) but seemed to have a different understanding of what "hard work" means. When asked about their work habits, Western students described lifestyles that did not underscore their statement that they worked "hard." Academic standards and achievement, as well as academic demands and work rates, tended to be much higher in St. Petersburg (before the massive changes that occurred in the social, economic, and educational systems of their country) than in the two Western countries. Russian students fully realized that effort (intensity) and persistence (duration) are essential to survive the harsh educational system, and they simply acted accordingly. Interestingly, Elliott and Hufton observed that Russian adolescents' conditions of growing up changed considerably after the massive changes. Their current understanding of freedom and authority is also different from before, and they follow their Western peers in their search for greater material gains. Like their Western peers, adolescents in the Russian Federation are nowadays confronted with multiple goals and many environmental distractions; they have to make many choices and their decision-making seems to impact favorably or unfavorably on their effort investment in school (see also R. Alexander's, 2000, results mentioned previously).

A word of caution is in order here. Many cross-country comparisons are restricted to a rather superficial description of the contrasting personality characteristics that different cultures value and promote during the

socialization process. Important aspects of children's and adolescents' everyday functioning are left out of the equation. In my view, students' self-regulation of motivation and effort can be understood only if we use a conceptual framework that casts children's and adolescents' behavior in terms of the self-regulation processes that they activate and generate to steer and direct their behavior.

GUIDELINES FOR FURTHER RESEARCH AND APPLICATIONS

In this section, I summarize what is presently known about students' self-regulation of motivation and effort in a set of principles that may guide further research and practice. I also point to some gaps in our understanding of the self-regulation of motivation and effort.

Principles for Research and Practice

Based on the literature reviewed previously, I have formulated 10 principles that may guide teachers when they coach their students to enhance their self-regulation:

1. *Mastery*: Effort investment leads to mastery.
2. *Compensation*: Effort might compensate for low ability.
3. *Familiarity*: Familiar activities create less uncertainty and cost less effort than unfamiliar or complex activities, which may create a phenomenological state of felt difficulty.
4. *Perceived demand-capacity ratio*: Effort is not needed if perceived capacity exceeds task demands.
5. *Interest*: Meaningfulness and task enjoyment create a phenomenological state that boosts motivation and effort.
6. *Cost-benefit ratio*: Students are prepared to invest effort if the perceived benefits exceed the perceived costs.
7. *Flow*: All-engrossing task engagement does not require conscious effort.
8. *Confidence and doubt*: When task demands are close to one's level of performance, confidence will increase effort and doubt will decrease it.
9. *Accommodation*: When new experiences cannot be accommodated, students need to understand that it is necessary to work through a series of tensions.

10. *Volitional strategies*: Self-regulation of effort requires that students are aware that volitional strategies are needed to achieve the goal, that they have easy access to these strategies, and that they are willing to use them.

These 10 principles are the cumulative results of current research from different research lines. What is the meaning of this information? Are these principles actionable? The good news is that, together, the 10 principles provide teachers and educational practitioners with a heuristic for predicting students' self-regulation of motivation and effort and for creating learning environments that stimulate students to invest effort. Taken together, the 10 principles predict low effort when students want to hide low ability, shy away from going through a series of tensions to accommodate new experiences, opt for activities they are already familiar with, doubt their capacity, are not aware of or do not have easy access to volitional strategies, expect high costs for low benefits, do not value the activity, or perceive the demand-capacity ratio as suboptimal.

Insight into the variables that impact students' self-regulation of motivation and effort is necessary to guide researchers who want to set up intervention programs, teaching consultants who advise teachers in the use of more effective instruction methods, and teachers who actually coach students in the classroom.

The bad news is that the 10 principles are of different breeds and that it is difficult to integrate them into a coherent framework. Some principles represent if-then rules of the type "If the task is such that the perceived benefits exceed the perceived cost, then students will invest effort." These principles describe the antecedents of effort. Other principles represent students' instrumentality beliefs about effort (e.g., effort is instrumental to achieve mastery). These principles describe the outcomes of effort. Principle 10 specifies the underlying mechanism of effort.

In other words, the 10 principles summarize what we currently know about the antecedents and outcomes of effort and about the mechanism itself. Unfortunately, next to nothing is known about whether all students are aware of these principles and endorse them, whether they are linked to specific content domains in a coherent way, or whether they exist in the individual's meaning system as fragmentary ideas about effort investment. Much is still to be learned about gender and cultural dif-

ferences in students' self-regulation of motivation and effort in different content domains.

Questions with Which the Field Is Still Struggling

At the beginning of this chapter, I observed that the concept of self-regulation is receiving increased attention because it represents a systems approach. A systems approach allows researchers to focus simultaneously on students' attempts to target their cognitions, feelings, and actions in the service of their goals and on their skill to pick up environmental cues to assist their self-regulation process. Studying all these aspects of self-regulation in one comprehensive framework offers several benefits for research, interventions, and classroom practice. A systems approach has the potential to interconnect areas of research and practice that have been studied in isolation. Integrating the results of isolated fields of study not only provides a richer description of the self-regulation processes that students engage in, it also provides an excellent framework for taking stock of our current knowledge and identifying gaps in our understanding.

Despite the large amount of information that is currently available on how students regulate their learning in the classroom, the literature has several gaps. It is in fact strange that we do not have access to a great deal of information on gender differences in self-regulation and that we have little information about the development of self-regulation over time. The evidence that I reviewed in this chapter suggests that the concept of self-regulation, particularly the self-regulation of motivation and effort, merits further exploration. Future research should address questions such as the following: How does the self-regulation of motivation and effort evolve over time? How do children build up their theory of engagement and effort? What types of contexts are beneficial (impede) the development of self-regulation of motivation and effort? How do differences in the self-regulation of motivation and effort affect school success? Answers to these and similar questions are essential to set up intervention programs that help teachers and schools to counteract the well-documented decline in intrinsic motivation after primary school. My conclusion is that the potential contribution of the self-regulation construct has yet to be realized, especially the *development* of self-regulation and the factors that influence this development.

| REFERENCES | 416 |

In the past 30 years, much has been written about the application of research to practice in order to promote the positive social development of children and youth. Many prevention and intervention programs have been designed to ameliorate the effects of risk factors that predict negative life experiences and promote positive contexts and capacities that optimize children's health, social welfare, and academic capabilities. The National Institute of Mental Health's report in 1977 (Klein & Goldstein, 1977), the publication of *14 Ounces of Prevention* in 1988 (Price, Cowen, Lorion, & Ramos-McKay, 1988), the Institute of Medicine report in 1994 (Mrazek & Haggerty, 1994), and the 2003 special issue of *American Psychologist*, "Prevention That Works for

Children and Youth" (Weissberg, Kumpfer, & Seligman, 2003) stand as historical markers of our progress. They document both the research and the debates that evolved over time as we moved as a discipline toward an emphasis on prevention and intervention in children's mental health and socioemotional competence. These documents expertly address the issues of children at risk and detail findings from intervention programs, thereby furthering our understanding of how to best help children and their families.

In contrast, we do not intend to write another review of evidence-based programs that prevent disorder or promote competence and wellness. Any one of the excellent summaries that have been published recently can direct

the practitioner, policymaker, or researcher to what is now called prevention science or evidence-based practice in the area of child and youth development (see, e.g., Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2002; Greenberg, Domitrovich, & Bumbarger, 2001; Nation et al., 2003; Wandersman & Florin, 2003).

Instead, this chapter is about the ways social development research in child psychology can be applied in school settings, and how research and theory in turn can be transformed by practice. The first part of the chapter begins by documenting the challenges faced by an urban public school in Boston as it negotiates the tricky terrain of choosing an intervention program designed to promote positive social development and reduce the risks of negative student outcomes such as school failure, conduct disorder, depression, and relational difficulties. In describing this school's story, we focus on the challenges faced by practitioners as they try to translate academic theory and research into daily practices that support social and emotional competence while under enormous pressure to achieve academic standards. Using this case study as a context, we focus on two critical questions: What aspects of social development are the teachers and administrators most interested in and How does research and theory fit into their everyday practice?

We outline and document some prevention/intervention programs that are available to the school and discuss the benefits and drawbacks of each as identified by the school in the process of choosing a program. This first part of the chapter introduces you to an "elementary school in distress," not the usual subject in developmental research or the usual patient in child clinical psychology. This story is about the challenges and problems of implementing research-based practice in an applied setting and the ways research may or may not meet the everyday needs and practices of an urban school.

The second half of the chapter begins by introducing a classroom in the school. Using our own domain of social development as a context, we describe the challenges and problems we faced in theory building and conducting research in an applied school setting. This case illustrates how our work in an applied school setting did not simply draw from previous research but also led to new knowledge. This second analysis not only considers what the academic discipline of social development has to offer to schools, but also shows how doing research embedded in a school contributes to the knowledge base of developmental psychology as a discipline.

Rather than simply evaluating research-based practice, we also discuss the process of what we call "practice-based research."

Finally, the chapter integrates the two cases to illustrate how we have come to a new way of thinking about the relationship among theory, practice, and research from what we believe is more common in academic, and even practical, settings. From the perspective of academics, we suggest that both researchers and practitioners alike overly privilege, if not idealize, the impact of theory and research on practice but do not always appreciate the value of the reverse. Despite the commonly heard rhetoric that practice and research ought to be integrated, we believe there remains a deeply held belief in the academic disciplines that there is a unidirectional, straight-line orientation from evidence generated by the sciences to its application in practice. Knowledge generated from research informs practice and policy: That is the tenet we have been consciously or unconsciously taught—by policymakers who seek to make informed policy decisions, by foundations offering us grants to further our work, by educators looking for ways to teach in their schools, for parents seeking help for their children. As researchers, we are seen as the "experts," and we often buy into this idea ourselves.

In the final section of the chapter, we suggest ways to reexamine this view. Using the two case studies describing the school and the children in the school, we demonstrate how and why we have begun to reevaluate our own definition of applied research. We use the discipline of social development as a base—our own area of so-called expertise—to show how we have attempted to bridge the gap between the researcher's scientific knowledge of child development and the practitioner's everyday experiential and clinical knowledge of children and adolescents.

Both case studies were taken from experiences we had while conducting research and managing prevention programs in Boston public schools over the past several years. The school and its administrators, teachers, school staff, and students are composites of real people and situations we have observed. We hope they will become as real to you as they have been to us.

PREVENTION RESEARCH IN THE LAST DECADES

Since the 1980s, prevention and intervention has become a dominant focus in child psychology. Just as medical

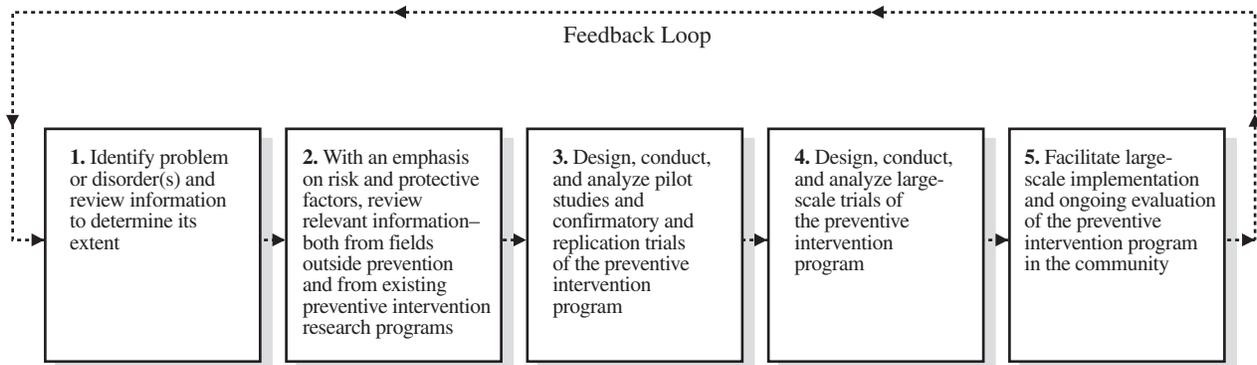

Figure 10.1 Institute of Medicine prevention intervention model.

health professionals are focused on reducing risks for heart disease, prevention and intervention programs are seen as essential for reducing the complex mental health risk factors facing today's children and youth (Mrazek & Haggerty, 1994). Research in developmental and child clinical psychology has been the foundation for many of the programs that have evolved. In these disciplines, a number of factors have been identified that can place children at risk for psychopathology and negative life outcomes. These factors range from biological, cognitive, and neurological problems to relational difficulties within families or with peers to contextual and environmental factors such as poverty and racial injustice (Cicchetti & Toth, 1998; Coie, Lochman, Terry, & Hyman, 1992; Dryfoos, 1990, 1997; Luthar & Zigler, 1992). At the same time, research has also identified assets and protective factors that can ameliorate these risks and promote healthy development, such as positive relationships with adults and peers, a sense of community, and success in school (Benson, Scales, Leffert, & Roehlkepartain, 1999; Catalano et al., 2003; Luthar, Cicchetti, & Becker, 2000; Roberts, Brown, Johnson, & Reinke, 2002; Scales et al., 2001).

In 1994, the Institute of Medicine (IOM) Committee on the Prevention of Mental Disorders established rigorous standards for prevention research. Although advances had been made in diagnosing and treating many mental illnesses, efforts to prevent the occurrence of problems in children and adults lagged behind (Mrazek & Haggerty, 1994). Although many programs had been created to reduce the risk of mental disorders, no clear guidelines existed to direct their development or evaluation. The Preventive Intervention Research Cycle (Figure 10.1) was created as a road map that researchers

should follow to foster psychological health among children and families in a systematic and scientific way. One of its main emphases was on making sure that program outcomes were scientifically evaluated using clinical trials. Too many programs, it seemed, were using research simply as support for their underlying principles and interventions, rather than making the next step toward using outcome research to discover whether the interventions actually worked (Wandersman & Florin, 2003).

Step 1 in the IOM cycle was to identify the problem and review research on its prevalence. Program developers, it was recommended, should inquire into the level of community concern around the problem, review its costs to the wider society, and develop a relationship with the members of the community who are most affected (Mrazek & Haggerty, 1994).

To illustrate how this step could play out in reality, we introduce you to our first case: the teachers, students, and staff at the Gilmore School in Boston, Massachusetts. This case is based on real people and real schools with whom we have worked over the past several years, although names have been changed to protect their privacy. It is, in effect, an introduction to a community of people who may be at risk for any number of negative outcomes, including psychopathology (at the student level) and school failure (a community problem).

Nothing that is worth doing can be achieved in our lifetime; therefore we must be saved by hope.

—Reinhold Niebuhr¹

¹Reinhold Niebuhr (1892–1971) was an American theologian and the author of *The Irony of American History* (1952).

CASE STUDY 1: THE SCHOOL HAS A MENTAL HEALTH PROBLEM, CAN IT BE TREATED?

The Gilmore School is located in an urban neighborhood in Boston. The Gilmore has a student enrollment of about 250 students, with 84% identified as Black or African American, about 10% Latino/Hispanic, 3% White, 1.5% Asian, and 2% other/mixed. These racial and ethnic categories reflect the U.S. census and the demographic categories used by the Boston city government and Boston Public School system (Auerbach, 2001).

The 2002/2003 school year was particularly difficult for the school. Like many schools struggling under state and federal mandates, the Gilmore was under state review and labeled an “underperforming school” because it had not made “adequate yearly progress” on the Massachusetts Comprehensive Assessment System (MCAS). Under the No Child Left Behind Act (2002), which links Title 1 funds to academic performance, schools that have not made adequate yearly progress for 5 years are “identified for corrective action” (Boston Public Schools, 2003). The MCAS is the statewide student assessment initiative; since its inception in 1999 the Gilmore students had performed poorly in both English Language Arts and Mathematics. Because of the lack of demonstrated improvement, a team from the Massachusetts Board of Education conducted regular evaluations of school functioning. Their presence contributed to an overall sense of uneasiness and stress felt by the teachers and the students alike.

In addition, the City of Boston had experienced a major budget crisis during the school year, and millions of dollars were cut from the education budget. The budget crisis depleted school resources and further contributed to teacher stress because it resulted in staff layoffs and undercut job security. Therefore, in the 2002/2003 school year, the Gilmore experienced both diminished teacher human resources, due to stress, and low monetary resources, due to budget cuts. The school was undernourished.

To help the students succeed academically, the school needed to focus on literacy. All teachers were trained to link assessment with instruction and used the Reader’s and Writer’s Workshop models to improve reading and writing skills (Boston Plan for Excellence, 2004). In addition, the school provided a number of other instructional resources: Title I Reading, Reading Recovery (Clay, 1993), a resource room, literacy/math

tutors, transition services for grades 3 and 4, and MCAS skills class for students in grades 2 through 5. For the 2002/2003 school year, the biggest challenges at the Gilmore were raising teacher morale and trying to help students succeed academically and raise their scores on the MCAS. Essentially, the staff from the State Department of Education gave the Gilmore an ultimatum: Grow (in the percentage of students who meet the minimal requirements for academic achievement) or go (be shut down, with the chance that teachers in the school would lose their jobs, for under state guidelines once a school enters this probationary period, the teachers are no longer protected by the union).

Mr. Martinez has been the principal of the Gilmore for the past 4 years. During his tenure, Mr. Martinez worked with Boston business leaders to raise funds for academic programs in school and after school. His approach to social development and mental health issues has been to partner with programs that provide classroom, family, and school climate support. Part of Mr. Martinez’s responsibility as principal is to ensure that the projects and interventions serving the school are appropriate to the school’s needs. When he came on board, one of the first things he did was to cut back on the number of outside interventions, as he felt the school was suffering from “projectitis.” He now believes that the programs in place are strong and relevant ones: A mental health agency provides pull-out counseling to supplement that offered by the school’s part-time counselor; a university partnership brings in graduate students to do social skills group work with students through classroom and small-group sessions; a local corporation sends volunteers once a month to read to students and provides considerable financial support; a religious organization from a nearby suburban community offers once-a-week literacy tutoring for targeted students; and Americorps provides similar tutoring services in math.

In addition, Mr. Martinez brought in an afterschool program that now serves over one-third of the student body. Although Mr. Martinez is aware that some of the coordinators of the various organizations feel they are competing for his attention, he believes that each is serving an important role and is loath to pare down the list any further. His challenge, however, is figuring out how to coordinate the programs better, so that the sum ends up equaling more than its combined parts. Whether or not he is successful in this goal, he at least knows that

each of the programs is delivering skills development. His number one assessment in considering any new or existing approach involves asking the following question: Are the students gaining skills?

This is a school in seriously poor health, at high risk for expiring within the next 12 to 24 months, and yet if one were to make a casual visit to it today, or examine the evidence as presented so far, one might not be able to diagnose the causes of its problems, let alone be aware of its precarious position. Disciplinary actions are down since several years ago, and the classrooms are bright and cheerful. Furthermore, since the summer, when the staff and principal worked through their vacation with the state examiners to develop a school improvement plan, morale among the faculty has perceptibly improved. Beginning with the start of school in the fall, all those involved with the Gilmore have been trying to follow the school improvement plan.

Also, as we can see, the Gilmore has many friends in the neighborhood: outside social and mental health agencies, volunteers from corporate organizations invested in tutoring and mentoring, and local businesses and corporate foundations of one kind or another who are trying to provide financial resources to help the children in the Gilmore do well in school. These attempts to meet the standards will be tested again in the spring, and that is when we will get another reading on the health and vital signs of the Gilmore School.

Our Involvement in the Gilmore

As a friend of the Gilmore for the past 5 years, we are a partner of the school based in a local university. We are interested in the social development of children and schools from the perspective of research, teaching/training, and education. The Gilmore School has been one of our practicum service and research training sites for the past 5 years. Master's-level students from the Risk and Prevention Program are trained in psychological prevention, both at the individual and the classroom climate level. Doctoral students are trained in research, with an emphasis on human development and cultural psychology.

Like many professionals whose interests in the development of children are expressed from a base in an academic setting, in our case a research-oriented professional graduate school of education, a major reason we are in the Gilmore is that several years ago we received funds from a private foundation to bring some of what we

call either "practice-based research" or "research-based practice" into the school as well as to several others in the Boston Public Schools. The focus of our own practice work is on the promotion of children's social development, a need the Gilmore principal and faculty felt their students warranted, but which, given the emphasis the school needed to place on instructional improvements, they felt they could not focus on by themselves. So, when we came with a well-funded service project that made sense to the school, we were generally welcomed in. But our progress at the school has been one of fits and starts as we continue to work toward improving both our delivery of social development programs and our understanding of what the school and the students need.

Our Expertise

We have been involved in psychosocial interventions (treatment, prevention, education/promotion) for over 30 years (Selman, 1980, 2003; Selman, Watts, & Schultz, 1997). Although we have worked in partnership with a wide range of child development professionals, each influenced by one or more disciplines, for the most part our approaches have been based in the discipline of basic and applied developmental psychology, with influences that also can be traced to clinical and educational psychology and child psychiatry (Beardslee, 2002; Beardslee & Gladstone, 2001).

Although over the past 5 years we have had many different relationships with the Gilmore School, for the purposes of this case, we have been cast in the role of "school doctors," that is, as "outside" professionals who are supposed to make a diagnosis of certain aspects of the school's health and write up a prescription. Our role may be unusual for traditional researchers in the field of developmental psychology, but in applied developmental psychology, working in similar school-based projects has become more common (Aber, Brown, & Jones, 2003; Adalbjarnardottir, 1993).

The Symptoms of the Problem

We next share with you the "symptoms," the concerns expressed by the principal as well as teachers and students about what we call school climate: the institutional policies, practices, structures, ethos, internal social, and community dynamics that support or do not support instruction. Each person's story is a composite

based on conversations we have had with a variety of individuals about their classes, individual students, and how they perceive their role within the school system. We then share information about four intervention and treatment approaches that are available to schools today.

We have selected these four programs for several reasons. First, they have each been reviewed for scientific merit by The Collaborative for Academic, Social, and Emotional Learning (CASEL, 2004). CASEL describes its mission thus: “To enhance children’s success in school and life by promoting coordinated, evidence-based social, emotional, and academic learning as an essential part of education from preschool through high school.” CASEL synthesizes the latest empirical findings and theoretical developments and provides leadership to foster progress in what they call social and emotional learning research and practice.

Second, we selected these four programs because they differ in ways that are reflective of programs that are generally available to schools. For example, some programs direct their intervention toward the prevention of disorders or the reduction of exposure to social and emotional risks; others focus on promoting social strengths and competencies. Some interventions are classroom-based, others work within the whole school, and still others work across districts, enlisting schools, families, and communities. A few of the programs are located in university settings and have their own research units, and others have grown out of applied settings and have recruited outside evaluators to do the type of outcome research that will enable them to claim they are evidence-based.

Each of the four approaches we describe is multidisciplinary, outcome-evaluated, and, to varying degrees, research- and evidence-based. Each program—or intervention, if you will—also has a cost, and we need to consider cost in our intervention planning. This case is designed to illustrate the services, preventions, interventions, and treatments available for an ailing school such as the Gilmore.

From Each Person’s Perspective: What Issues of Social Relationship Matter the Most to Teachers, Students, and Administrators?

We have selected six key individuals to be profiled: two students (Robert and Reanna), two teachers (Ms. Li and

Ms. McCarthy), the school adjustment counselor (Ms. Curtis), and the principal (Mr. Martinez).²

Robert

Robert sits in one of the three red chairs lined up against the wall to the right of the principal’s closed door. He contemplates swinging his feet up onto the adjacent chair to curl up with knees to chest, but thinks again when his eyes meet those of the school secretary, who sits in her office directly across the hall. Some of the kids in the school love Ms. Thompson, bringing her drawings they’ve done in art class and always calling out her name when passing by in the hall. But nearly all of Robert’s interactions with the secretary have been antagonistic. Earlier in the year, when he was sent to her office, his head would always hang low. Only when she demanded that he look at her partway through the reprimand would he force himself to meet her gaze. Now he matches her stare from the moment he appears at the door, and the phrases she barks at him, repetitive and rhetorical, roll right by. He has learned the routine and has chosen the chair closest to the window as his regular favorite.

Today, Robert has been sent to the office for being disruptive in music class. It started when Jamil pushed him from behind as the class entered the music room, crammed together in a line that neither the hallway nor the classroom could fully accommodate. Robert, along with most of his classmates, finds Jamil annoying; he talks too much and has trouble keeping his hands to himself. Robert is able to tolerate Jamil’s talking but has no patience for his pushing and shoving. Today, Robert had pushed back a little harder than usual, his level of frustration heightened by the fact that the whole class had been forced to stay in for recess yet again. The Friday before, a group of boys in Robert’s fourth-grade class, including Jamil, had gotten into a fight on the playground. As a result, the teacher, Ms. McCarthy, decided that the entire class would be kept in from recess for 2 weeks. Robert and a number of his classmates had complained that this was unfair punishment, but Ms. McCarthy said her mind was made up and no one could unmake it. Students would have to think twice about the consequences of bullying. Robert didn’t understand why

²We would like to thank Miranda Lutyens, a former EdM student in the Risk and Prevention Program, for her assistance in writing the story of this school.

the teacher called a regular old recess fight “bullying,” unless it was because Jamil had been involved and she always defended him. Maybe if Jamil hadn’t been one of the boys who got pushed around, Ms. McCarthy wouldn’t have punished the entire class. Jamil lost even more points with Robert for being the teacher’s pet.

Denial of recess time had particularly harsh repercussions in Robert’s world. Apart from the physical frustration of not being able to run around outside, Robert felt his recent playground successes slipping away. A few weeks back, he had started playing football with some of the fifth-grade boys—the fourth and fifth grades share recess time after lunch—and he was just beginning to win their respect. They had even let him play quarterback a couple of times, and a few of the fifth graders would call out his name and shake his hand when passing in the hallway. Then recess had been taken away, and within a few days Robert felt the attention from the older boys fade away. Now, sitting in the red chair, Robert gets angry again, thinking about all the outside time that has passed without him. Grabbing onto the edge of the chair with both hands, he shifts angrily in his seat, but then looks up to see that Ms. Thompson is watching him.

Reanna

Twenty minutes later, Reanna walks into the secretary’s office, her backpack over her shoulder and her coat stuffed under her arm. Ms. Thompson smiles at the new arrival, greeting her with a “Hi, Sweetheart!” Reanna grins back and squeezes behind Ms. Thompson’s desk to seat herself at a little table by the window. She pulls out a book and begins reading silently to herself. Reanna is one of the few students in the school who actually likes Drop Everything and Read (DEAR) time, which is supposed to comprise the last 15 minutes of every school day. She’s not sure her teacher, Ms. Li, likes DEAR, since she rarely has her students engage in the intended practice. Or maybe it’s just that her teacher can’t manage to get 24 kids to read silently at the end of the day, especially when she’s trying to work with individual students on incomplete homework assignments, test preparation, and all the other things the class needs.

Not long after Reanna was chosen as the Thursday bus announcer, she had asked Ms. Li if she could report to the office 15 minutes early to do DEAR on her own. Tired of being made fun of openly for her studious habits and worn down by the whispers and looks directed toward her by other girls in her class, Reanna

looks for escape options. She jumps at any opportunity to spend time away from the classroom—deliveries from Ms. Li to the office, visits to the nurse for her asthma shots, working with John, the Americorps student who tutors her in math once a week. Not surprisingly, Ms. Li agreed to Reanna’s spending her DEAR time with Ms. Thompson on Thursdays. Reanna senses that Ms. Li understands and is sympathetic to her plight, and she appreciates Ms. Li’s efforts in helping her avoid the unfriendly environment of the classroom. She’s not sure what else her teacher could do for her, nor is she certain that she’d want her teacher to take any further measures. For now, at least, Thursday afternoons in the office seems her best defense.

Reanna looks forward to Thursday afternoons. She is happy to have the attention from Ms. Thompson and she appreciates the quiet space, far from the afternoon commotion of her classroom upstairs. Most of all, Reanna loves announcing buses. Hearing her voice amplified throughout the halls and seeing the waves of students bustle by on her command, gives Reanna great pleasure. Whatever the girls in her class might be saying about her, it matters much less when she is safely separated from them and when her voice drowns out theirs. She also likes the sense of responsibility that comes with the position. If it weren’t for her accurate announcements, students would be stranded and the school would be thrown into chaos. All the adults in the school are constantly talking about “responsibility,” and the word seems to be printed or posted on everything she sees throughout the school day, often coupled with “respect.” But until being chosen as a bus announcer, Reanna had not found many opportunities in her school to demonstrate responsibility. Even as a fifth grader, she doesn’t feel like a leader. Only when her voice guides the younger students and her peers through the exit and out to the bus stop does she feel that she is proving herself as a responsible member of the school.

Unlike the children she directs onto the crowded buses, Reanna has always walked to school. Next year, she will take the bus to the local middle school, which is over a mile from her home. Although she is excited at the prospect of traveling far to school, she is also nervous. Plenty of stories have circulated at school and in her neighborhood about scary things happening on middle school buses. A seventh-grade friend was forced to smoke part of a joint before two eighth graders would let her off at her stop, and Reanna has heard rumors of worse, such as forced sexual acts encouraged by other

kids on the bus. She wonders how she will protect herself next year and is glad to know that some of her friends live further from the school than she does. They will be on the bus when she gets on in the morning and when she gets off at the end of the day. Reanna's big hope for middle school is that a larger student body will allow her to have a strong group of friends and avoid the persecution she's lived through this year. Reanna wants nothing more than to keep a low profile.

Ms. Li

As Reanna's voice rings out in her fifth-grade classroom, Ms. Li urges the remaining few students in her room to remember to bring back their signed permission slips for the upcoming field trip. The math instruction professional development workshop scheduled for the afternoon has been cancelled, and although Ms. Li knows she should stay and put up a new display of student work—a recently mandated activity, aimed at demonstrating standards-based achievement—she decides to head home. The day has been no more exhausting than any other, but the week feels as if it should be over. Perhaps today was more challenging, as the resource teacher had been out sick, which meant that the entire class had been with Ms. Li for the full day. She has come to anticipate eagerly the period when she is relieved of six of her more challenged learners, the majority of whom are her most difficult students. When the class is at its full size, Ms. Li has trouble accomplishing anything of substance. And she feels that this is beginning to be reflected in her students' work.

A second-year teacher, Ms. Li came to the profession from the world of management consulting, where she felt professionally challenged but personally unfulfilled. Committed to city life, she saw urban education as a field that would allow for an important give-and-take: She'd be contributing to positive social change, and, in turn, her work would be meaningful and motivating. Although less overwhelmed now than during her rookie year, Ms. Li feels that her master's degree in education left her completely unprepared for the reality of the classroom. The theory learned in her teacher training practices—advocating for a constructivist, child-centered approach—seems unattainable given the circumstances in which she finds herself on a daily basis. She is fond of her students and recognizes a desire to learn in many of them. Moreover, she believes that all her students have potential, both academically and so-

cially. But the behavior of a few consistently disrupts the classroom environment, and other students, worn down by the constant interruptions, quickly lose motivation. As a result, Ms. Li feels incapable of tapping into her students' strengths, let alone helping them realize and appreciate their own potential. Her greatest fear is that she will reach the point of exhaustion or desperation where she resorts to the tactics used by other adults in the school. The constant yelling of her colleague across the hall is distracting. Ms. Li also refuses to employ the tactic used by the third-grade teacher, who keeps his cell phone within reach and pretends to dial home whenever a child misbehaves. Ms. Li prefers to promote positive feelings in her class, rather than fear and mistrust. She sees the bullying that goes on among her students and wants to discourage, not emulate, this behavior. How can she discourage the use of threats among students if she herself employed threats as a behavior management tactic?

Ms. Li is not naive about the stance of her principal and of the school system as a whole: Academics must come first. But as hard as she works to support her students' academic learning, she feels that she can't be successful without devoting some of her focus to social and emotional learning. She holds the philosophical belief—one that she keeps close to her chest—that the teacher's role as promoter of social and ethical awareness is just as important as that of academic instructor. This belief, however, only takes her so far. When she is actually faced with a challenge in the classroom, she feels unequipped to respond in a way that leads to positive results for everyone involved.

Ms. Li is well aware of the teasing and whispering among the girls in her class. Part of the reason she had chosen to teach at the elementary rather than middle school level was to avoid dealing with the challenges of girls' peer relations at that age. Now, as a fifth-grade teacher, she realizes that girls being mean to one another also occurs in elementary school. Ms. Li talked with the school counselor about the problem, and the counselor spent a few lunchtimes with the most egregious offenders, but the results were undetectable. Ms. Li knows it is her responsibility to work on these social issues in the classroom, but she doesn't know how to address them in a way that might have a lasting effect. Instead, she tends to look for opportunities to split up the perpetrator girls, and when that isn't possible, she tries to relieve the victims being trapped among the victimizers. Ms. Li well

remembers being teased by mean girls during her own school years. She knows that, despite the phenomenon now having the more official title of “relational aggression,” the feelings of girls like Reanna are no different from what she experienced years ago.

Ms. McCarthy

It’s the time of day when Ms. McCarthy closes all the windows she has left ajar during the day, an attempt to counteract the building’s overactive heating system. It’s also the time of day when Ms. McCarthy pays a visit to the vending machine in the faculty room, two doors down, to buy a package of chips. As much as she hates to see her kids eating so much junk food, by the time her classroom empties out she needs a pick-me-up. To put it mildly, her class this year is a nightmare; her kids fight and bully each other, disrespect her and other teachers, steal, and swear. Ms. McCarthy didn’t come into the year blindly, either. The third-grade teachers had warned her about this class: As the cohort progressed through each grade level, their behavior had worsened until pervasive poor behavior was the norm. In anticipation of inheriting this notorious group, Ms. McCarthy had voiced her concerns to the school principal, Mr. Martinez, and had even talked about trying to transfer within the system. Days into this year at the school, Ms. McCarthy began expressing her grievances to the principal, claiming that in her 21 years of teaching she had never had such a troublesome class. The veteran teacher also questioned how a group like this could have moved through the school without the students’ individual and collective behavior problems being more systematically addressed. No doubt regarding this question as a direct attack, the principal had countered that efforts had been made by the student support services team to deal with the extreme challenges of this specific class. However, like many of her colleagues, Ms. McCarthy sees the student support services as unorganized and ineffective. Most of the services seem to involve Band-Aid approaches to individual students, rather than the macro-level behavior management problems she faces in her classroom.

Over her 2 decades of teaching, Ms. McCarthy has seen a general trend of chronic behavioral dysfunction among the students. She knows that the recent economic downturn may be exacerbating the poverty experienced by many of her students. She is also aware of the cultural shifts playing into the lives of youngsters, from sex and violence in the media to less opportunity for creative play, exercise, and quality time with family. These so-

cial realities, however acute and actual they may be, all blur together and fade into the background when it comes to Ms. McCarthy’s everyday experience in the classroom. Disruptive behavior is disruptive behavior, whatever the causes. She feels that the rise in behavior problems has been answered by increased numbers of professional development trainings on behavior management, none of which she has found particularly useful.

As a result, Ms. McCarthy has resorted to collective punishment, such as the recent recess ban resulting from a playground fight. At this point, she believes that peer pressure may be the only language her students understand. Maybe being denied time outside will lead to a critical mass of students discouraging others from repeating such behavior. Ms. McCarthy is especially frustrated by students’ behavior on the playground and in the hallways. One minute she feels she is making some progress in the classroom, with students speaking to her in respectful ways and asking if anyone has seen a missing item rather than shouting out the blanket accusation of “who stole my _____?!” The next minute, her students are mouthing off to other teachers in the hallway or fighting on the playground. Even when in class they seem to understand what it means to behave acceptably toward others, they are rarely able to turn that thought into action once they are out from under the eyes of Ms. McCarthy.

Ms. Curtis

Picking up the toy trucks and teddy bears strewn about the carpet, Ms. Curtis looks around to make sure she hasn’t left anything else in the resource teacher’s room. Permitted the use of the sunny, spacious room due to her colleague’s absence that day, the school adjustment counselor dreads returning to her tiny closet of an office on the north side of the building. She sits there 3 days a week, doing her best to manage a caseload of students with problems ranging from withdrawn behavior that looks like diagnosable depression to chronic aggression, which is harder to diagnose because in some students it seems reactive to perceived threats and in others it seems to be the way they want to manage their social relationships. Currently, she sees some students individually on a regular basis, pulling them out of class time to engage in 30- to 45-minute counseling sessions. She also runs lunch groups and social skills groups when she can. The majority of her students are boys, and most of them are referred for reasons relating to aggressive behavior.

Ms. Curtis is a trained clinical social worker with a background in working with families. As an African American raised by a single mother, Ms. Curtis believes one of the strengths she brings to her job is being able to culturally understand and connect with the families in the school district. Unfortunately, she has a difficult time making contact with the families. Many parents simply won't show up at the school. One boy's mother has missed four appointments, despite friendly reminder phone calls each time from Ms. Curtis. Unable to work with children without parental consent, Ms. Curtis feels that her hands are tied.

In contrast, she finds herself wanting to throw her arms around those parents who take an active interest in their child's counseling. One mother showed up one morning at the school, unannounced, and asked to speak with the school counselor. Luckily, it had been one of Ms. Curtis's days at the school, and she ended up talking with the mother for over an hour. The mother shared her concerns about her fourth-grade son, Robert, whose father had just been sent to jail for the second time in 5 years. She was seeing increasingly violent tendencies in her son and was concerned that this behavior would begin to crop up in school. In fact, Ms. McCarthy had been talking about this student repeatedly in student support services meetings, and Ms. Curtis was surprised that Ms. McCarthy had not already been in touch with the boy's mother. But rather than share this fact, Ms. Curtis chose to focus their conversation on the mother's own assessment of her son. The mother explained that she worked until six each night, so she only got to spend a couple of hours with the boy. In her place, his grandmother looked after him in the afternoons, and he was allowed to play and do homework at their housing development's community center from the time he returned from school until the center closed at five. He had recently been kicked out of the community center three times in one week for pushing and even hitting other kids, and the mother was concerned that this would become a pattern.

As Ms. Curtis sat and listened, her emotions were mixed. On the one hand, she was disturbed to hear the details of this boy's situation. At the same time, she was thrilled that a parent was taking the time to share these kinds of details with her. Without an understanding of students' home life, Ms. Curtis often feels that she is the blind leading the blind.

Even when Ms. Curtis sees progress in her one-on-one sessions with her students, the reports from the teachers are rarely as encouraging. Behavior contracts

and other methods involving rewards for positive behavior seem to have only a limited effect with the more difficult students. As much as she believes that her work with the students has merit, she is well aware that what ultimately counts is how well they are able to adjust to the social and emotional demands of the classroom. Occasionally, Ms. Curtis spends time in her students' classrooms, observing their behaviors and interactions with other students and the teachers. She sees how the environment in many classrooms only exacerbates her students' problems: a constant exchange of put-downs, arbitrary reprimands from teachers, and overlooked acts of bullying. She is not surprised that fights break out frequently, both inside the classroom and on the playground. Realizing that she needs to help her students develop concrete skills in resisting the urge to act out toward others, Ms. Curtis knows that these skills must be reinforced in the classroom. But she doesn't see much hope of it at present.

Mr. Martinez

Robert has long since vacated the red chair outside the principal's door when Mr. Martinez emerges from his office, ducking slightly to reduce his towering size as he passes under the door frame. Accompanying him is the school's literacy coach, who shares her time among four elementary schools in the city. They have been meeting for over 2 hours to discuss their joint concerns regarding English Language Arts (ELA) instruction at the school. Fourth-grade MCAS results were released a week before and were not encouraging: ELA passing scores are down 20% from the previous year. At such a small school—250 students in total—one class's scores count for a lot. Last year's fourth-grade class had difficult behavior issues, and he's even more concerned about this year's fourth graders. He has heard nonstop from Ms. McCarthy regarding her class's chronic behavior problems. His discussions with her, a veteran teacher who has held a leadership position among the faculty ever since he took the principal's position 4 years ago, always come back to one central issue: school support services. Both principal and teacher know that these services should be creating a better school atmosphere. But while Mr. Martinez believes there is overall school improvement, Ms. McCarthy sees little evidence at the classroom level.

Problems relating to classroom and school climate frustrate Mr. Martinez. Under constant pressure to improve instruction and raise test scores, he realizes that these aims are unrealistic when behavior management
