Since the 1980s, research in the field of children and the law is one of the fastest growing areas in all of developmental psychology mainly because it calls on the expertise of researchers in such a variety of areas. Yet, despite the diversity of topics, all share the common goal of studying behaviors and processes that impact the legal status of children both in and out of the courtroom. Although the research is oriented toward applied issues, it is grounded in developmental theory and in some cases has produced innovative developmental paradigms, theories, and frameworks.

The wide set of topics included in research on children and the law reflects their importance to current societal problems. For example, there is a growing literature on the effects of family constellations and parenting on children's adjustment, such as the effects of gay or lesbian parenting (Golmbok et al., 2003; Patterson, 1997), effects of divorce and custody arrangements (Amato, 2000; Bauserman, 2002; Emery, Laumann-Billings, Waldron, Sbarra, & Dillon, 2001; Gindes, 1998; Kelly & Lamb, 2003), and adoption and foster parenting (Goodman, Emery, & Haugaard, 1998; Haugaard & Hazan, 2002). Another recent avenue of study involves the child in the juvenile justice system when the

child is the perpetrator. In part, this interest is due to rising crime in this age group and to the fact that a number of jurisdictions have become more conservative in dealing with this group of children in the forensic area. Some of these studies, which mainly focus on older children, examine the extent to which they understand the legal proceedings and their legal rights (Grisso & Schwartz, 2000; Grisso et al., 2003; Salekin, 2002; Steinberg & Cauffman, 1996; Steinberg & Scott, 2003).

The greatest amount of work in the field of children and the law has focused on issues related to the maltreatment of children. In 2002, an estimated 896,000 children in the United States were determined to be victims of child abuse. Although the annual rate of victimization per 1,000 children in the U.S. population has dropped from 13.4 in 1990 to 12.3 in 2002, these figures greatly underestimate the extent of the problem because they are based on cases reported to agencies only. A general theme of the research in this area is the prevalence, correlates, consequences of, and treatments for maltreatment (Kendall-Tackett, Williams, & Finkelhor, 1993).

Issues of maltreatment have also been responsible for perhaps the most significant area of study in children and the law: factors related to children's ability to pro-

vide accurate testimony about experienced events. For several reasons, these studies have mainly focused on young children (ages 3 to 7) and have been framed to address issues concerned with sexual abuse. First, there has been a growing awareness and concern about the incidence of child sexual abuse in our society. In the United States, where national archives are kept for each type of maltreatment, the numbers are telling: For the 49 states reporting in the National Center on Child Abuse and Neglect's (NCCAN) 1998 national data system, there were 103,600 cases of *substantiated* sexual abuse (1.5 per 1,000 children), nearly 38% of which involved children age 7 and younger. In 2002, the rate dropped to 1.2 per 1,000 children (Child Maltreatment, 2004).

Second, prior to the 1980s, children were rarely admitted as witnesses in the legal arena (see Ceci & Bruck, 1995). This pattern changed as a result of society's reaction to the dramatic increases in child abuse¹ and as a result of the ineffective prosecution of child abuse cases. During the 1980s, all but a few jurisdictions in the United States dropped their corroboration requirement for children in sexual abuse cases, a crime that by its nature lacks corroboration. Many states began to allow children to testify regardless of the nature of the crime, permitting the jury to determine how much weight to give to the child's testimony. In Canada, with the adoption of Bill C-15, the court could now convict on the basis of a child's unsworn testimony. In England, children over 3 years of age were admitted as witnesses in the courtroom and could provide unsworn corroborated testimony in sexual abuse cases.

Third, in addition to those children who enter the forensic arena for issues related to sexual abuse, there are many others who come into contact each year with the juvenile and criminal justice systems for other reasons (witnesses to domestic violence, hearings for persons in need of supervision, neglect/permanency hearings, and custodial disputes). The numbers of young children involved in the various parts of the justice system become frighteningly large. In all of these situations, children may be asked to provide sworn or unsworn statements, be deposed, and sometimes be required to testify in court proceedings. Thus, young children represent a large and growing legal constituency,

one that possesses a special set of constraints involving basic developmental competencies, involving cognitive, social, and emotional domains, that may constrain their effective participation.

Fourth, beginning in the 1980s, there were a number of highly visible cases that came to court in which young children claimed that their caretakers had abused them. The claims often included a commingling of plausible allegations with fantastic reports of ritualistic abuse, pornography, human and animal sacrifice, multiple perpetrators, and multiple victims (e.g., *California v. Raymond Buckey et al.*, 1990; *Commonwealth of Massachusetts v. Cheryl Amirault LeFave*, 1998; *Lillie and Reed v. Newcastle City Council & Ors*, 2002; *New Jersey v. Michaels*, 1994; *North Carolina v. Robert Fulton Kelly Jr.*, 1995; *State v. Fijnje*, 1995). The defendants in a number of these cases were convicted.

When these types of cases first came to trial, the major issue before the jury was whether or not to believe the children. Prosecutors argued that children do not lie about sexual abuse, that the child witnesses' reports were authentic, and that their bizarre and chilling accounts of events, which were well beyond the realm of most preschoolers' knowledge and experience, substantiated the fact that the children had actually participated in them. Furthermore, they argued that patterns of delayed disclosures and denials and recantations were typical, if not diagnostic, of sexual abuse in children.

The defense argued that the children's reports were the product of repeated suggestive interviews by parents, law enforcement officials, social workers, and therapists. Although the defense was able to point out some of the potentially suggestive interview techniques that were used in eliciting allegations with the children, in the absence of any direct scientific evidence to support the view that such techniques could actually lead children to make incorrect disclosures of a sexual nature and in light of the common belief of that time that children do not lie about sexual abuse, many of these cases eventuated in convictions (for details of the early cases, see Ceci & Bruck, 1995; Nathan & Snedeker, 1995).

The issues raised by these cases were taken up by social scientists and resulted in the most heavily researched topic in children and the law. There are several major areas of study. The first concerns the accuracy of children's autobiographical memory: how well they remembered their past and how well they recalled traumatic events and how they disclosed the traumatic event of child abuse. A second related area

¹ Consider the rarity of perceived incest just 35 years ago: "Incestuous sexual relations are indulged in by less than one in every million people in English-speaking countries" (Verville, 1968, p. 372).

concerns the degree to which children will make false reports of nonexperienced events as a consequence of suggestive interviews. A third area concerns the credibility of children's statements using both a juror decision-making paradigm (e.g., McCauley & Parker, 2001; Nightingale, 1993; Quas, Bottoms, Haegerich, & Nysse-Carris, 2002) and, as described later in the chapter, more objective measures of credibility. A fourth area concerns modifications that could be made in and outside of the courtroom to increase the accuracy and the safeguarding of children's testimony. This area has resulted in the development of scientifically validated interviews, the examination of the positive impacts of various courtroom modifications (closed-circuit TV), and the pros and cons of electronically recording interviews with young children.

CASE EXAMPLE AND PRESENTATION OF RELEVANT SCIENTIFIC EVIDENCE

In this section of this chapter, we review the literature on the four major areas of research spurred by the day care cases, with a particular focus on accuracy and suggestibility of autobiographical memory. We do this by drawing on one of the actual cases, *Lillie and Reed v. Newcastle City Council & Ors*,² 2002 to illustrate the application of developmental psychology in informing the court about some of the key issues of study in children and the law. Because neither this nor any other case can cover all key issues in this field, we discuss other issues in the second section of this chapter.

Case Facts

Chris Lillie and Dawn Reed were two British day care workers who were accused of sexually abusing 27 children at a day care facility in Newcastle, a city in the northeast of England. The defendants were first declared innocent at their criminal trial in 1994. However, in 1998, a special review committee set up by the town accused them anew of abuse. In 2002, Reed and Lillie then sued the review committee, the town counsel, and the local newspaper for libel. The judge in that case found them innocent of all charges and awarded them monetary damages.

The initial allegation was reported to the police by Mrs. Roberts in April 1993. She claimed that her 2-year-old son, Tim, had indicated that Chris Lillie had touched him in the genital area. However, when interviewed by the police and social services a few days later, Tim denied that Lillie had hurt him; physical examination also failed to show any positive evidence of abuse. Nonetheless, the investigation continued, and Chris Lillie was suspended from his duties at the day care. Mrs. Roberts continued to supply the police with additional details that Tim was abused in a house with black doors and Lillie's coworker, Dawn Reed, was involved.

Several weeks after Mrs. Roberts's report, social services met with the parents of the day care children and announced that one of the workers had been suspended because of an allegation of sexual abuse. Dawn Reed was officially suspended from the school soon after that meeting.

Social services contacted families to determine whether the children had made any allegations or whether parents were concerned. At times, they provided parents with advice on how to question their otherwise silent children. Approximately 25 children were interviewed at least once by the police and social services. A number of the children were interviewed two and even three times to elicit allegations of abuse. In June 1993, after 4-year-old Mandy Brown claimed that she had been vaginally penetrated with a crayon at least 9 months previously, Lillie and Reed were arrested. They were successfully granted bail, but just as they were leaving their cells, they were rearrested on the basis of the statement of a 5-year-old child who had not attended the day care for over 1 year. At the end of her third interview, this child alleged that she, too, had been abused. All interviews in this case were videotaped.

On the basis of a disciplinary hearing held by social services in February 1994, Lillie and Reed were dismissed from their positions at the day care, and in July 1994, their criminal trial commenced. There were 11 counts involving 11 children (the index child, Tim, was not a witness). It was a very short trial because the judge dismissed the entire case on the grounds that the evidence was too weak to present to a jury. Lillie and Reed were legally free. However, due to the outrage of the parents and based on the city council's belief that that the pair were guilty, an independent review team was set up to determine what, if anything, went wrong in the inves-

²For a detailed account of this case, see <http://www.richardwebster.net/cleared.html>.

tigation. The review team's mandate was to examine how the allegations of abuse arose and to investigate specific complaints made by parents. They were not asked to judge the guilt or innocence of Lillie or Reed. After 4 years of investigation, in 1998 the review team issued its report, titled *Abuse in the Early Years* (Barker, Jones, Saradjian, & Wardell, 1998) and concluded, "From the evidence we have seen it is clear that Chris Lillie and Dawn Reed had conspired as a pair to abuse children and it is also clear that other people outside the nursery were involved" (p. 264). Lillie and Reed became the objects of public hatred, in part incited by the headlines in the local newspaper. They went into hiding. Eventually, due to the efforts of two journalists, they brought suit against the city council, the local evening newspaper (the newspaper made an out-of-court settlement), and the review team itself.

There were two prongs to their case. The first was for the original plaintiffs to show that Lillie and Reed were indeed guilty of child abuse. The second was to show that the plaintiffs acted in bad faith and were indeed guilty of malice and libel toward Chris Lillie and Dawn Reed. After a 6-month trial, the judge ruled in favor of the complainants, awarding them the maximum penalty of £200,000 each. The review team was found guilty of libel; the city council was not found guilty on the grounds of "qualified privilege."

One of the authors of this chapter (MB) served as an expert witness for the complainants. This involved writing a brief that was submitted to the court before the trial and that was to serve as the basis for her cross-examination during the trial. Major parts of the chapter that follow are excerpts from this document that have been updated in terms of the scientific foundation that was presented in 2002.

We selected this case because it contains a variety of ideas that have been examined in research in children and the law. In addition, it shares the following set of characteristics with other cases involving allegations of sexual abuse in institutional settings, usually day cares, that spurred the initial research interest in this area.

First, the children in these cases were all preschoolers attending day care programs; most were 3 or 4 years olds. Second, the first child to make an allegation (the index child) did not initially make spontaneous statements but was questioned by an adult who was suspicious that something had happened to the child. When first questioned, the index child denied harm or wrong-

doing; however, with repeated questioning, allegations began to emerge. Third, on the basis of the index child's uncorroborated allegations, parents of children in the day care were informed that a child had been abused or that abuse was suspected. Parents were instructed to look for symptoms of abuse (bedwetting, crying, nightmares) and to question their children about specific events. Fourth, as was the case with the index child, children at first told their interviewers that nothing had happened; however, after repeated questioning by parents, police, social workers, and/or therapists, some of these children also reported abuse. Sometimes it took months of questioning for them to provide an acceptable report. Fifth, there were a number of contaminating factors that could account for the common allegations of the children: In each case, the same small group of professionals interviewed all of the children, provided therapy for them, and evaluated them for sexual abuse. In addition, parents and children interacted with each other and spoke about the newest claims or rumors. Sixth, although, for the most part, there was no reliable medical evidence of sexual abuse, most parents reported changes in their children's behavior around the time of the alleged abuse, such as nightmares, bedwetting, baby-talking, resistance to going to the bathroom alone, refusal to attend day care, and much more. Finally, the children's reports became more elaborated with time; for example, after naming a specific perpetrator, children began to make disclosures about other workers at the day care, and sometimes they made disclosures about other people in the town. Over a period of time, the children's allegations became quite disturbing and bizarre; they alleged that they were taken out in boats or thrown into pools of sharks or taken to unknown places where they were tied up in chains or hung upside down from trees or ceiling hooks.

The most unifying characteristic of all these cases was the methods or strategies used by interviewers to elicit the children's allegations of abuse. These included, but were not limited to, the following ingredients:

- The child was given little opportunity to say in his or her own words what, if anything, had happened.
- Interviewers quickly resorted to the use of questions that required monosyllabic responses.
- Interviewers' statements and questions contained sexual content and details about the case that may not have been part of children's initial knowledge.

- Questions were repeated within and across interviews.
- Interviews continued or were repeated until the child provided information consistent with sexual abuse.
- Interviewers used bribes or threats of punishment (“I will give you a treat if you tell me” or “We can’t go home until you tell what happened”).
- Interviewers used selective reinforcement in response to children’s statements (rewarding the child for abuse-consistent statements but ignoring or making negative comments in response to denials of abuse or related activities).
- Interviewers made “atmospheric” statements that conveyed the theme that something bad had happened (e.g., telling the children not to be afraid, that they are being brave, that they are going to be protected, or that they are helpers in an investigation).
- Interviewers invoked statements of other people (“Your mom told me that . . .” or “All your friends have talked about this, now it’s your turn”).
- Interviewers induced negative stereotypes of the suspected perpetrator (e.g., telling the child that the suspect does bad things, that he is in jail).
- Props, such as dolls, toys, sandbox enactments, and drawings, were used to elicit statements about touching.

Bringing Developmental Psychology to the Courtroom

The ultimate goal of presenting to the court the scientific literature on memory and memory distortions is to provide a scientific basis for evaluating the reliability of the witnesses’ statements. In this context, reliability refers to the *trustworthiness* of the evidence, not to the honesty or credibility of a witness. Statements or reports can be unreliable due to normal processes of forgetting, of distortion, and of reconstruction. Statements can also be rendered unreliable if they are elicited in certain suggestive contexts. Thus, the expert’s testimony focuses on the factors that enhance or degrade the quality of children’s and adults’ reports. This was the primary focus of the expert testimony presented to the court in *Lillie-Reed*. Although an assessment of the credibility (believability) of the children’s statements and a determination of whether the child witnesses were abused by the defendants are issues within the province of the

jury, not the expert witness, the provision of information on the reliability of the evidence to jurors or to judges is crucial to allow them to draw conclusions about the credibility of the children’s allegations and, in this case, about the guilt of Lillie and Reed.

The scientific literature has little to say about the *competence* of a witness. There are several reasons for this. First, there appears to be little if any relationship between children’s truthfulness in their recall of experienced events and their performance on competence-type interviews that are often used in the courtroom (e.g., London & Nunez, 2002; Talwar, Kang, Bala, & Lindsay, 2004). Second, because the competence standard is quite undemanding (witnesses are deemed competent if they are sufficiently intelligent to observe, recollect, and recount an event and have a moral sense of obligation to speak the truth), most witnesses are deemed competent by the judge. Thus, the expert’s analysis is not that the children were incompetent but that the methods used to gather information from them rendered their statements, and thus the inherent quality of the evidence, unreliable.

The Nature and Time Course of Children’s Disclosures of Sexual Abuse

In this section, we first summarize the evolution and landmarks of children’s allegations of sexual abuse in Lillie and Reed. Next we summarize the scientific literature on how children disclose abuse and the interpretation of the pattern of disclosure in the target case.

Case Facts

In the present case, none of the children³ spontaneously told of sexual abuse (with the possible exception of Rosie’s statement to her mother that Lillie had touched her privates; this statement was made in September 1992, months before the investigation began; the mother did not know what she was talking about). According to the parents, when they first asked their children if they had been abused, five of the children denied wrongdoing. The electronically preserved recordings of the first official forensic interviews,

³Examples provided in this chapter focus on the index child and the six child witnesses who were to appear in the 1994 criminal trial.

which occurred days to months after the parents' first questioning, show that none of the children provided consistent allegations that Lillie or Reed had sexually abused them. Consequently, five of the children were interviewed a second time, during which three gave some kind of statement consistent with sexual abuse. One child was interviewed a third time, and only after a very long session, with three interviewers, did she finally provide a few abuse-consistent statements.

Scientific Evidence

It is of primary importance to examine the evolution of the children's reports of sexual abuse. The pattern that occurred in the present case has raised the most concerns: The child is initially silent; she does not make any unsolicited or spontaneous statements about abusive acts. Rather, the allegations emerge once an adult suspects that something has occurred and starts to question the child. At first, the child denies the event happened, but with repeated questioning, interviewing, or therapy, the child may eventually make a disclosure. Sometimes, after the disclosure is made, the child may recant, only to later restate the original allegation after further questioning. The most popular embodiment of this idea is Summit's (1983) description of the *child sexual abuse accommodation syndrome* (CSAAS).

Because the CSAAS model was based not on empirical data but on clinical intuitions, we recently reviewed the literature to determine its empirical support (London, Bruck, Ceci, & Shuman, 2005). We identified 10 studies in which adults with histories of childhood abuse were asked to recall their disclosures in childhood. Across studies, an average of only 33% of the adults remembered disclosing the abuse in a timely fashion. In some studies, approximately 30% of adults reported that they had never told anyone before the current interview about their childhood abuse (Finkelhor, Hotaling, Lewis, & Smith, 1990; Smith et al., 2000). These data support the CSAAS model in that sexually abused children are silent about their victimization and delay disclosure for long periods of time.

Although informative on the issue of delay of reporting, these data are silent with regard to the phenomena of denial and recantation, because the participants were never asked, "As a child, did anyone ever ask you or question you about abuse?" We simply have no way of knowing whether these individuals denied having been abused and then perhaps subsequently recanted their re-

luctant disclosures. Another set of studies provides some data relevant to this point. We identified 17 studies that examined rates of denial and recantation by sexually abused children who *were* asked directly about abuse when they were assessed or treated at clinics. The rates of denial at assessment interviews were highly variable (4% to 76%), as were the rates of recantation (4% to 27%). We found that the methodological adequacy of each study (the representativeness of the sampling procedures and the degree to which sexual abuse was validated) was directly related to the rates of denial and recantation: The weakest studies produced the highest rates of denial and recantation. For the 6 methodologically superior studies, the average rate of denial was only 14% and the average rate of recantation was 7%. Thus, although the retrospective studies of adults show that children often do not disclose their abuse, the studies of sexually abused children's responses in a formal interview indicate that if they are directly asked, they do not deny, but rather disclose that they were abused.

In part, the myth about children's patterns of disclosure has persisted because documentation of the first stage of the CSAAS model (children are silent and delay disclosures) has been interpreted as evidence for the full model, according to which denial and recantation are common. Also, as shown by our recent review and analysis, the most commonly cited studies in the literature are those that support the model—but sadly, these are the methodologically weakest of the studies.

Interviewers of children suspected of abuse who are not aware of the scientific evidence, but rather follow the clinical lore that sexually abused children are afraid to talk, deny abuse, and then recant abuse, may not accept the child's initial statements that nothing occurred and continue to interview until allegations emerge. For example, in the present case, a mother questioned her 3-year-old child, Ned, about abuse in the spring of 1993. He said that nothing had happened to him. As a result, she had no concerns, until August 16, when a social worker explained that in some cases it took children a long time to disclose abuse. By August 18, after additional questioning, there was now enough concern to have Ned interviewed by the investigators.

To summarize, the most consistent finding in the scientific literature is that although a significant proportion of sexually abused children will never report their abuse (spontaneously), when questioned about it by authorities, most will disclose and few will recant. If the

children in *Lillie-Reed* had been sexually abused, then based on the scientific literature, one might predict (conservatively) that at least some of them, when directly asked, would have readily admitted that abuse occurred. And only a small proportion would recant allegations once they were made.

Because the patterns of disclosure of the children in *Lillie-Reed* were so discrepant from those reported in the methodologically strongest scientific studies, it raises the hypothesis that children's eventual disclosures were the product of suggestive influences that can sometimes eventuate in false allegations of sexual abuse. This hypothesis requires an analysis of the record to document how the children were questioned and an analysis of the scientific literature to determine the effects of such questioning techniques on the accuracy of children's statements. The next section undertakes such an analysis.

Research on the Effects of Suggestion on Children's Reports

Until the end of the 1980s, most developmental studies of suggestibility focused on children's answers to leading questions or children's incorporation of misleading suggestions into their reports. This focus on leading questions and misinformation did not, however, capture the essential features of the problematic interviews that occurred in a number of legal cases mentioned at the outset of this chapter. Because of the discrepancy between the structure and content of interviews in scientific studies and those occurring in actual cases, at the beginning of the 1990s, the scientific model of suggestibility was greatly expanded into a model of *interviewer bias*.

Interviewer Bias

According to our model of the architecture of suggestive interviews (Ceci & Bruck, 1995) interviewer bias is the defining feature of many suggestive interviews. Interviewer bias characterizes those interviewers who hold a priori beliefs about the occurrence of certain events and, as a result of such beliefs, mold the interview to elicit statements from the interviewee that are consistent with these prior beliefs. One of the hallmarks of interviewer bias is the single-minded attempt to gather only confirmatory evidence and to avoid all avenues that may produce negative or inconsistent evidence. The biased interviewer does not ask questions

about the allegations that might provide alternative explanations that are inconsistent with his or her primary or only hypothesis. When provided with inconsistent or bizarre evidence, biased interviewers either ignore it or else interpret it within the framework of their initial hypothesis. This belief is transmitted to the child via a range of suggestive interviewing techniques that are associated with the elicitation of false reports. Consequently, the child may come to inaccurately report the belief of the interviewer rather than the child's own experience. Finally, it is important to note that a biased interviewer may be a police officer, a therapist, or even a parent.

Interviewer bias has been the focus of much study by developmental forensic psychologists. The following two studies provide a flavor of the methodologies and results of some of these studies.

Chester the Janitor. Thompson, Clarke-Stewart, and Lepore (1997) conducted a study in which children viewed a staged event that could be construed as either abusive or innocent. Some children interacted with a confederate named Chester as he cleaned some dolls and other toys in a playroom. Other children interacted with Chester as he handled the dolls roughly and in a mildly abusive manner. The children were then questioned about this event. The interviewer was (a) *accusatory* (suggesting that the janitor had been inappropriately playing with the toys instead of working), (b) *exculpatory* (suggesting that the janitor was just cleaning the toys and not playing), or (c) *neutral* and nonsuggestive. In the first two types of interviews, the questions changed from mildly to strongly suggestive as the interview progressed. Following the first interview, all children were asked to tell in their own words what they had witnessed and then were asked questions about the event. Immediately after the interview and 2 weeks later, the children were asked by their parents to recount what the janitor had done.

When questioned by a neutral interviewer, or by an interviewer whose interpretation was consistent with the activity viewed by the child, children's accounts were both factually correct and consistent with the janitor's script. However, when the interviewer was biased in a direction that contradicted the activity viewed by the child, those children's stories quickly conformed to the suggestions or beliefs of the interviewer. In addition, children's answers to interpretive questions (e.g., "Was he doing his job or just being bad?") were in agreement

with the interviewer's point of view, as opposed to what actually happened. When asked neutral questions by their parents, the children's answers remained consistent with the interviewers' biases.

Surprise Party. Bruck, Ceci, Melnyk, and Finkelberg (1999) showed how interviewer bias can quickly develop in natural interviewing situations, and how it not only taints the responses of child interviewees but also the reports of the adult interviewers. In this study, a special event was staged for 90 preschool children in their school. In groups of three and with the guidance of research assistant A, the children surprised research assistant B with a birthday party, played games, ate food, and watched magic tricks. Another 30 children did not attend the birthday party; in groups of two, they simply colored a picture with research assistants A and B. These children were told that it was assistant A's birthday.

Interviewers (who were recruited from university graduate degree programs in social work or counseling and who had training and experience in interviewing children) were asked to question four children about what had happened when special visitors came to the school. The interviewers were not told about the events but were simply told to find out from each child what had happened. The first three children that each interviewer questioned attended the birthday party and the fourth child attended the coloring event.

Bruck, Ceci, Melnyk, et al. (1999) found that the children who attended the coloring event and were interviewed last produced twice as many errors as the children who attended the birthday party; 60% of the children who only colored made false claims that involved a birthday party. This result suggests that the interviewers had built up a bias that all the children had attended a birthday party. By the time they interviewed the fourth child, they structured their interviews to elicit claims consistent with this hypothesis. Thus, if interviewers have the belief that all the children they are interviewing have experienced a certain event, it is probable that many of the children will come to make such claims even though they were nonparticipants (or nonvictims). Another important finding was that even when the fourth child denied attending a birthday party, 84% of their interviewers later reported that all the children they interviewed had attended a birthday party. These data suggest that regardless of what children actually say, biased interviewers inaccurately report the

child's claims, making them consistent with their own hypotheses.

These two studies and others like them provide evidence that interviewers' beliefs about an event can influence their judgments as well as their style of questioning. This, in turn, can affect the accuracy of children's testimony. The data highlight the dangers of having only one hypothesis about the event in question—especially when this hypothesis is incorrect.

Interview Bias in Lillie-Reed

Although some children in the present case did utter words or statements that were consistent with the hypothesis that they were touched by Chris Lillie or Dawn Reed, they also made other allegations about other teachers or adults that seem to have been ignored.

One child told the investigative interviewer that Chris Lillie had hurt her bum with a crayon at Lillie's house. When questioned further, she stated in three different parts of the interview that her father was also present:

Interviewer: Was anybody else there?

Child: No. Daddy was . . .

Interviewer: And who did you say was there at Chris's house?

Child: Nobody.

Interviewer: I thought you said somebody called dad was there?

Child: [inaudible]

Interviewer: Was it your dad from home?

Child: Yes.

Interviewer: What did he look like?

Child: He looked at me and he said I see you later. That's what he said. . . .

Interviewer: Do you know when you said that you'd been to Chris's house?

Child: I know my daddy was there.

Interviewer: Your daddy was there?

Child: My daddy [inaudible] was and my mummy wasn't.*

Like other children, this child also named other people who were present or involved in the alleged abuse,

Interviews with children in all cases in this chapter were presented in court and are in the official record. Segments of these interviews that are quoted in the present paper are marked with an asterisk and were reported by Bruck in her testimony before the court.

such as Helen, Tommy, Lynn, and the man with the sack at the library. A classmate claimed that Diane and other teachers had driven the children to Lillie and Reed's flat and that Diane had given her a bath. The police did question each of the day care workers, who, like Lillie and Reed, denied any knowledge of the reported activities. But for some reason, whereas the denials of others were accepted, Lillie and Reed were not believed. The multitude of names provided by the children led some to assume that there was an organized group of pedophiles abusing all the children. However, this ring of pedophiles also included adults explicitly mentioned by the children such as their fathers, their doctors, their parents' friends, and their teachers. The investigators seem to have ignored this discrepant evidence.

During the videotaped interviews, at least four children made exculpatory statements about Dawn Reed (and some also did about Chris Lillie), but these were ignored. For example:

Interviewer: What about Dawn because you had some things to tell me about Dawn as well, didn't you, eh?

Child: No.

Interviewer: You said there were some silly things about Dawn, eh?

Child: No, that was ages ago when I come here. . . .

Child: But don't say nothing to Dawn cos she wasn't silly. . . . She just went into jail for nothing. Say Dawn can come out today. Say that. Don't let Chris out!*

When this interviewer presented the evidence of abuse to the disciplinary panel that subsequently dismissed Lillie and Reed, she edited out what *she* thought was irrelevant; she omitted to tell them of this child's denials in two different interviews.

Investigators argued that the children remained silent or denied abuse because they were too frightened to tell of their actual abuse. Nowhere is there evidence that they considered the possibility that the children remained silent because there was nothing to tell. Rather, children were interviewed until they simply could stand it no longer (e.g., Rachel ended up moaning in her mother's lap; Mary whimpered; Nora begged her mother to stop and when she did not, Nora simply left the room). The interviewers interpreted these behaviors as further signs of resistance, reflected in their

continuing to question the children. For example, the two social workers who were present during Rachel's interview interpreted her behavior as follows:

Social Worker 1: Towards the end of the interview, she appeared to become restless. I had visited her at home and not seen her display this sort of behaviour before. Although the interview had been fairly long I do not think she was tired, but rather pretending to be tired in order to avoid answering our questions. I recall that when we went out of the room she was running around and playful.

Social Worker 2: I recall that after the video interview was over, she walked along the street holding on to Social Worker's hand with great relief that she was out of the video room. My impression was that she had been quite frightened.*

These interviewers did not consider the hypothesis that the contents and structure of the interview were aversive to the child rather than any trauma-induced secrecy resulting from past abuse.

Behavioral symptoms pre- and postdisclosure were viewed as primary or additional evidence of sexual abuse. There did not seem to be any recognition that as parents became more convinced that their children were abused, they changed their reports on the frequency, severity, and onset of the symptoms. There was no consideration that the children's symptoms could reflect normal developmental patterns, that they could reflect problems in the household (divorce, leaving of partners, merging of new households, violence, etc.), nor was there any realization that the symptoms may have emerged or become exacerbated because of the manner in which the children were interviewed or treated.

The focus on behavioral symptoms in this case was based on the assumption that there is a common constellation of symptoms that are diagnostic of sexual abuse. However, there are no behavioral symptoms that are diagnostic of sexual abuse. Many of the problems cited by the parents (anxiety, enuresis, fears, night terrors, and even sexual behaviors) either are common in children of this age or can be associated with other types of childhood behavioral disorders (see Kendall-Tackett et al., 1993). Also, a majority of sexually abused children are asymptomatic. Thus, the fact that so many of these children had problems indicates that perhaps other causes should have been examined but they were not.

Suggestive Interviewing Techniques Used by Biased Interviewers

Interviewer bias influences the entire architecture of interviews and is revealed through a number of different component features, some of which were listed in the first section of this chapter (e.g., repeated questions, selective reinforcement, peer pressure). As will be described in the next sections, the results of the scientific literature indicate that the use of these suggestive techniques, especially in the hands of biased interviewers and especially when used in combination, can bring children to make claims about events that they have never experienced.

Open-Ended versus Specific Questions

To confirm their suspicions, biased interviewers may not ask children open-ended questions, such as “What happened?” but instead quickly resort to a barrage of very specific questions, which require the child to provide one-word answers (yes or no). Sometimes the questions are very leading (e.g., asking the child “Where did your teacher touch you?” is very leading if the child never previously mentioned touching by the teacher), and often the questions are repeated until the child provides a desired response.

Although the strategy of using specific questions, leading questions, and repeating questions ensures that the child will provide information, it is also problematic because children’s answers to these types of questions are often inaccurate. For example, Peterson and Bell (1996) interviewed children after they had been treated in an emergency room for a traumatic injury. They were first asked free recall questions (“Tell me what happened”). Then, to obtain additional information, the children were asked more specific questions (e.g., “Where did you hurt yourself?” or “Did you hurt your knee?”). Peterson and Bell found that children were most likely to accurately provide important details in free recall. Across all age groups, errors increased when children were asked more specific questions. The percentage of errors elicited by free recall and specific questions was 9% and 45%, respectively.

Specific questions include yes/no questions (“Did the lady have a dog?”) and forced-choice questions (“Was it the man or the woman?”). One reason using these questions is risky is that children rarely reply “I don’t know” even when explicitly told that this is an option (Peterson & Grant, 2001) and even when the ques-

tion is nonsensical and thus incomprehensible (Hughes & Grieve, 1980; Waterman, Blades, & Spencer, 2000). One of the reasons that children so willingly provide answers to specific yes/no or forced-choice questions even though they may not know the answer or understand the question is that young children are cooperative conversational partners, and they perceive their adult interviewer as truthful and not deceptive. To comply with a respected adult, children sometimes attempt to make their answers consistent with what they see as the intent of the questioner rather than consistent with their knowledge of the event (see Ceci & Bruck, 1993, for a review). Because of this compliant, cooperative characteristic, and because of young children’s poor performance on specific questions, it is particularly important in interviews to avoid these types of questions until after the child has first provided evidence in response to open-ended questions.

As illustrated throughout this chapter, interviewers in *Lillie-Reed* rarely asked open-ended questions and mostly asked specific questions that can be answered with little effort in one or two words. In the following example, the prosecution’s best witness is interviewed by the police and social services for the third time in a period of 3 weeks. She had told her mother in the car prior to the interview that it was all a stupid joke. In the first half of the interview, when bombarded with specific questions by the two interviewers (Helen and Vanessa), she mainly replied that she did not know or did not remember. When she did provide answers to questions, these were so disjointed that it seemed the child had given up and decided to answer each question as it came with no attention to the content or the sequence of previous questions or answers.

Interviewer: Did he have anything on underneath his pants?

Child: Yes, underpants.

Interviewer: Did he take those down?

Child: Yes.

Interviewer: And did you see any bits of his body?

Child: Yes.

Interviewer: And what did that look like?

Child: It was big.

Interviewer: Can you remember which way it was pointing, pointing up or pointing down.

Child: Pointing up, I mean down it was up then down, up then down.

Interviewer: So it was going up and down all the time.

Interviewer: Was it doing that on its own?

Child: Yes.

Interviewer: What colour was it?

Child: Pink.

Interviewer: It was pink; it was going up all the time, and then what?

Child: That was all, those were the only two things that, that I had to tell to do.*

When examining transcript examples, such as this one, it is instructive to focus simply on the child's words to estimate how much the child actually said and how much the interviewers said. As shown in this excerpt, this child said very little besides "Yes," "It was big," and "Pink" before stating that she had fulfilled her promise to tell about two things.

The low frequency of open-ended questions and the high frequency of specific questions are not specific to this one case, but appear to characterize forensic interviews with children in general. For example, analyses of 42 child protective services interviews with children ages 2 to 13 years in one state revealed that 89% of the questions about the suspected abuse were specific (Warren, Woodall, Hunt, & Perry, 1996).

Interviewers often state that they do not frequently use open-ended questions because of cognitive, emotional, and motivational barriers that inhibit children's spontaneous disclosure of abuse and because children must be encouraged to disclose by being asked specific questions over a period of time. Even though there are known risks of using leading or specific questions, perhaps these are necessary to elicit reports or details from sexually abused children who feel frightened, ashamed, or guilty.

This claim has recently been challenged by Lamb and colleagues (2003), who constructed a structured interview protocol and then trained interviewers in its use. The protocol requires trained interviewers to encourage suspected child abuse victims to provide detailed life event narratives through the guidance of open-ended questions (e.g., "Tell me what happened"; "You said there was a man; tell me about the man"). The use of specific questions is allowed only after exhaustive free recall. Suggestive questions are highly discouraged. In a recent study, Lamb et al. examined the interviews of police officers trained on the protocol with 4- to 8-year-old children who had made allegations of sexual abuse. Lamb et al. found that 83% of all allegations and disclo-

tures were elicited through free recall questions (78% for preschoolers), and 66% of all children identified the suspect through open-ended questions (60% for preschoolers). These data dispel the belief that interviewers need to bombard children with suggestive techniques to elicit details of trauma; rather, children can provide detailed information through open-ended prompts, and if a child denies abuse when asked directly, there is no scientifically compelling evidence that the child must be "in denial." As argued in the previous section, abused children usually disclose the abuse when directly asked.

Repeating Interviews and Repeating Questions

In formal investigations, children are often interviewed on many different occasions. There are numerous concerns about the influence of these repeated interviews on children's reports, especially when conducted by biased interviewers. As shown next, the results of several studies indicate that repeated questioning and interviewing in suggestive interviews increase the number of false allegations.

For example, preschool children were interviewed on five different occasions about two true events and two false events (Bruck, Ceci, & Hembrooke, 2002). The two true events involved the child helping a visitor in the school who had tripped and hurt her ankle, and a recent incident where the child was punished by the teacher or the parent. The two false events involved helping a woman find her monkey and witnessing a man steal food from the day care. In the first interview, children were simply asked if each event had ever happened. If they said yes, they were asked to describe the event. During the next three interviews, the children were suggestively interviewed (e.g., they were asked repeated leading questions, they were praised for responses, they were asked to try to think about what might have happened, they were told that their friends had already told and now it was their turn). In the fifth interview, a new interviewer questioned each child about each event in a nonsuggestive manner. Across the five interviews, all children consistently and accurately assented to the true event about helping a woman who fell in the day care. However, children were at first reluctant to talk about the true punishment event; many of the children denied that the punishment had occurred. With repeated suggestive interviews, increasing numbers of children agreed that the punishment had occurred. Similar pat-

terns of disclosure occurred for the two false events; that is, children initially correctly denied the false events, but with repeated suggestive interviews, they began to assent to these events. By the third interview, most children had assented to all true and false events. This pattern continued to the end of the study.

One of the rationales for reinterviewing children is that it provides them additional opportunities to report important information that was forgotten or simply not reported in earlier interviews. Thus, it is assumed that when children provide new details in subsequent interviews, these new reports are accurate memories that were not remembered in previous interviews. Another rationale is to allow children to rehearse so that their memories will not fade over time. However, the results of recent studies dispute this claim. One set of studies consistently shows that reports that emerge in a child's first interview with a neutral interviewer are the most accurate. When children are later interviewed about the same event and report new details not mentioned in a previous interview, the newer details are less accurate than those repeated from the first interview (Peterson, Moores, & White, 2001; Pipe, Gee, Wilson, & Egerton, 1999; Salmon & Pipe, 2000). In some studies, the inaccuracy rates of new, inserted details in neutrally conducted interviews rise to a level of 50% (Peterson et al., 2001; Salmon & Pipe, 2000). Similar results are obtained when children are suggestively questioned about an actual event (Bruck et al., 2002; Scullin, Kanaya, & Ceci, 2002). Thus, insertion of new but inaccurate details can be a natural memory phenomenon; it can be due to prior suggestions that become incorporated into later reports; but it can also be due to the demand characteristics of the interview. When interviewers urge children to tell them anything (that is consistent with the bias of the interviewer), these requests for additional information will sometimes result in false reports that are supplied by the children to comply with their perception of the interviewer's wishes.

Although these studies show the detrimental effects of repeated interviews, there is an important qualification to this conclusion: There are a number of studies in which children who are provided with misinformation across multiple interviews are no more likely to incorporate this information into a later report than children who receive only one suggestive interview. The major factor appears to be the timing of the suggestive interviews: If the first suggestive interview occurs soon after

an event and the second interview occurs close to the final interview, then misinformation effects are maximized (Melnik & Bruck, 2004). There are several points to bear in mind, however; as shown in some of the studies in this chapter, one suggestive interview can destroy the reliability of a child's report; also, it may take several suggestive interviews to move the child from making simple assents to providing some elaboration to the false allegations (see Bruck et al., 2002, in which repeated suggestive interviews were associated with more elaborated narratives of false events).

Just as there are risks associated with repeated interviews, there are also risks associated with repeating questions within the same interview. Biased interviewers sometimes repeatedly ask the same question until the child provides a response that is consistent with their hypothesis. Poole and White (1991) found that asking the same question within an interview, especially a yes/no question, often results in young children changing their original answer (see Cassel, Roebbers, & Bjorklund, 1996, for similar effects when children are asked repeated leading questions). Furthermore, when children are asked the same question on numerous occasions, they sound increasingly confident about their statements even if these are false.

It also appears that when interviews contain a preponderance of (mis)leading questions, children will initially resist the suggested response, but with repeated misleading questions (that differ in content), their resistance dissipates. Garven, Wood, Shaw, and Malpass (1998) found that preschoolers provided increasingly inaccurate responses to misleading statements and questions as a suggestive interview proceeded. In this study, children were suggestively interviewed for 5 to 10 minutes about a stranger who came to read their class a story. As a result of the suggestive devices used by Garven and her colleagues, children falsely claimed that the visitor said a bad word, that he threw a crayon, that he broke a toy, that he stole a pen, that he tore a book, and that he bumped the teacher. Of particular importance, the children came to make more false claims as the interview progressed; that is, within a short, 5- to 10-minute interview, children made more false claims in the second half than in the first half of the interview. It seems that it is not simply repeating questions but repeating questions about a specific theme (e.g., the visitor doing bad things) that may compromise the reliability of children's reports.

Forced Confabulation Effects

As will be seen from some of the examples of *Lillie-Reed*, not only were the young child witnesses asked repeated questions within the same interview and across interviews, but this questioning often continued until the children provided answers amid protests that they did not know the answer (i.e., they were forced to give an answer). This practice raises the following question: If the children were forced to knowingly provide an inaccurate answer to a question, would they not correct themselves when given the next opportunity (e.g., in the next interview, or in the same interview)? In other words, if a child first denied abuse until he or she was coaxed to provide abuse-related information and then later produced an abuse-consistent disclosure, doesn't this mean that the child's second statement is unreliable?

Two studies conducted by Zaragoza and colleagues (Ackil & Zaragoza, 1998; Zaragoza, Payment, Kichler, Stines, & Drivdahl, 2001) show that when children are forced to provide an incorrect answer (confabulation), they will not only continue to provide the same incorrect answer but will actually come to believe in the validity of the wrong answer. For example, in the latest study (Zaragoza et al., 2001), children came to a laboratory and played computer games; during this time, a handyman came into the room and fixed some broken things. Immediately after, the child was asked a number of questions about the event and was told to provide an answer no matter what. Children were asked questions about things that really happened and they were asked misleading questions about things that did not happen. For example, children were asked how the handyman had broken the videotape (he had not even touched the videotape). Although most children claimed that he had not broken the videotape, they were told to provide an answer anyway. Sometimes it took several rounds of coaching to get the children to provide an answer. For example:

Interviewer: There's a videotape on top of the VCR that is broken. How did he break it?

Child: I have no clue.

Interviewer: Can you tell me how you think he might have broken it?

Child: I have no clue.

Interviewer: Just make something up then.

Child: I can't think of anything.

Interviewer: Well, what might, what, what might someone do to break a videotape?

Child: Drop it.

Interviewer: That's right! He did drop it.*

Two weeks later, these children were brought back to the laboratory and informed that the original experimenter had made some mistakes and had asked them questions about things that had never happened. The children were asked to report only those things that they actually saw. In this second interview, children at all ages (6 to 10 years) reported that the confabulated false items had actually occurred (they saw it). For example, 60% of the 6-year-old children now reported in the second interview that they saw the handyman break the videotape.

This is an important study because it shows that no matter how resistant to misleading questions a child may be in an earlier interview, with sufficient pressure not only will he or she come to report this false information in a later interview, but he or she will report that it actually happened. Using a milder version of the forced confabulation interview, similarly dramatic suggestibility effects have been reported (Bruck, London, Landa & Goodman, in press; Finnila, Mahlberga, Santtilaa, Sandnabbaa, & Niemib, 2003).

In summary, if children's allegations are elicited by specific leading questions that have been repeated within the same interview or across interviews, there is a high risk that the children's statements will be unreliable. Conversely, children's answers to open-ended questions asked prior to any suggestive interviewing have a high probability of being accurate.

Following are examples of repeated questions and repeated interviews from *Lillie-Reed*:

Interviewer: Did you have anything to tell me about the nursery?

Child: Not actually.

Interviewer: Not actually or I've got that wrong. Can you tell me what it is?

Child: Can't. Don't know what it is.

Interviewer: You don't know what it is. Okay. Is there anything you want to tell me about anything that happened at nursery?

Child: Don't know.

Interviewer: Did anybody do anything at the nursery that they shouldn't have done?

Child: What's this?[about something she has in her hand]

Interviewer: Did anyone do anything at the nursery that they shouldn't have done?

Child: No.
 [Child's mother enters the room]
Interviewer: Did Chris do anything to you? Can't you tell me, 'cause I can't hear very well. Can you just tell me?
Mom: Will you tell me?
Child: I can't.
Interviewer: Why can't you tell, 'cause it's alright here, you know? To tell Mummy and me. Hmm? And you won't have to tell anyone again, will you? You just tell us now. Hmm?
Mom: Did something happen that you didn't like?
Child: No! Yeah!
Mom: What?
Child: Chris, Chris hit me and Jill.*

When interviewed for a second time in December 1993, this child's denials of abuse became allegations of abuse after repeated specific questions and perhaps as a result of the repeated interview:

Interviewer: What about Dawn because you had some things to tell me about Dawn as well, didn't you, eh?
Child: No.
Interviewer: You said there were some silly things about Dawn, eh?
Child: No, that was ages ago when I come here.
Interviewer: But you said that you got touched by Dawn and can you—I just need to know where she touched you? It's all right.
Child: On my fairy. [Children used the term fairy to refer to their vagina.]*

The next example shows how suggestive techniques used in one interview may show their influence only in a later interview.

Mom: Right, can you remember when you were sitting in the house? Can you remember when you had a sore fairy? You tell Helen [the interviewer], right, what you said to me when you said a sore fairy. Has anybody ever touched your fairy in the nursery? [child shakes her head "no"] That's not what you told me.
Mom: Remember when you had a sore fairy?
Child: No/What?
Interviewer: Did you have a sore fairy when you went to nursery school?

Mom: Didn't you? You used to have a sore fairy. Did you?
Child: No.
Mom: You did. You told me you did, didn't you? Its ok you know, we're not going to get a smacked bum or anything. . . . You're a good girl. 'Cause you know when you told us you had a sore fairy and I asked you has anybody ever touched your fairy at nursery and you said yes, didn't you? Didn't you?
Child: No.
Mom: [laughing] You did. Stop telling fibs. . . .
Mom: Listen, can you remember when we were talking in the house and you said you had a sore fairy? Come here a minute, two minutes while I just ask you this. Can you remember when we were talking in the house and you said you had a sore fairy? Can you remember? Hmm? [child shrugs no] You can. Tell the truth. Be a big girl like you were, 'cause you're not going to get wrong, you know for a fact you're not. And didn't I say to you has anybody ever touched your fairy at nursery?
Child: No. . . .
Mom: Tell Auntie who touched your fairy.
Child: I don't think so.
Mom: You don't think so? . . .
Mom: Well, can you remember? Can you remember who, who touched your fairy? Can you remember?
Auntie: Are you going to tell us your secret? I'll tell you my secret if you tell me yours.*

In interview 2, when first asked about touching, this child now gave the following answer:

Interviewer: So, what did you want to tell me about this person called Chris?
Child: Touched me.
Interviewer: Can you show me where? If that was you, where did he touch you?
Child: On my fairy.*

Although this analysis focuses mainly on the children's statements in the videotaped interviews, it is important to note that the children were questioned before these official interviews were recorded. The record shows that children had several to many sessions with parents, friends of parents, relatives, and professionals. For example, although one child, Mandy, first told her parents about abuse in May 1993, her parents had questioned her a few times before. It was not until June 28,

however, that the parents gave permission for their daughter to be interviewed by the officials; the major reason was that Mandy had made more disclosures when they were questioning her.

Another mother first suspected that her child may have been abused in May 1993. Her child was interviewed at the police station in June 1993 but made no allegations consistent with sexual abuse. Then she was questioned many times between June and December. On December 1, 1993, when she was interviewed for the second time at the police station, she made a few allegations consistent with abuse. Given the denial of wrongdoing in the June interview, followed by an enormous amount of repeated interviewing during the next few months, the few allegations that emerged in the December 1 interview are not “fresh” utterances but may have been contaminated by multiple retellings and questionings.

Atmospherics or Emotional Tone of the Interview

Interviewers can use verbal and nonverbal cues to communicate their bias. These cues can set the emotional tone of the interview. Research shows that children are quick to notice the emotional tones in an interview and to act accordingly. For example, in some studies when an accusatory tone is set by the examiner (e.g., “It isn’t good to let people kiss you in the bathtub” or “Don’t be afraid to tell”), children are likely to fabricate reports of past events even in cases when they have no memory of any event occurring. In some cases, these fabrications are sexual in nature.

In one such study, children played with an unfamiliar research assistant for 5 minutes while seated across a table from him. Four years later, researchers asked these same children to recall the original experience (Goodman, Batterman-Faunce, Schaaf, & Kenney, 2002). The researchers created “an atmosphere of accusation,” telling the children that they were to be questioned about an important event and saying things like, “Are you afraid to tell? You’ll feel better once you’ve told.” Although few children had any memory of the original event from 4 years earlier, 5 out of the 15 children incorrectly agreed with the interviewer’s suggestive question that they had been hugged or kissed by the confederate, 2 of the 15 agreed that they had their picture taken in the bathroom, and one child agreed that he or she had been given a bath. In other words, children may give inaccurate responses to misleading questions about events for which they have no

memory when the interviewer creates an emotional tone of accusation.

Rewards and punishments shape the emotional tone of an interview and provide another means for interviewers to express bias. The use of rewards and punishments in interviews with children can be beneficial by motivating children to tell the truth. On the other hand, there may also be negative consequences; children may learn that if they produce stories that are consistent with interviewers’ beliefs, their interviewers will reward them.

A study conducted by Garven, Wood, and Malpass (2000) illustrates how the use of rewards and punishments in an interview can quickly shape the child’s behavior and have long-lasting consequences. Children between the ages of 5 and 7 attended a special story time led by a visitor called Paco. During this 20-minute visit, Paco read the children a story, handed out treats, and placed a sticker on the child’s back. One week after the visit, the children were asked mundane questions (“Did Paco break a toy?”) and fantastic questions (“Did Paco take you somewhere in a helicopter?”). There were two interviewing conditions. In the neutral-no reinforcement condition, children were simply asked a list of 16 questions and provided no feedback after each question. In the reinforcement condition, children were asked the same 16 questions, but they were provided with feedback after each question, as illustrated by the following example:

Interviewer: Did Paco take you somewhere on a helicopter?

Child: No. [Note this is an accurate denial]

Interviewer: You’re not doing good. Did Paco take you to a farm?

Child: Yes. [Note this is an incorrect assent]

Interviewer: Great. You’re doing excellent now. [The next question is asked.]*

The reinforcement had large negative effects on the accuracy of children’s responses. Children in the reinforcement condition inaccurately assented to 35% of misleading mundane questions and to 52% of the misleading fantastic questions. The comparable rates for the nonreinforcement group were 13% and 15%. In a second interview, a week later, all children were asked the same questions without any reinforcement. The same high error rates continued for the reinforcement children. When children were challenged and asked in the second

interview, “Did you see that or just hear about that?” children in the reinforcement group stated that they had personally observed 25% of the misleading mundane events and 30% of the misleading fantastic events. Children in the nonreinforcement group made these claims only 4% of the time.

These findings show how quickly reinforcing statements can shape children to provide inaccurate responses no matter how bizarre the question. Furthermore, the inaccurate responses persist on second questioning, with a number of children claiming that they actually observed the suggested but false event. Of course, as shown in some of the excerpts, rewards and punishments can take a more explicit form, such as promising children a treat if they tell the right answer or threatening the children if they provide an undesirable answer.

Examples from the Lillie-Reed Case

The following excerpts are statements by a child’s mother and by her aunt, who were both allowed to help investigators interview the child. These statements were made to induce this young child to make abuse-consistent disclosures.

Aunt: You promised to tell me your secret if I got all the Barbie toys for you and you didn’t tell us. Didn’t you not?

Aunt: Yes. All right, I’ll get them, but are you going to tell me your secret, then? Because you said you would.

Mom: If you can remember who it is, or who it was, we’ll get you some clothes for the Barbie.

Aunt: Do you want us to take you to Fenwicks and buy you some clothes for your Barbie?

Aunt: You tell me what you told your mummy last week, right? Are you listening? And I’ll let you come sleep at my house a night.

Mom: After you tell AUNT what happened, right and then we’ll go downtown and buy your Barbie some new clothes, eh? If you’re a good girl, if you tell Auntie Joan.

Aunt: Do you want to tell me about the nursery, eh, and then we’ll go to Fenwicks for a McDonald’s burger.*

In addition to positive and negative reinforcement, rewards, and bribes, the children were repeatedly told not to be frightened, not to be afraid, and that they were

brave. For example, the word “frighten” was used 9 times in the following excerpt, which also shows the potentially damaging effect of this strategy that was repeated by the investigator, the mother, and the mother’s friend.

Interviewer: I was wondering if maybe Grace was frightened.

Interviewer: Do you think she’s frightened to tell me?

Friend: I think so and I think I know what she’s frightened of.

Interviewer: Grace, have we got this bit right? Grace?

Mom: Listen, Grace, are you frightened?

Interviewer: What of?

Grace: Chris.

Interviewer: What for? You’re safe. . . .

Interviewer: We’re all there to look after you and there’s nothing for you to be frightened of.

Friend: So that nobody can harm her, can they not, Grace. . . .

Friend: What did he do when he was naughty, Grace?

Interviewer: I think Grace’s still a little bit frightened but she doesn’t have to be.

Mom: What did Chris tell you to be frightened of, Grace? Why were you frightened?

Grace: Monsters.*

Stereotype Induction

Suggestions do not always take the form of explicit (mis)leading questions, such as “Your Dad was mad, right?” One suggestive interviewing technique involves the induction of negative stereotypes by telling a child that the suspect “does bad things.”

As a study by Lepore and SESCO (1994) shows, some children will incorporate this negative information into their reports.

In this study, children played games with a man called Dale. Dale played with some of the toys in a researcher’s laboratory room and he asked the child to help him take off his sweater. Later, an interviewer asked the child to tell her everything that happened with Dale. For half the children, the interviewer maintained a neutral stance whenever they recalled an action. For the remaining children, the interviewer reinterpreted each of the child’s responses in an incriminating way by stating, “He wasn’t supposed to do or say that. That was bad. What else did he do?” Thus, in this condition, the bias that Dale had misbehaved was induced. At the conclusion of these incriminating procedures, the children

heard three misleading statements about things that had not happened: “Didn’t he take off some of your clothes, too?” “Other kids have told me that he kissed them, didn’t he do that to you?” and “He touched you and he wasn’t supposed to do that, was he?” All children were then asked a series of direct questions, requiring yes or no answers, about what had happened with Dale.

Children in the incriminating condition gave many more inaccurate responses to the direct yes/no questions than children in the neutral condition. Interestingly, one-third of the children in the incriminating condition embellished their responses to these questions, and the embellished responses were always in the direction of the incriminating suggestions. The question that elicited the most frequent embellishments was “Did Dale ever touch other kids at the school?” Embellishments to this question included information about who Dale touched (e.g., “He touched Jason, he touched Tori, and he touched Molly”), where he touched them (e.g., “He touched them on their legs”), how he touched them (e.g., “And some he kissed . . . on the lips”), and how he took their clothes off (“Yes, my shoes and my socks and my pants. But not my shirt”). When they were reinterviewed 1 week later, children in the incriminating condition continued to answer the yes/no questions inaccurately and they continued to embellish their answers.

In *Lillie-Reed*, the children were repeatedly told that Chris Lillie and other people had done “silly” things and they were constantly asked to talk about the silly things.

Interviewer: Why. Because I’ve heard some stories about silly people at the nursery school doing silly things. So I said to your mummy has Mary told you anything about these silly things at nursery and she said “Oh, yes, shall I bring her to talk to you?” I said “Oh, please. I don’t know what all these silly things are.” Do you? Did you tell your mummy about them though?*

Interviewers told the children that Lillie was in jail and asked if he had hit or hurt them.

Mom: Remember when mum and you were talking this morning and I asked you if Chris had ever hurt you [The child is lying on her mother’s lap and moaning], and I said that the policeman took him away now and he can’t ever hurt you again and nothing bad’s going to happen to you because you

can tell now? Can you remember what you said to me when I asked if Chris had ever hurt you?*

The children were also asked about “naughty” things that happened or to tell about the naughty things that Chris Lillie and Dawn Reed had done. During one child’s first interview, the investigators used the word “naughty” approximately 53 times. The following was the child’s response after “naughty” had been mentioned 15 times:

Interviewer: Well, I don’t want him to be naughty. You’ve told us he’s been naughty and I don’t want him to be.

Child: Why?

Interviewer: ’Cause I don’t think he should be, but I need—

Child: He’s been nice before and now he’s being naughty.*

In the next exchange, “naughty” had been mentioned another 9 times:

Interviewer: So it was something to do with Charlie. Is it something to do with some part of Charlie’s body?

Child: No.

Interviewer: Is it something naughty? Is it something nice?

Child: Uh-huh.

Interviewer: I’m still a bit stuck, ’cause it’s hard guessing that.

Child: I know something naughty.

Interviewer: It was something naughty, right. That’s the bit I cannot think. So it was something naughty and mummy’s forgotten and now you’re the only one who knows.

Child: I don’t know.*

And finally, after approximately 29 more repetitions of the word “naughty,” when questioned by the mother’s friend, the child produced the major allegation of the interview:

Interviewer: He’s naughty, though, isn’t he? Why do we say he’s naughty? ’Cause what did he do again?

Child: ’Cause he’s naughty.

Interviewer: ’Cause what did he do, though, to make him naughty?

Child: He smacked me bum.*

Many of the children's first allegations involved hitting. Vanessa Lyon, one of the main interviewers, also noted this trend and declared that children often begin to disclose abuse by describing the least abusive incident, which allows them to gauge the reactions of people they tell. But in examples such as the present one, the children did not have to gauge the reactions of the adult, who willingly accepted any statement of wrongdoing that involved Chris Lillie or Dawn Reed. Thus, another interpretation of this pattern is that it was the repetitious words and concepts like "naughty" that, when paired with questions about Chris Lillie, prompted Grace to come up with the naughtiest answer that she could think of: Chris smacked her bottom. In this case, as in others, allegations of sexual abuse emerged later, as interviewers provided the children with sexual information that, prior to the interviews, was unfamiliar to these children.

Peer Pressure

The effect of telling children that their friends have "already told" is a much less investigated area in the field of forensic developmental psychology. Certainly, the common wisdom is that a child will go along with a peer group. But will a child provide an inaccurate response just so he or she can be one of the crowd? The most recent and most relevant studies in the literature suggest that the answer is yes (Principe & Ceci, 2002; Principe, Kanaya, Ceci, & Singh, in press).

Preschoolers in groups ranging in age from 6 to 8 took part in a contrived "dig" with a fictitious archaeologist named Dr. Diggs (Principe & Ceci, 2002). Dr. Diggs led the children through an event in which they used plastic hammers to dig pretend artifacts (e.g., dinosaur bones, gold coins). Dr. Diggs also showed the children two special artifacts: a map to a buried treasure and a rock with a secret message. The children were warned not to touch these because they could be ruined. All children in the study participated in or viewed these core events. However, one-third of the children also saw Dr. Diggs ruin the two special artifacts (heretofore referred to as the target activities) and show upset about their loss. A second third of the children were the classmates of those in the first group but did not witness the extra target activities. The remaining children were not the classmates of those who witnessed the target activities, nor did they witness the target activities themselves; they thus served to provide a baseline against which to assess the effects of peer contact. Following

the dig, the children were interviewed in either a neutral or a suggestive manner on three occasions. The suggestive interviews for children who did not view Dr. Diggs ruining the special artifacts provided children with this information. Children in the neutral interview were not given information about the two target events. In a later interview, children were asked questions about the dig. Children who had not reported the two absent special activities were prompted to tell more by the interviewer's telling them that their friends had already told.

Children who were classmates of those who saw Dr. Diggs ruining the two artifacts were more likely to claim that they had viewed the target activities (i.e., they incorporated the misinformation from the previous interview) than children who did not view the special activities and were in another classroom. These data suggest that there was contamination from classroom interactions; children who had not experienced the target events learned of them from their classmates and thus were more likely to assent to false events. Finally, telling children that their friends had told increased their false assent rate.

Principe et al. (in press) conducted another study in which they found that children who overheard a child talking were as likely to falsely claim to have seen the event in question (a rabbit that escaped from a magician) as were peers who actually saw it escape. Moreover, in this study, the effect of suggestive questioning did not notably increase their false reports; they were as likely to report falsely if they overheard peers talking about the rabbit, regardless of whether interviewers employed suggestive questions.

In *Lillie-Reed*, Children were told that their friends had come and talked about "silly things":

Interviewer: You know your friends that you played with at nursery school? I've been talking to them . . . They were telling me about some silly things that happened at the nursery. Do you know about them things? . . .

Child: Don't know that.

Interviewer: Shall I help you a bit? They were telling me about their teachers, when they were in your class.*

After the accusations of abuse, teachers in the day care kept "disclosure logs" to record children's statements about abuse. Some of the examples show how children talked among themselves about abusive subjects in what seemed to be a very playful atmosphere.

Child 1 They had real snakes, they went SSS, they were toys in the cage outside.

Child 2: I saw the snakes and cage, but I ran up the steps, the snakes are called Mandy the same as me. [Note this is the first time Mandy mentions snakes.] . . .

Child 2: And do you know what? Chris and Dawn kicked me.

Child 3: Why did they kick you?

Child 2: 'Cause they thought I was a pirate lady.

Child 1: And they slapped me 'cause they thought I was a doggy. [Both Child 1 and Child 2 laugh and begin to jump on a piece of equipment.]*

It appears that the first allegations of Child 2 and Child 3 may have emerged from these sessions.

Nonverbal Props

Because of the limited language skills of young children, many interviewers use nonverbal props to help children provide details of their past. These props have been particularly used in interviews of sexually abused children as a way to question children about how and where they were touched. Although the use of props seems intuitively useful, the scientific literature indicates that at times, these devices will increase inaccuracy in children's reports. One of the reasons for this is because the prop is being used as a symbol and young children are not symbol-minded. According to DeLoache (DeLoache & Smith, 1999), who has conducted the pioneering work in this field, for the child to become symbol-minded, the child must come to understand that symbolic objects have a dual nature: They represent the object itself (e.g., a doll) as well as a specific referent (e.g., the doll represents the child). Until 4 years of age, children do not have this appreciation. One result is that they end up "playing" with the symbol. In this respect, the symbol is a suggestive influence. Some examples of research on the influence of props on children are now presented.

Anatomically detailed and undetailed dolls are frequently used by professionals when interviewing young children about suspected sexual abuse. The major rationale for the use of anatomical dolls is that they allow children to manipulate objects reminiscent of a critical event, thereby cuing recall and overcoming language and memory problems as well as motivational problems of embarrassment and shyness. However, research con-

ducted in the past decade has raised concerns about the suggestiveness of the dolls and their influence on the accuracy of children's reports. There are several important findings of this research. First, there is no consistent evidence to suggest that there are characteristic patterns of doll play for abused children. Many studies show that the play patterns thought to be characteristic of abused children, such as playing with the dolls in a suggestive or explicit sexual manner or showing reticence or avoidance when presented with the dolls, also occur in samples of nonabused children. Second, more recent studies indicate that use of the dolls does not improve accuracy of young children's reports, and in some cases they decrease accuracy. For instance, we found that 3-year-old children (Bruck, Ceci, Francoeur, & Renick, 1995) and 4-year-old children (Bruck, Ceci, & Francoeur, 2000) who had just completed a medical examination at their pediatrician's office made a number of errors when asked direct questions about where the pediatrician had touched them and that these errors increased when children were asked these same questions in conjunction with dolls. Specifically, children inaccurately showed that the doctor had touched their genitalia or buttocks when this did not happen. These inaccurate answers reflect the novelty of the dolls, which prompted the children to explore the genitalia, often in very creative ways; the inaccurate answers also reflect the implicit demands of the interview, which were to show and talk about touching.

There is also a single case study that suggests that repeated exposure to the dolls may lead young children to fabricate highly elaborate accounts of sexual abuse. After a third exposure in a period of a week to an anatomically correct doll, a nonabused 3-year-old told her father that her pediatrician had strangled her with a rope, inserted a stick into her vagina, and hammered an ear scope into her anus (see Bruck, Ceci, Francoeur, & Renick, 1995).

Researchers have examined the effects of giving children real objects (e.g., a stethoscope) or a toy object (e.g., a teddy bear to represent the child, or a toy car to represent a real car) to report their past experiences. In a recent review of the experimental studies examining the use of props in interviews, Salmon (2001) concluded that although real props increase the amount of information that children report about an event, they also increase the number of errors. Further, she concluded that free access to a large number of real

props is associated with a relatively large number of errors in children's reports about touching, particularly for younger children. For example, Pipe et al. (1999, experiment 2) reported that repeated interviewing with real props introduced a disproportionate amount of new inaccurate information into children's reports after a 1-year delay. Steward and Steward (1996) found that when children had the opportunity to manipulate real props, the situation turned from one of reporting what actually happened to playing. Similar findings have been found for toys or for small-scale props (i.e., giving the child a toy piece of furniture and asking him to show how he was sitting).

Asking the Child to Draw

In her review, Salmon (2001) concluded that asking children to draw a picture about a specific event in combination with nonleading verbal prompts can enhance the verbal reports of children over the age of 4 years, but it is less effective for younger children. She also concluded, however, that after a long delay, not only will drawing elicit less information than not drawing (i.e., just asking), but it also introduces additional errors into children's accounts. A recent study found that when drawing is accompanied by misleading questions, it is associated with very high error rates in children's subsequent reports (Bruck, Melnyk, & Ceci, 2000).

A striking aspect of the interviews in *Lillie-Reed* was the number of toys available to the children during investigative interviews. On the one hand, these seemed to have put the children at ease and allowed them to enjoy some of the experience. However, generally, their presence was distracting and resulted in the children spending more time playing with the toys than focusing on the interview. As a result, there are times when it is not clear if the child was actually playing or directly responding to the interviewer's question.

Children were shown dolls and sometimes asked to draw or point to body parts to elicit allegations of abuse. The problem with this strategy is that it signals to the child that the focus of concern is the touching of certain areas of the body. Children may provide abuse-consistent responses because they think this is what the adults want to hear. Also, the use of these props makes it easier for adults to ask leading questions about touching ("Show me where he touched you. What do we call this part? Did he touch you here?").

On July 12, Kristen reported in an investigative interview with that Chris Lillie had hurt her bottom with a crayon, that he had tickled her with a crayon, and that he had put a crayon in her "fairy." The context of this last disclosure is as follows. First, Kristen asked to play with a doll and the interviewer encouraged her to undress the doll and name the body parts. When directly asked, the child denied twice that anything bad happened to her at the day care. The interviewer then pointed to the doll and asked:

Interviewer: Has anybody ever hurt those bits on your body?

Child: No. Chris.

Interviewer: How did Chris hurt those bits?

Child: He's hurt mine bum and it's sore now.

Interviewer: So you know you're pointing to that bit between your legs and you said Chris had hurt you. How did he do it?

Child: He'd do it this hard. [As she says this, Kristen, who is sitting on a child's tiny wooden chair, lifts her skirt and points or presses a finger or fingers between her legs—what looks like the vagina area.]

Interviewer: And what was he using to do it with?

Child: He was . . . [there is a brief pause while she looks at the table of toys in front of which she is sitting and then stretches her hand out to a plastic bucket of crayons that she was earlier using to draw] using a crayon.*

Thus, Kristen's disclosure that Chris Lillie had inserted a crayon in her vagina was actually a demonstration with props that were laid out on the table in front of her. Perhaps she named the prop to provide an answer to a question that she had no answer for. In research settings, it is common for children to name surrounding props when asked questions to which they do not know the answer. For example, in the monkey-thief study (Bruck et al., 2002), when children were asked what the thief had stolen, a number of children named objects that were in the interviewing room (e.g., video camera, clock, books). When children in this study were asked to describe the thief, they would often look at the experimenter and describe the very clothes she was wearing. (Interestingly, there were children in the *Lillie-Reed* case who, when asked what they were wearing when they were abused, replied, "These clothes that I am wearing now.")

Kristen's claim that she had a crayon inserted in her fairy is reminiscent of the children in the Bruck, Ceci, Francoeur, and Renick (1995); Bruck et al. (2000) studies; when these children were asked how the doctor touched them, they used available props to make false demonstrations or statements that these had been inserted into their buttocks or genitals. Thus, it is possible that Kristen's initial response reflected her use of an available object to fill in the answer to a question with no knowable answer. It was a response that, once elicited, she repeated and elaborated. On July 20, the medical examiner noted that "Kristen told her" that Chris Lillie had put a crayon in her vulva and made her bleed in her knickers. On the basis of her statements, Lillie was arrested and put in prison on July 24.

Combining Suggestive Techniques

For ease of exposition, we have attempted to discretely categorize a number of suggestive interviewing techniques. As can be seen from so many of the excerpts, these elements rarely occur in a vacuum; each interview was filled with a variety of suggestive interviewing techniques. The scientific literature demonstrates that as interviews become more suggestive, the number of false allegations increases (e.g., Bruck et al., 2002; Leichtman & Ceci, 1995; Scullin et al., 2002). One reason for this is that as the number of techniques increases, the bias of the interviewer becomes clearer.

Generally, the interviews in the *Lillie-Reed* case are so filled with suggestive interviewing techniques that they are best described as chaotic. Children were given toys, they were asked to draw, or the interviewer would draw. Never was there any attempt to identify whether the children were playing or actually describing their alleged abuse. In addition to the props, toys, and drawings, when one interviewer could not deal with the situation, another one was called in, and sometimes parents or friends of parents were asked to join in or take over the interview. Sometimes one of these interviewers would leave (on the promise that the child would tell when the interviewer left), only to reappear later in the interview. Children were promised trips to restaurants if they would tell. Children were told to be brave, or they were told that they were safe because the bad people were in jail. Children were asked leading questions or provided with direct information about touching, about abuse, about Lillie, about Reed, and about trips to Lillie's apartment. And all of this information was repeated within and across interviews, with the goal that

the children would come to make statements consistent with the prevailing belief that they had been abused by Lillie and Reed.

The Effects of Suggestion on the Credibility of Children's Reports

It is one thing to demonstrate that children can be induced to make errors and include false perceptual details in their reports, but it is another matter to show that such faulty reports are convincing to an observer, especially a highly trained one. In a series of studies, Ceci and colleagues (Ceci, Loftus, Leichtman, & Bruck, 1994; Ceci, Huffman, Smith, & Loftus, 1994; Leichtman & Ceci, 1995) showed videotapes to experts of children's reports that emerged as a consequence of repeated suggestive interviews. In some cases, the experts also saw videotapes of children who resisted suggestions and denied that anything had happened. These experts were asked to decide which of the events reported by the children actually transpired and then to rate the overall credibility of each child. Experts who conduct research on the reliability of children's reports, who provide therapy to children suspected of having been abused, and who carry out law enforcement interviews with children generally failed to detect which of the children's claims were accurate and which were not, despite being confident in their judgments.

Some professionals state that they can detect suggestion because the children simply parrot the words of their investigators. However, evidence from the past decade provides no support for this assertion. First, children's false reports are not simply repetitions or monosyllabic responses to leading questions. Under some conditions, their answers go well beyond the suggestion and incorporate additional details and emotions. For example, in the Bruck et al. (2002) study, children's false reports contained the prior suggestion that they had seen a thief take food from their day care; but the reports also contained nonsuggested details such as chasing, hitting, and shooting the thief (also see Bruck, Ceci, Francoeur, & Barr, 1995; Ceci, Huffman, et al., 1994).

Finally, linguistic markers do not consistently differentiate true from false narratives that emerge from repeated suggestive interviews. In the Bruck et al. (2002) study, where children were repeatedly and suggestively interviewed about true and false events, the children's narratives of the false events actually contained more embellishments (including descriptive and emotional terms) and details than their narratives of the true events.

Also the false narratives had more spontaneous statements than the true narratives. Although for the most part, the details in false stories were realistic, as suggestive interviews continued, children inserted bizarre details into their stories, a point that we now consider.

In *Lillie-Reed*, some of the children's disclosures became bizarre or fantastic with repeated interviewing. For example, after one suggestive investigative interview, one of the children, Ned, reported that he had been penetrated with a knife (there was no physical evidence); that Dawn Reed had put needles into his bottom; that Chris Lillie had urinated in his face; that Lillie and Reed had swapped bodies, putting each other's head on and different hair and clothes. Ned also spoke of monsters in an elevator. He said that Reed picked him up and put him in a cupboard with no handles or windows but that he turned into a gladiator and killed everyone.

Three hypotheses have been offered to account for the occurrence of such bizarre details. The first is that they are false and are the result of suggestive interviews (Bruck et al., 2002). Second, although reports of fantastic or bizarre events may themselves be false, their presence is claimed by some to be symptomatic of trauma, and as such may be markers for narratives that are otherwise true. According to this latter hypothesis, as a consequence of their abuse, children may misperceive actions or events or use fantasy to deal with their anxieties and to empower themselves to regain control over their victimization (see Everson, 1997, for a full account of explanations). Finally, children may make bizarre allegations because their abusers maliciously suggest false events to the children so that they will not be believed at all. For these reasons, reports of abuse should not be discounted as false if they contain fantastic or bizarre details because fantastic details occur with some frequency in the reports of children who were actually abused (Dalenberg, Hyland, & Cuevas, 2002).

Some of the professionals involved in *Lillie-Reed* expressed belief in the children's bizarre allegations, as reflected by the following statement of the chief medical examiner:

The bizarre nature of the abuse, almost certainly involving instrumentation, drugs and pornography, at a time when the children's cognitive abilities were so immature, means that triggers are not easily recognized. For example, a soda siphon sound in one room caused hysteric panic to a child in another.

The review team argued that although the content of each and every statement made by the children may be incorrect, nonetheless the substance of the disclosures is correct. Thus, statements that the children had been penetrated with scissors or that they had been taken to specific locations by Lillie and Reed or that Lillie and Reed had swallowed bleach are said to contain important kernels of truth. The argument is that either because the children did not have the vocabulary or because they were misinformed about specifics, there are errors in their statements.

Although some of these arguments seem plausible, there is strong scientific evidence to support only the first hypothesis: that evolving bizarre disclosures reflect suggestive interviewing techniques. The argument is not that interviewers suggested these bizarre details to the children, but that it became clear to the children that the more details they could produce, the more they pleased their interviewers, even if they produced very fantastic and bizarre details.

To summarize, when children have undergone suggestive interviewing or are exposed to some of the components of suggestive interviews, they can appear highly credible when they are inaccurate, even to well-trained professionals. Accordingly, once children have been exposed to the suggestive influences discussed here, it is impossible to support a claim that the reports obtained from them are reliable. Demeanor, affect, spontaneity, and other traditional criteria used to determine credibility are rendered irrelevant to the determination of the accuracy of the postsuggestion report.

Adults' Memories for Conversations with Children

As we have demonstrated, information on the exact wording of each question asked of children during interviews, as well as the number of times questions are repeated and the tone of questioning, is necessary to determine whether strategies recognized as capable of affecting the reliability and accuracy of children's reports were used by interviewers. In *Lillie-Reed* the lack of such information for the parents', the physicians', and other professionals' reports makes it impossible to make such a determination. Therefore, videotaped interviews of the children must be relied on to examine the instances when children made or denied allegations of abuse.

It is a well-documented fact in the psycholinguistic literature that when asked to recall conversations,

most adults may recall the gist (the major ideas, the core content), but they cannot recall the exact words used, nor the sequence of interactions between speakers. This latter linguistic information rapidly fades from memory, minutes after the interactions have occurred (for a review, see Rayner & Pollatsek, 1989). Bruck, Ceci, and Francoeur (1999) videotaped mothers interviewing their 4-year-old children about a play activity that had taken place in the laboratory. Three days later, mothers were asked to recall this conversation. The mothers could not remember much of the actual content of the interview, omitting many details that had been discussed, but much of what they did recall was accurate. Of particular importance, the mothers were especially inaccurate about several aspects of their conversation: They could not remember who said what (e.g., they could not remember if they had suggested that an activity had occurred or if the child had spontaneously mentioned the activity). Mothers also could not remember the types of questions they had asked their children (e.g., if they had used an open-ended question or a series of leading questions to obtain a piece of information). For example, although some mothers in this study remembered that they learned that a strange man came into the room when the child was playing, they could not remember if the child spontaneously gave them this information, or if it was obtained through a sequence of repeated leading questions that the child assented to with monosyllabic utterances. To summarize, although mothers could accurately remember parts of the general content of the conversation, they could not remember how or if they questioned their child.

A similar study was conducted with mental health trainees. This study (the birthday party study; Bruck, Ceci, Melnyk, et al., 1999) was described earlier in the section on interviewer bias. Mental health trainees interviewed four children about an event. They were encouraged to make notes after each of the interviews. A few weeks later, their memories for two of the conversations were tested. The mental health trainees showed the same pattern as the mothers. Even though they were allowed to consult their notes, they could not remember who first mentioned certain pieces of information; also, they could not remember if the child's statements were spontaneous or the result of leading questions. In addition, these trainees mixed up which of the four children said what. That is, they often attributed the actual report of Child A to Child B.

Warren and Woodall (1999) obtained results similar to those reported for mothers and mental health trainees. These researchers studied experienced investigators who created summaries immediately after their interview with a child. When asked what types of questions they had used to elicit information from the children, most of these experienced interviewers answered that they had asked primarily open-ended questions, few stated that they had asked specific questions, and only one reported asking any leading questions. Their estimates were highly inaccurate, as most (over 80%) of the questions asked by these interviewers were specific or leading.⁴ Returning to the Bruck, Ceci, Melnyk, et al. (1999) birthday party study, as reported earlier, the interviewers also made factual errors about the content of the children's statements. That is, the interviewers reported that the fourth child had attended a birthday party when it was clear in a number of cases that the child had made no such statement. A recent study conducted by Lamb and colleagues (Lamb, Orbach, Sternberg, Hershkowitz, & Horowitz, 2000) indicates that the findings that are obtained in the laboratory with mothers, mental health trainees, and skilled interviewers generalize to investigators who interview children suspected of sexual abuse. Verbatim contemporaneous accounts of 20 investigative interviews of 20 4- to 14-year-old alleged sexual abuse victims were compared with audiotaped recordings of these interviews. More than 50% of the interviewers' utterances and 25% of the incident-relevant details provided by the children were not reported in the "verbatim" notes. The structure of the interviews was also represented inaccurately in these accounts. Fewer than half (44%) of the details provided by the children were attributed to the correct eliciting utterance type. Investigators systematically misattributed details to more open rather than more focused prompts. In view of the quantity of errors in the Lamb et al. study, where notes were made at the time of the interview, one can begin to appreciate the large number of errors that can occur when adults attempt to recall conversations that occurred days or months previously.

These data provide an empirical basis for the importance of obtaining electronic copies of interviews with children. They suggest that summaries of interviews

⁴A number of parents stated that they did not ask leading questions or put words into their children's mouths. The scientific literature shows how difficult it is to evaluate just how we conduct conversations. Our memories are probably molded by how we would like to see ourselves rather than how we are.

based on interviewers' notes and memories may be inaccurate for a number of reasons. Usually, notes contain only pieces of information that the investigator thinks are important at the moment. If the investigator has a bias that the child was sexually abused, this could color his or her interpretations of what the child said or did, and it is this interpretation that appears in the summary rather than a factual account of what transpired. If a number of children are interviewed and the reports are not immediately written, the investigator may confuse which child said what. Finally, summaries of interviews based on interviewers' notes are exactly that—summaries. They do not contain a detailed accounting of how many times the same question was asked or how many times the child denied before finally assenting. No one without stenographic training can possibly record each and every time a question was asked that was not answered. Thus, the literature on adults' inability to accurately recall what children told them, when paired with the literature on forgetting, memory distortions, and biases, highlights the real problem of relying on parents' and investigators' reports of children's behaviors and statements that occurred in the past and that were not recorded at the time of their occurrence.

Examples from Lillie-Reed

All the children in the *Lillie-Reed* case made their initial disclosures to their parent(s), who were the first to question them about abuse. The parents recollected these conversations days, weeks, and months after they allegedly occurred. Some of these descriptions contain contextual statements, such as "I asked . . ." and "He said . . .," but, as the literature clearly shows, the potential for error is extremely high in these recollections, and as a result, the investigators of this case cannot determine the following: (a) whether the child's statement was spontaneous or prompted by dozens of questions (as was the case in the videotaped interviews); (b) how many questions the parent asked and how many different times the parent questioned the child to get any response; (c) whether the parent reported what he or she had said or what the child had said; (d) whether the parent accurately recalled the content of the child's statement; and (e) how much of the original interaction the parent omitted either because it was forgotten or because it was considered nonessential material at the time of recall. Because it is impossible to recapture this information, the most reliable evidence (and maybe the only reliable evidence) of the children's disclosures, and the

amount of prompting required to make these disclosures, is that obtained from the videotaped evidence.

This first example shows changes in one parent's memory of her child's pretend phone call in April 1993:⁵

May 13 1993 Social Worker Report: Around Easter 1993, her mother left Rachel with some friends while she went shopping. On her return, her friend said that Rachel had said, "My Dad did something with his willie." Her friend had replied "no, no." Rachel did not say anymore when she was questioned further.

August 17 1993 (Mother's statement to the police). On one occasion when Rachel was with a neighbor of mine, she was playing with a toy telephone and pretending to ring her Dad. She said something like someone's willie had been on her hand. When I tried to ask her further about this, she totally clammed up and rushed to another neighbor for reassurance saying, "I'm not naughty, I'm not naughty, am I?" We reassured her that she wasn't.

March 1994 (Signed Statement). On one occasion, I left Rachel to be cared for by two friends. I went out shopping. Jeanie had reported to me when I returned that Rachel had been playing on a toy phone pretending to ring her Daddy. She said that someone's willie was on her hand. When she realized that Jeanie was listening she put the phone down and said, "I am not naughty am I." The next day I tried to talk to Rachel about it but she wasn't able to explain to me what she had said.

This example shows that the content of Rachel's utterance had changed from "My Dad did something with his willie" to "she told her dad that someone's willie was in her hand." With time, the statement became more consistent with the idea that someone besides her father had done something. This example also shows that although the words "no" or "naughty" continued to be mentioned, the specification of the speaker changed. Initially, it was the mother's friend, then it was Rachel in response to her mother's questioning, and finally it was Rachel's response to the adult's listening in on her pretend conversation.

In another example, according to the notes of a social worker who was present at the child's police interview, the child said that Chris Lillie and Dawn Reed were married. However, this statement was not made by this child in the interview.

Throughout their report, *Abuse in the Early Years* (Barker et al., 1998, pp. 210–214), the review team

⁵This interchange is a central theme in statements by Rachel's mother, probably because she interpreted it as Rachel's attempt to tell about the abuse.

provided examples of children's statements such as the following:

Boys and girls describe being sexually assaulted and witnessing other children being sexually assaulted by Chris Lillie and to a lesser extent by Dawn Reed. These assaults were said to have taken place in the toilets, in a cupboard, and in the play house at the nursery. For example, one boy said that Chris Lillie had held his penis and rubbed it until it hurt. . . . Another child describes Chris Lillie weeing on his hair. . . . Several children told of a house with a black door in a named road. Children also talked of being taken in lifts to flats. . . . One child described Chris Lillie's willie pointing to the ceiling . . . one child described how Chris Lillie had put his tiddler in her fairy while she was sitting on the edge of a settee in his house . . . several children described being given an injection which we deduce from their descriptions contained some form of analgesic. . . . Children variously stated that they have been shouted at, sworn at, smacked, hit. . . . Children described how they were threatened, they said that a boy and a girl had been stabbed because they told their mum. . . . Other threats that the children were able to talk about were of monsters and a dog that would hurt you or scratch your fairy.

If indeed these statements were spontaneous, were not preceded by any forms of suggestion, and were the direct words of the children (rather than parents' summaries of conversations or the review team's summary of interactions in an interview), then the children's words would provide important evidence to support the hypothesis of abuse. However, a review of the case facts show that these purported statements of the children were often parents' reports of their child's statements; in other cases, these represent a combination of monosyllabic responses provided to a stream of leading questions or at the end of a very suggestive interview.

To produce their report, the review team interviewed more than 40 sets of parents/carers of children and more than 112 other witnesses. If the interviewing began in October 1995, these adults were recalling events, ideas, and impressions from 3 to 4 years earlier. Examination of the statements of parents at this last inquiry show how much their testimony changed from their first reports of their children's statements. Clearly, the review team relied on unreliable evidence from witnesses who deeply believed that their children had been abused.

The review team concluded that there was no evidence of suggestion in the interviews with the children.

They wrote: "The Review Team saw the evidential videos made by the children. These would not support the view that the questions were in any way leading" (Barker et al., 1998, p. 221). Their impression of the three interviews conducted with one of the child witnesses was this:

Over three video interviews, she detailed abuse of herself and other children by Chris Lillie, to a lesser extent Dawn Reed, and she also mentioned other nursery staff's names. Her testimony in these videos, which we have seen, is extremely powerful and provided persuasive evidence of her abuse in the nursery and elsewhere. (p. 148)

Based on the analyses of the videotape by the plaintiffs' experts (including the first author of this chapter), it is difficult to understand how the review team came to such a conclusion; these interviews were highly suggestive. The judge agreed with this assessment.

Impact and Criticism of Scientific Studies Cited in Lillie-Reed

The child and law research conducted by developmental psychologists has had a large impact on many aspects of the legal arena. First, as a result of this new scientific evidence, many of the guilty verdicts of the 1980s and early 1990s have been or are being overturned. On appeal, the defendants presented relevant and appropriate scientific evidence to show how suggestibility and memory distortion could produce inaccurate statements of abuse in young children (e.g., *New Jersey v. Michaels*, 1994; *People v. Scott Kniffen*, *Brenda Kniffen*, *Alvin McCuan*, and *Deborah McCuan*, 1996; *Snowden v. Singletary*, 1998; *State of Washington v. Carol M.D. & Mark A.D.*, 1999; *State of Washington v. Manuel Hidalgo Rodriguez*, 1999). It is now rare to find similar cases cropping up in the legal setting, at least in North America. Second, as a result of this scientific literature, there is an awareness of the importance of developing scientifically validated protocols to be followed when interviewing children (e.g., Davies & Westcott, 1999; Lamb et al., 2003). Third, there is a growing awareness of the importance of videotaping the first and all subsequent investigative interviews with children in order to evaluate the degree to which children's initial statements were spontaneous and the degree to which they were elicited by various suggestive interviewing techniques.

Although this work is scientifically based, it is not without its critics (e.g., Lyon, 1999; Meyers, 1995). These critics claim that this area of science has created a backlash that has undermined the credibility of children, that focuses on the weaknesses rather than the strengths of their memory, and that denies the reality of child abuse. They also argue that because scientists have based their studies and analyses on a handful of trials (preschool multivictim, multiabuser cases) that represent the worst-case scenario in terms of interviewing young children, the scientific analyses are overgeneralized to nonproblematic interviews of children involving sexual abuse.

However, this literature should not be viewed as an attack on the credibility or the competence of children, but rather on adults' mishandling of young children and their reports. Although it is true that the suggestibility literature focuses on the ways adults can distort children's memories, it does not deny the strengths of children's memories when these are not tainted by exogenous forces. For example, in cases when children make spontaneous disclosures to parents about past abuse and then report the same event to the police, it is inappropriate to call on the suggestibility literature to demonstrate that children's reports can be tainted by interviewing methods. Clearly, that would be an inappropriate extension of this literature. Similarly, it is just as illogical to dwell on literature that shows how well children can recall their past when asked neutral questions, when the case at hand reveals a multitude of suggestive techniques. Nothing about the strengths of children's memories can inform such cases other than to stress the point that their initial disclosures prior to suggestive interviewing may have been accurate.

The claim that research on suggestibility denies the reality of sexual abuse is a straw man. Researchers who conduct research in this field uniformly agree that most claims that children make of sexual abuse are probably accurate. The scientific findings merely indicate that there are clearly defined situations in which some children's claims should be carefully examined. Just because there are some false allegations does not mean that all allegations are false.

Finally, the argument that the scientific literature rests on issues raised by the very worst of cases is also to some degree a red herring. Cases such as *Lillie-Reed* are of interest to social scientists not simply because of their dramatic components, but also because their complexity provides a vast number of examples and details

that are relevant to many types of cases that end up in the legal arena. Although *Lillie-Reed* may be among those "worst-cases scenarios," it nonetheless shares important structures or components with other cases that commonly come to court.

Further, a specific case does not render the literature on children's suggestibility and autobiographical memory valid or not valid. It is the extent to which the literature is relevant to each individual case. The literature on children's suggestibility is applicable to any type of case in which child witnesses make statements only after suggestive interviewing practices; it does not matter if the case is a day care case or if it involves allegations of abuse by a parent, boyfriend, or stranger.

Summary

If a child's indicting statements are made in the absence of any previous suggestive interviewing and in the absence of any motivation on the part of the child or adults to make incriminating statements, then the risk that the statement is inaccurate is quite low. If, however, the child initially denies any wrongdoing when first asked about a criminal action but later, as a result of suggestive interviewing practices, does make allegations, the statements may be unreliable.

Errors that result from suggestive techniques involve not only peripheral details, but also central events that involve children's own bodies. In laboratory studies, children's false reports can be tinged with sexual connotations. Young children have made false claims about "silly events" that involved body contact (e.g., "Did the nurse lick your knee? Did she blow in your ear?"), and these false claims persisted in repeated interviewing over a 3-month period (Ornstein, Gordon, & Larus, 1992). Young children falsely reported that a man put something "yuckie" in their mouth (Poole & Lindsay, 1995, 2001), and falsely alleged that their pediatrician had inserted a finger or a stick into their genitals (Bruck, Ceci, Francoeur, & Renick, 1995), or that some man touched their friends, kissed their friends on the lips, and removed some of the children's clothes (Lepore & SESCO, 1994). A significant number of preschool children falsely reported that someone touched their private parts, kissed them, and hugged them (Bruck et al., 2000; Goodman, Bottoms, Schwartz-Kenney, & Rudy, 1991; Goodman, Rudy, Bottoms, & Aman, 1990). In addition, when suggestively interviewed, some children will make false allegations

about nonsexual events that could have serious legal consequences were they to occur. For example, preschoolers claimed to have seen a thief in their day care (Bruck, Ceci, & Hembrooke, 1997).

The mix of suggestive interviewing techniques in conjunction with the degree of interviewer bias can account for variations in suggestibility estimates across studies. If a (biased) interviewer uses more than one suggestive technique, there is a greater chance for taint than if he or she uses just one technique.

At times, suggestive interviewing techniques result in false beliefs. Children who incorporate the suggestions of their interviewers come to truly believe that they were victims.

Suggestive interviewing affects the perceived credibility of children's statements. The major reason for this lack of accurate discrimination between true and false reports is perhaps due to the fact that suggestive techniques breathe authenticity into the resulting false reports. When false reports emerge as a result of suggestive interviews, these are not simple repetitions or monosyllabic responses to leading questions. Under some conditions, these suggested reports become spontaneous and elaborate, going beyond the suggestions provided by their interviewers. There are no valid scientific tests to determine which aspects of a report or which reports are accurate accounts of the past. There is no scientific "Pinocchio test" that indicates that the child's metaphorical nose is growing longer when his or her statement is inaccurate.

Final Judgment of Lillie-Reed

In a 446-page judgment that reviews in detail all aspects of the case, Judge Eady found the review team guilty of malice on the grounds of a biased and inaccurate investigation that was based on opinion rather than scientifically based findings. As for Lillie and Reed, Judge Eady wrote:

The allegations made against them were of the utmost gravity and received sustained and widespread coverage. I decided, therefore, that each Claimant was entitled to what is now generally recognised to be the maximum amount for compensatory damages in libel proceedings. I award each of them £200,000. . . . What matters primarily is that they are entitled to be vindicated and recognised as innocent citizens who should, in my judgment, be free to exist for what remains of their lives untouched by the stigma of child abuse. (Approved Judgement *Lillie and Reed v. Newcastle City Council & Ors*, 2002, p. 443)

AUTOBIOGRAPHICAL MEMORY, DEVELOPMENTAL DIFFERENCES, AND MECHANISMS OF SUGGESTIBILITY

In this section, we cover some topics that, although important in the field of children and the law, were not germane to the discussion of *Lilly-Reed*.

Children's Memory for Traumatic Events

The discussion of *Lillie-Reed* focused on the suggestive influences that can compromise reliable reporting because, as noted earlier, children in this case did not provide any abuse-related narratives before this type of suggestive questioning occurred. Although it might be argued that children are incapable of reporting traumatic events without this type of support, the literature clearly does not support this view. Rather, as detailed in this section, a large number of studies show that children are capable of providing accurate, detailed, and useful information about actual events, some of which are traumatic. It is important to note that the studies in this section are characterized by the neutral tone of the interviewer, the limited use of misleading questions (for the most part, if suggestions are used, they are limited to a single occasion), and the absence of any motive for the child to make a false report. When such conditions are present, much, but not all, of what children report can be quite accurate. Unfortunately, these conditions were not present in the interviews of the children in *Lillie-Reed*.

Does Memory for Trauma Differ from Memory in General?

A widespread notion is that memory for traumatic events operates differently from memory for everyday experiences. The origin of this belief can be traced to the psychiatry of the late nineteenth century. From interviews with his patients, Pierre Janet (1889) concluded that traumatic experiences disrupt normal memory and become "dissociated" or split off from conscious awareness as the result of a psychological defense that works to block the recall of painful events. Like Janet, Sigmund Freud (1896/1953) asserted that traumatic memories are subject to "repression" and can seep into consciousness indirectly by way of symptoms of psychological disorders. Freud's claim that memory for trauma operates differently from memory for nontraumatic events has pervaded the clinical literature. Paradoxically, two competing theories have emerged in

modern clinical thought. Consistent with Freud's original beliefs, some have asserted that traumatic experiences are too overwhelming for children to endure and are pushed underground and remain difficult to access (e.g., van der Kolk & Fislser, 1995). Others have argued that traumatic experiences are so shocking that they are indelibly fixed in memory and preserved over time in a pristine form (e.g., Koss, Figueredo, Bell, Tharan, & Tromp, 1996).

Two Types of Traumatic Memory?

One widely cited solution for these disparate effects of trauma has been proposed by Terr (1991, 1994). Terr distinguishes between two types of trauma: Type I involves a single, shocking event, such as an attempted murder or a natural disaster, and Type II deals with repeated, chronic traumatic experiences, such as multiple incidents of sexual abuse. According to Terr, Type I traumas create detailed and precise memories, whereas Type II traumas lead to fragmented or even nonexistent memories. After many traumatic events, children learn to cope with the fear or pain by dissociating, or separating themselves from the experience as it is occurring, thereby causing impoverished encoding and limited or no memory.

Evidence for this distinction comes from clinical case reports. Most notably, Terr (1988, 1991) contrasted a group of 5- to 14-year-old children who were kidnapped from their school bus and buried in a truck trailer, with 20 children who were abused repeatedly before 5 years of age. Terr reported that all of the kidnapped children recalled the event in vivid detail after a 5-year delay, whereas the repeatedly traumatized children exhibited poor or no verbal recall because they had learned to repress their memories.

Although seemingly sensible, a careful examination of Terr's (1988, 1991) comparison reveals numerous problems. First, the Type I and Type II children differed in age; the older (Type I) children should have better memory than the younger (Type II) children for any experience, not just traumatic experiences. Second, only four of the Type II children endured repeated sexual abuse, and three of them were under the age of 2 years when they were abused. Based on the empirical literature (reviewed later), however, all events, not just traumatic events, experienced before 2 years of age are inaccessible to verbal recall. Third, Terr's argument that repeated trauma leads to alterations in memory implies that well-organized memories for such occurrences should never be available for retrieval because

these were never completely registered in memory in the first place.

Empirical Studies of Memory for Stressful Events

Given claims in the clinical literature regarding the special nature of traumatic memories, how well have empirical studies squared with these claims? As a whole, the empirical literature on children's recall of distressful events is inconsistent with beliefs that memory for trauma operates differently from memory in general. Rather, existing evidence suggests that memory for traumatic events behaves very much like memory for everyday experiences.

Recall of Traumatic Events Is Generally Accurate. First, numerous investigations have demonstrated that, like everyday experiences, traumatic experiences can be recalled quite well, even by children as young as 3 years of age. Studies of children's memory for natural disasters, such as Hurricane Andrew (Bahrnick, Parker, Fivush, & Levitt, 1998; Shaw, Applegate, & Schorr, 1996) and the explosion of the space shuttle *Challenger* (Warren & Swartwood, 1992), present evidence of detailed and generally accurate memories over long delays. Likewise, examinations of children's recall of highly distressful medical procedures, such as emergency room visits for trauma (Howe, Courage, & Peterson, 1995; Peterson & Whalen, 2001), bone marrow transplants (Stuber, Nader, Yasuda, Pynoos, & Cohen, 1991), lumbar punctures (Chen, Zeltzer, Craske, & Katz, 2000), and chemotherapy treatments (Howard, Osborne, & Baker-Ward, 1997), show that children retain enduring and largely faithful memories for these experiences.

To illustrate, research by Ornstein and his colleagues on children's retention of a voiding cystourethrogram (VCUG)—a painful and stressful radiological procedure involving urinary catheterization—has demonstrated that 3- to 7-year-olds can provide highly accurate accounts of this event over a 6-week delay (Merritt, Ornstein, & Spicker, 1994). Related work has shown generally accurate memory for this procedure for children over delays of 5.5 years (Pipe et al., 1997).

Investigators who employ the VCUG paradigm to study the effects of trauma on memory argue that the VCUG is a forensically relevant event because in some ways it is similar to situations of sexual abuse. Children, some of whom are restrained, are handled by adults while the genital area is uncovered. The event is quite painful, as it involves passing a catheter into the urinary

bladder and filling the bladder to capacity with contrast fluid. Also, the child is asked to urinate on the examining table—a potentially embarrassing activity, especially for young children who have been toilet-trained recently.

Despite the high levels of anxiety experienced by most of the children who undergo this examination, however, some have questioned the relevance of the VCUg to situations involving sexual abuse because it is a socially sanctioned procedure. However, this criticism may be irrelevant to situations in which an abusive adult provides the young victim a misleading framework characterizing their interactions as conventional, such as describing the abuse as a secret game or a special relationship. Further, to the extent that children lack an understanding of the diagnostic value of the VCUg, some may conceive of this procedure as a betrayal by trusted caregivers rather than a medically necessary examination.

Memories for Trauma Are Subject to Forgetting.

Like ordinary memories, memories for trauma become less accessible as the delay interval increases. Usually, with the passage of time, peripheral or inconsequential details are lost most readily and the gist or central details persist (Goodman, Hirschman, Hepps, & Rudy, 1991; Peters, 1997; Peterson & Bell, 1996). To illustrate, Peterson and Whalen (2001) showed that although children maintained generally accurate memory over a 5-year period for an accident (e.g., lacerations, bone fractures, burns, and dog bites) and medical attention in a hospital emergency room, some aspects of the experience, particularly the details of the treatment, were lost during the delay. Moreover, the general components of the injury were retained better than smaller details.

Memories for Trauma Are Susceptible to Constructive Distortions from External Events. Trauma memories, like memories for more mundane events, are vulnerable to constructive distortions or confusions from other, similar experiences. That is, existing memories of trauma can be altered during the course of the interval between the experience and the report of it, when information from intervening experiences becomes incorporated into the original memory. For example, Principe, Ornstein, Baker-Ward, and Gordon (2000) provided evidence that television programs can produce later fabrications of medical procedures that were nonexperienced but seen on television.

Howe et al. (1995) have shown that, as the delay between a trauma and later interviews increases, children

become increasingly likely to erroneously incorporate information from intervening, like traumatic events into their accounts of the original occurrence. For example, one child who was asked to recall the details of an emergency room treatment for an eye injury that had taken place 6 months prior mistakenly reported that the doctor had fixed his tooth and put medicine in his mouth—activities consistent with another hospital room visit that had occurred in the preceding month. Of particular importance, although nonexperienced details imported from intervening experiences generally do not hinder the accuracy of children's reports, an interviewer who is not privy to the details of the original event likely would not be able to differentiate the children's reports in terms of actually experienced events versus intervening events—an important point given that forensic interviewers rarely know exactly what happened.

Memories for Trauma Are Vulnerable to Constructive Distortions from Internal Factors.

Memories for distressful events may change over time as the result of internal thoughts, such as expectations, feelings, preferences, and goals. To illustrate, Pynoos, Steinberg, and Aronson (1997) reported that some children who witnessed brutal domestic violence erroneously recalled intervening to help the abused parent. Likewise, consider an investigation by Ornstein and his colleagues (1998) in which 4- and 6-year-old children's memory was assessed for a mock physical examination that included some highly expected medical features (e.g., measuring weight) while omitting others, and incorporated several atypical, unexpected features (e.g., collecting a sputum sample). After a 12-week delay, but not during an immediate interview, the children exhibited a relatively high frequency of spontaneous intrusions of typical, but not atypical, medical features that had not been included in their checkups. In fact, 42% of the 4-year-olds and 72% of the 6-year-olds made at least one such intrusion at the 12-week assessment, whereas essentially none of the children reported in their spontaneous recall any of the atypical procedures that had not taken place during their examinations.

Taken together, empirical studies demonstrate convincingly that memories for traumatic experiences act like memories in general. Children's trauma memories are not repressed or hidden from consciousness; rather, the core of the event tends to be well remembered over time. Although trauma memories are enduring, they are not indelibly preserved in storage in their original form.

Rather, their details tend to fade from memory with time. Nor are traumas immune to constructive distortions; intervening events and internal ruminations can alter memory. Thus, it seems that traumatic memories are not of a unique nature, nor do they require special principles to explain their operation.

There is one qualification to these general conclusions, and this involves the long-term memories of very young, often nonverbal children who are later asked to recount an event. In other words, can children or adults accurately recall events that occurred during the first 2 years of life? This is a very complicated issue about which much has been written, but it can be summarized with a few major points.

First, it is clear that throughout infancy, nonverbal memories for certain types of sequenced events develop such that some infants as young as 13 months at the time of original exposure to a simple event are able to nonverbally reenact three-step sequences following delays as long as 12 months (Bauer, Wenner, Dropik, & Wewerka, 2000). Although these investigations provide ample evidence that infants are capable of retaining information about the past, exactly what aspects of their experiences they can remember is unclear. In the infancy work, retention is inferred on the basis of changes in behavior, such as kicking more vigorously or reproducing a set of actions. Behavioral responses, however, are not equivalent to demonstrations of autobiographical memory. Autobiographical memory involves a process in which stored information is made consciously available and remembered as an actual experience, that is, occurring at a particular time, in a particular place, and under particular circumstances.

Nonetheless, these findings of infant retention may be relevant to discussions of children's testimony if early memories first expressible only through behavior later become verbally expressible once children have acquired the ability to talk about past experiences. A number of investigations, however, have provided compelling evidence that children cannot gain verbal access to memories stored without the benefit of language. In a study of children's recall of traumatic injuries that occurred between 13 and 34 months of age, Peterson and Rideout (1998) found that 2-year-olds who were unable to provide a narrative account of the injury immediately after it took place produced fragmentary and moderately inaccurate accounts of this event during subsequent interviews. Similarly, when 3-year-old children were asked to recall a novel event that they had experi-

enced 1 year earlier, they used only words that were part of their vocabulary when the event was experienced (Simcock & Hayne, 2002). These provocative findings suggest that children cannot translate memories into language if the words were not available when the memories were formed. This work indicates, then, that it is difficult, if not impossible, for children or adults to provide verbal testimony about events that occurred before the onset of productive language.

Are Traumatic Events More or Less Memorable Than Everyday Events?

Although it is clear that traumatic memories are subject to the same mechanisms as normal memories, the question remains whether traumatic events are more or less memorable than more mundane events. It is somewhat difficult to answer this question because few studies have directly compared memory for traumatic experiences with memory for nontraumatic experiences within the same children. Nonetheless, what evidence exists suggests that traumatic events often have certain features that make them more or less memorable than most experiences. As such, it is important to understand when and how distress might translate into more or less detailed, accurate, or enduring memories. Factors such as the distinctiveness of an experience, children's understanding of the experience, and their level of distress during the experience can affect the processes involved in encoding, storage, and recall, and consequently affect the memorability of traumatic occurrences.

The Distinctiveness of the Experience. One factor that might affect the memorability of trauma concerns the distinctiveness or uniqueness of the event against the background of the particular child's past experiences (Howe, 1998). Studies of event memory demonstrate that unique events, whether negative or positive in tone, tend to be better remembered than familiar or routine events (Fivush & Schwarzmueller, 1998; Hudson, Fivush, & Kuebli, 1992). For example, by 3 years of age, children are able to retain generally accurate and detailed memories over extended delays for novel events such as airplane rides and visits to Disney World and special museums (see Fivush, 1993, for a review). However, children have great difficulty recalling single episodes of familiar or repeated events, such as what happened one time that they went to McDonald's or what happened on a specific day at preschool (Fivush, 1984; Hudson & Nelson, 1983; Myles-Worsley, Cromer,

& Dodd, 1986). These patterns indicate that single distinctive experiences are more memorable than single episodes of familiar events.

Extending this logic to traumatic events, trauma may be better remembered than other events to the extent that it deviates from the typical experiences of children, rather than merely as a function of the distress that it brings about (Howe, 1998). A fire at a preschool that prompts an emergency response by the fire department might be recalled better than last Monday's snack or trip to the park, not necessarily because of the distress evoked by the situation, but because it stands out from the usual. Like the fire, a visit by the SPCA or a trip to the planetarium might be well remembered because such events are inconsistent with children's expectations of what usually happens at school.

In support of this account is work by Ornstein (1995) examining memory for the VCUG that shows that children's reports of this distressful medical procedure are more complete and more accurate than their accounts of a routine pediatric checkup. One explanation for this finding is that the VCUG is better remembered because it is a single distinctive experience made up of unfamiliar activities, such as a catheterization, a fluoroscopic filming, and urinating on the examining table. In contrast, the well-child checkup is a repeated, familiar event made up of recognizable actions, many of which are often part of young children's pretend play.

Further supporting the notion that the uniqueness of trauma enhances memorability is work by Stein (1996), who found that children's accounts of emotional experiences, both positive and negative, tend to focus on those aspects that are novel or different from what is expected. Stein argues that it is the violation of the typical, not direction of the emotion evoked by the event, that facilitates memory, as distinctive events can elicit positive as well as negative emotions. Consistent with this contention is an investigation by Fivush, Hazzard, Sales, Sarfati, and Brown (2003) that revealed that children living in violent, inner-city neighborhoods recalled positive events in more descriptive detail than negative events. Fivush and her colleagues attribute the heightened recall of positive events to a violation of expectation; for children living in conditions of chronic violence, positive experiences may be distinctive and therefore more completely remembered than negative events. In contrast, a single traumatic event may not stand in stark contrast to their daily lives and would not be expected to persist in memory.

As noted by Howe (1998), this argument is in line with studies showing that as the novelty of stressful situations dissipates, so does their memorability. Consider, for example, individuals in emergency response teams who acclimate to experiences that may seem upsetting to most. This example illustrates that previously distinctive experiences may lose their uniqueness, and hence their memorability, with additional experience. In the next section, we review evidence that directly examines the effects of repeated experience on memorability.

Effects of Repeated Experience on Event Memorability. Despite the lack of evidence supporting Terr's (1994) distinction between Type I and Type II trauma, the experimental literature on children's memory makes it clear that memories of repeated experiences are quite different from memories of single events. However, the reasons for these differences are not the ones proposed by Terr.

Repeated experience with an event can have both beneficial and baleful effects on children's memory, depending on the nature of the event details being recalled. After multiple occurrences of an event, details that generally are experienced the same way during each occurrence are strengthened in memory. Consequently, with repeated experience, children's reports become increasingly general or script-like, focusing on what usually happens (Pezdek & Roe, 1995; Powell & Thomson, 1996). However, with regard to children's recall of details that vary across occurrences (e.g., remembering what clothing was worn by a person the last time the event was experienced, when the items of clothing differed each time), repeated experience has detrimental effects on children's ability to remember a particular occurrence. Specifically, the number of correct details reported about a particular episode of a repeated event is lower than when recalling a one-time event, as details of specific occurrences are omitted or confused among episodes (Hudson, 1990). Although children's general reports of repeated events are largely accurate, in the sense that they describe the gist of what usually happens, they lack detail and may not be veridical with any one instance of the event.

The problems associated with children's recall of the variable details of an occurrence of a repeated event are accentuated under certain conditions. The more frequently events are experienced, the longer the time delay between the event and the interview; the greater the similarity between the events, the more difficult it is

for children to keep track of which details were included in a particular occurrence (Lindsay, Johnson, & Kwon, 1991). Further, the accuracy of children's recall of an occurrence of a repeated event is shaped by the manner in which memory is tested. When children are asked to freely report what happened in an occurrence of a repeated event, they provide few specific features that discriminate one occurrence from others in the series. In contrast, when questions are asked that focus the child on specific aspects of the event that were likely to have varied, confusion between the occurrences is more evident (Powell & Thomson, 1997).

Unlike Terr's (1994) speculation that multiple experiences lead to poorer memory, it simply may be that the details of individual episodes are not recalled as well when they have happened on numerous occasions than when they have happened only once. But, as discussed earlier, although the details of repeated events fade as the memory becomes increasingly general and abstract, the gist tends to be well maintained and largely accurate.

The only study to examine children's memory for repeated trauma was done by Howard et al. (1997). Children who were in remission from cancer were asked to recall the details of chemotherapy treatment that had lasted for an average of 21 months and had ended over 2.5 years earlier. The children's reports of their treatment were quite extensive and highly accurate. Further, no parent agreed with the statement "My child cannot recall the treatment because he/she has actively blocked it out." Thus, Terr's (1994) contention that repeated, or Type II, trauma is unavailable to conscious recall is not supported by empirical evidence.

Existing knowledge. A central determinant of what is selected for attention and placed in memory is existing knowledge. Knowledge influences how children monitor the world, interpret events, and encode incoming information (Bjorklund, 1985; Chi & Ceci, 1987; Ornstein & Naus, 1985). One implication of the literature is that in situations where a child does not understand what is happening, he or she will have little basis for later remembering what was experienced. For example, when child abuse victims are young enough to have almost no sexual knowledge, they likely will have trouble interpreting and remembering what took place. Although children as young as 2 or 3 years will understand that "something is wrong" if they experience the physical pain associated with anal or vaginal penetration, when they experience milder forms of abuse, such as

genital touching, they may not be aware of the inappropriateness of genital fondling versus everyday hygiene and, as a result, construct a very different memory for the encounter than do older children who have learned the impropriety of this behavior.

This argument is most relevant to young sexual abuse victims because most abuse with this age group does not involve vaginal or anal penetration. It most often includes exhibitionism, fondling, photography, and oral fellatio. To the extent that children do not interpret these activities as sexual or inappropriate, they may not be perceived as any more distressful than ordinary forms of affection, cleaning, or diapering, and would not be expected to be any more memorable. The important point here is that what is considered traumatic by adult standards might not be construed as such by a young child.

Stress. A number of investigators have proposed that individual differences in children's behavioral reactions to stress can impact their encoding and retention of a traumatic experience (Howe, 2000; Ornstein, Manning, & Pelphrey, 1999). If one child responds to anxiety by closing her eyes and covering her ears, she is preventing encoding of visual and auditory stimuli associated with the event. However, if another child deals with his feelings of fear by asking questions about what is being experienced, he may likely generate a well-organized and enduring memory for the event.

Despite the intuitive appeal of this prediction, measures of stress have fared poorly in how well they predict children's memory for a traumatic event. Some authors argue that stress experienced as an event is taking place strengthens children's abilities to focus and thus facilitates the encoding of information (Fivush, 1998; Goodman, Hirschman, et al., 1991; Shrimpton, Oates, & Hayes, 1998), whereas others have found that elevated levels of stress impede memory (Howard et al., 1997; Merritt et al., 1994; Peters, 1997). Still others have shown mixed or no significant effects of stress on memory (Bruck, Ceci, Francoeur, & Barr, 1995; Goodman & Quas, 1997; Howe et al., 1995; Peterson & Bell, 1996).

To some extent, these discrepancies may be due to the various indices of stress that have been used. Measures used range from self or parental behavioral ratings of stress (ratings of stress as adduced by a parent or objective observer) to physiological (heart rate, blood pressure) and neuroendocrine indicators (salivary cortisol). Not only are few of these measures associated with one another, but few of these measures show a consistent

relationship with recall. For example, in an investigation of children's memory for a VCUG, Merritt and her colleagues (1994) observed a negative association between stress and memory with behavioral ratings of stress but not with salivary cortisol.

As discussed by Ornstein and his colleagues (1999), an adequate understanding of the effects of stress on memory may involve using moment-by-moment indicators of arousal as an event is occurring rather than summary measures (be they behavioral, physiological, or neuroendocrine) that essentially result in an estimate of the average level of anxiety experienced during the event. This is important because the amount of stress experienced may vary considerably as the event unfolds, with some moments accompanied by high levels of arousal and other moments experienced with nonchalance.

On the basis of this brief review, it is apparent that special mechanisms are not needed to account for memory for traumatic experiences. Whether the event is a single occurrence or repeated on multiple occasions, traumatic experiences are remembered as least as well as if not better than more mundane experiences. Traumatic memories, however, like ordinary memories, can be fallible, incomplete, and malleable. What a child remembers about a traumatic event is based on constructive processes that result from the complex interactions of a wide range of cognitive and social variables that affect the encoding of the original event, the storage of information memory, and the retrieval of material from storage.

Developmental Differences in Suggestibility and Autobiographical Recall

In the review of the literature that was pertinent to the *Lillie-Reed* case, we focused on studies of preschoolers (because this was the age group under consideration) without discussing developmental differences. Although the research findings demonstrate that preschool children are especially susceptible to the deleterious influence of suggestive interviewing techniques (Ceci & Bruck, 1993; Ceci & Friedman, 2000), their greater vulnerability is a matter of degree only; even much older children and adults will succumb to suggestions and pressures (Bruck & Ceci, 2004). For example, Finnila et al. (2003) staged an event (a version of the Paco visit we described earlier) for 4- to 5-year-olds and 7- to 8-year-olds. One week later, half the children were given a low-pressure interview that contained some misleading questions with abuse themes (e.g., "He

took your clothes off, didn't he?"). The other children received a high-pressure interview; they were told that their friends had answered the leading questions affirmatively, they were praised for assenting to the misleading questions, and when they did not assent, the question was repeated. In both conditions, there were no significant age differences in the percentage of misleading questions answered affirmatively, although a significant number (68%) were assented to in the high-pressure condition (see also Bruck et al., in press; Zaragoza et al., 2001). It has also been found that under some conditions, older children are more suggestible than younger children (e.g., Finnila et al., 2003; Zaragoza et al., 2001).

Many of the suggestive techniques used in the child studies also produce tainted reports or false memories in adults (e.g., see Loftus, 2003). An illuminating piece of evidence for this assertion is the work of Kassin and Kiechel (1996). They have shown that college students will often erroneously claim they broke a computer after being told that they did by an experimenter. Moreover, they will internalize this belief, tell others they accidentally broke the computer, and sign a statement to this effect, agreeing to donate 8 hours of service to the experimenter in reparation for the alleged breakage.

Thus, although suggestibility is highest among preschool children, this type of memory distortion occurs at all ages.

In terms of autobiographical recall, preschoolers are also least able to provide details of actually experienced events (e.g., Baker-Ward, Gordon, Ornstein, Larus, & Clubb, 1993; Cassel et al., 1996; Ceci & Bruck, 1995; Lamb et al., 2003; Quas et al., 1999). When asked open-ended questions, preschool-age children can recall relevant and accurate information, but they often are less responsive and provide fewer spontaneous memory reports than older children and adults (Bahrick et al., 1998; Goodman, Hirschman, et al., 1991; McCauley & Fisher, 1995; Ornstein et al., 1992; Peterson, 1999; Saywitz, 1987).

Mechanisms Underlying Children's Suggestibility

The search for mechanisms underlying children's suggestibility is an enterprise that attempts to integrate developmental differences in basic cognitive skills and social behaviors with developmental differences in suggestibility. The general strategy is to link the reduction

in suggestibility with the development of social and cognitive skills. Methodologically, hypotheses that emerge from this exercise are tested in correlational studies whereby the levels of children's suggestibility are correlated with their performance on a range of tasks that assess the predicted mechanisms (see Bruck & Melnyk, 2004, for a review).

Some of the attempts to pinpoint the mechanisms underlying children's suggestibility examine the relative importance of social versus cognitive factors that underlie suggestibility effects. On the one hand, it is argued that the child (or adult) adopts suggestions in order to defer to or comply with the agenda of the questioner. In other words, for social reasons, the children repeat suggestions that they know to be inaccurate. At the other extreme, there is the view that suggestibility effects reflect cognitive weaknesses. For example, the child may incorporate a suggestion because he or she forgets the original event or is confused as to whether he or she saw the original event or the suggestion. Of course, both factors may underlie suggestibility effects; for example, social factors may first influence assents to misinformation or misleading questions, but with time, the assents may lead to cognitive impairments involving memory changes (see Ceci & Bruck, 1995). Or, because of children's less developed cognitive skills, they may be more willing to defer to the perceived agenda of their adult interviewer. In the following paragraphs, we attempt to provide a bird's-eye view of the various hypotheses that have been put forward to account for age-related reductions in children's suggestibility. As will become evident, some of the proposed cognitive mechanisms also account for age-related changes in children's autobiographical memory.

The focus on children's memory is of central interest because it is commonly found that children with poor memory of an event are more suggestible about that event (e.g., Marche, 1999; Marche & Howe, 1995; Pezdek & Roe, 1995). This has led to the following observations and proposals. As children grow older, their memories become more efficient because of the acquisition of strategies, knowledge, and self-insights about their memory (so-called metamemory). Preschool-age children have limited skill at using encoding, storage, and retrieval strategies (Brainerd, 1985; Brainerd & Ornstein, 1991; Loftus & Davies, 1984). They often fail to encode new events efficiently due to their selective focus on salient or central features (Bower & Sivers, 1998), their lack of knowledge about the events

(Ricci & Beal, 1998), and their tendency to rely more on verbatim than gist memory (Brainerd & Reyna, 1990; Foley & Johnson, 1985). Young children have weaker memory traces and show steeper forgetting curves (Baker-Ward et al., 1993; Brainerd, Reyna, Howe, & Kingman, 1990). They are also inferior to school-age children in terms of the strength of stored representations, because use of storage strategies, such as rehearsal and organization of stimuli, is uncommon among preschool children. They exhibit production deficits when it comes to retrieval strategies (e.g., use of category information) needed to search and facilitate their memories (Cox, Ornstein, Naus, Maxfield, & Zimler, 1989; Schneider & Bjorklund, 1998). All of these deficits conspire to render them dependent on external cues, such as an interviewer's prompts or questions, to retrieve information stored in long-term memory (Priestley, Roberts, & Pipe, 1999).

Young children's limited knowledge constrains their ability to incorporate and organize new information (Chi & Ceci, 1987; Johnson & Foley, 1984; Lindberg, 1980; Ornstein, 1990; Schneider & Bjorklund, 1998). Because of a lack of knowledge, they do not introspect into the inner workings of their memories to monitor when they need to engage in more mental work to consolidate a memory. Because young children fail to engage in strategies and insights, their memories are sometimes weaker and more susceptible to alteration by insinuations and false suggestions.

In addition, preschoolers lack skill at distinguishing between two or more sources of input into their memories (Gopnik & Graf, 1988; Wimmer, Hogerfe, & Perner, 1988), thus confusing things they heard with things they saw, and vice versa (Johnson & Foley, 1984; Lindsay et al., 1991). They also are more likely than older groups to exhibit a confusion between reality and fantasy that can lead at times to the belief that something was directly experienced when, in reality, it was merely dreamed about or imagined (Foley & Johnson, 1985; Foley, Santini, & Sopsakis, 1989; Lindsay & Johnson, 1987). This is called "source confusion," and young children are more likely to exhibit it, such as when they misattribute an interviewer's suggestions to actual experiences (Ackil & Zaragoza, 1995).

Another limitation of preschoolers that may be related to suggestibility concerns so-called scripted knowledge. Scripts are temporally organized expectations regarding typical and habitual routines of an event (Ceci & Bruck, 1993). It has been reported that young children are more

susceptible than older children to the negative effect of scripted knowledge (Farrar & Goodman, 1992; Hudson, 1990; Hudson & Nelson, 1986; Powell & Thomson, 1996). For example, young children might report erroneously that a certain event occurred as it usually happens in their script, even though the event was not witnessed at that instance. In other words, young children have trouble recalling novel details of a single event that are inconsistent with their generalized script of the event (Farrar & Goodman, 1992). This tendency to overly rely on the scripted knowledge might lead them to be more vulnerable to overgeneralizing their scripts.

For the cognitively unarmed child, an interrogation by experts is no contest: Children can be made to say things that are incriminating, even if they are false. In the summer of 1999, the city of Chicago witnessed a grisly murder and sexual assault of an 11-year-old girl named Ryan Harris. In the aftermath of discovering Ryan's body, two boys, ages 7 and 8, confessed to murdering her. The boys made their confessions without counsel present during a lengthy interrogation. Later, a 27-year-old ex-convict's semen was found on the dead girl's body, and he now stands indicted for her murder. Why would those two boys falsely admit to things they didn't do? One possible answer lies in their eagerness to please adult authority figures by complying with the boys' beliefs about what the police wanted them to say. Children might respond with a very compliant attitude during an interrogation, especially if they are highly praised and given attention that is rare in their everyday life. The boys in the Chicago case sat around a table with two uniformed officers; they held hands around the table and pledged to be on the "same team." The officers bought the boys food and explained that they could go home as soon as they helped the rest of the team clear up Ryan Harris's murder. After several hours of interrogation without the presence of an attorney or family member, each boy ended up admitting to a series of behaviors that they almost certainly could not have enacted, including raping the dead girl.

Without foreseeing the ramifications of their statements, children learn that noncompliance is met with negative reaction by adults, and so they avoid challenging adults' suggestions in their daily experiences and in the courtroom situations as well (Saywitz & Moan-Hardie, 1994). Children's eagerness to please adults is easily exploitable by interrogators as well as defendants seeking their help.

The socioemotional pressure to comply in forensic interviews may result from children's limited perspective-taking skill (Flavell, 1992). They lack the knowledge of the interviewer's motivation, the purpose of questioning, and the forensic relevance of their responses. They sometimes acquiesce to suggestive questions to avoid humiliation, assuming that their lack of knowledge may be viewed unfavorably.

Despite this long list of possible mechanisms, there are very few data to support any of these hypotheses (see Bruck & Melnyk, 2004). One of the implications of this is that at present, we cannot accurately predict the types of children who might be most suggestible.

FUTURE DIRECTIONS

Since the end of the 1980s, developmental psychology has made enormous progress in providing a scientific basis for the studies in children in the law. In this chapter, we have shown the extent of this progress in understanding aspects of children's testimony before they come into the courtroom and once they are there. Although there may be new areas of interest in the coming decade, spurred by current basic research or by current societal problems, the existing research calls for important modifications and changes in the current system.

First, the most significant implication of the research on adults' memories of interviews with children is that interviewers should be mandated to electronically preserve all (and especially the very first) of their interviews with children. If courts are interested in historical accuracy, there is simply no substitute for a tape that can be played to verify the accuracy of the interviewer's recall and the details of the discussion that took place between the interviewer and child. Although there may be times when it is not feasible to electronically record interviews (specifically, when parents question their children at home or in the car), it is nevertheless important for jurors and judges to know how to interpret hearsay testimony and to consider the potential for different types of errors, even though the testimony may be compelling and be offered in good faith.

Despite the dramatically consistent scientific findings that interviewers have poor recall of both the content and the structure of their interviews with children, only a handful of states mandate electronic recordings.

Agencies or jurisdictions defend the absence of this procedure on a number of grounds, including the claim that videotaping would provide the defense with evidence to be used against the child victim, or that agencies do not have the facilities to carry out these procedures, or that the child had already been interviewed prior to the first investigative interview. These are not viable reasons. First, if there is evidence of suggestive interviewing, then this exculpatory evidence must be turned over to the defense. If the interviews are well carried out, however, electronic copies will be useful to the prosecution. In this electronic age, the cost and ease of obtaining videotaped or audiotaped statements from children is negligible. It should be part of every professional's training to know how to obtain the best quality records possible. Finally, although it is true that children are sometimes (suggestively) interviewed by parents or other caretakers prior to their first investigative interview, this does not preclude the necessity of videotaping the first official and subsequent sessions. For example, in *Lillie-Reed*, before the first investigative interview, all parents had reported that their children had disclosed abuse (and their reports also revealed suggestive interviewing techniques); however, careful inspection of the first videotaped interviews with the children by the police showed that the children did not disclose what the parents had reported. With suggestions from the police, the children eventually did disclose. Without the videotape, the nature of the children's police disclosures would have been lost. What would have remained was the parents' reports of disclosures and the police reports of disclosures.

When a crime has been committed and evidence is being collected from the crime scene (the weapon, blood samples), the investigators are not permitted to simply inspect these pieces of evidence, make notes about their appearance, and then throw the evidence away. This would not be allowed into a court of law because the investigators' reports would be unreliable. For the very same reasons, children's reports of victimization should be handled in the same careful way required for physical evidence at crime scenes. The only means to achieve this goal is through electronic recording.

Second, there is a clear need for further work on the development of empirically validated interview schedules for interviewing children. The developmental research has proved the basic foundation for the general structure and constraints of such protocols. Michael

Lamb and his colleagues from National Institute of Child Health and Development have taken the lead in this field. They have developed one such protocol (for details of the protocol, see Orbach et al., 2000; Sternberg, Lamb, Orbach, Esplin, & Mitchell, 2001) that emphasizes the use of open-ended questions to obtain detailed reports from children; specific and leading questions should be used only when necessary and only at the end of the interview. This interview schedule was specifically developed for children suspected of being sexually abused; however, with a few modifications, it is also applicable for interviewing children about a variety of topics.

Although this team of researchers has made enormous contributions to the field, there need to be further studies that examine modifications to protocols (e.g., having different protocols for different age groups). In addition, it is important that these protocols be tested in the laboratory as well as in the field (i.e., interviewing children suspected of abuse). The latter methodology provides information about feasibility, whether it is possible to train interviewers to follow the protocol, whether children can follow the instructions, as well as the amount and quality of information that children provide. However, these studies do not provide information on the reliability or the accuracy of children's reports. This is because interviewers simply do not know the details about the event that the children are reporting. To address issues of accuracy and reliability, the accuracy of children's reports must be verified; this can be achieved through laboratory studies in which children are asked to recall events about which the researcher has full knowledge.

Third, even though there is some progress in the construction of standardized interviewing protocols, this must be accompanied by the development of programs to teach interviewers how to use these protocols. This is not an easy task; training is intensive, often lasting days and sometimes weeks. In part, this is because interviewers in training must give up previous automatic strategies, many of which they may not be aware of using. Anecdotal reports suggest that even after intensive training, interviewers will not faithfully follow the protocols unless there are intermittent reeducation sessions. The cost and time required to retrain a large workforce in this area will be great. However, as a start, one would hope that all professional training programs (undergraduate, graduate, and certificate) would redesign their curriculum to ensure that their graduates will be properly trained to interview children.

The second half of the twentieth century has seen what some have called a “revolutionary change” in the role of media in the lives of American children and teenagers (Roberts & Foehr, 2004). The change began with the introduction of television in the late 1940s. This was a new kind of medium—in the home and more convenient and attractive than anything that had preceded it. By the end of the 1950s, almost 9 out of 10 households would have a set. However, it was during the last 2 decades that the most rapid proliferation of media in the lives of young people occurred in the United States. What have changed are the circumstances of growing up. Symbolic models and vicarious experience play a much greater role (Bandura, 1986). Entertainment is starkly predominant in the media use of the young, and much of this entertainment is violent. This scenario raises questions about the consequences of media use for scholastic performance and of entertainment for interpersonal behavior. Media are usually—but not exclusively—supported by advertising, and advertising for cereals, candies, fast foods, toys, and apparel are directed at the young, including those in the early years of childhood. This raises issues of deception, manipulation, and, in the case of

some food products, health. Finally, these media of the twentieth century have stripped from parents their ability to control the symbols and information reaching children—a task that was straightforward in the early 1940s, when there were only newspapers, magazines, radio, and the Saturday matinee (and, in some homes, a phonograph) that could intrude. In fact, in the new environment, a substantial amount of media use occurs out of the sight and hearing of parents in the privacy of the bedrooms of children and teenagers.

Our treatment of the influence of media and popular culture in the lives of the young has three emphases. We cover a wide range of media, but much of our attention goes to television because it is by far the medium with which the young spend the most time—at least until the late teenage years, when music takes up almost as much time. We draw largely on academic research in child development, social psychology, sociology, and communication. The television and advertising industries, as well as manufacturers, engage regularly in research to market products and television programs to the young, but most of this work is not publicly available and not too much would have much application to theory or practice

outside of successful marketing. Finally, we identify the pertinence and applications of research on policymaking and in parenting.

Practice has been well-informed by research. One testament is the 39 chapters of the recent *Handbook of Children and the Media* edited by Dorothy G. Singer and Jerome L. Singer (2001). Another is the approximately 900 references in G. Comstock's (1991) *Television and the American Child*. However, the path to application is usually through theory or judicious interpretation of accumulated evidence. It is the rare instance when research directly affects practice, such as the monitoring by Children's Television Workshop of children's attentiveness on a scene-by-scene basis during production to ensure the attention necessary for the intended educational impact of *Sesame Street* (Lesser, 1974).

We cover five topics: the allocation of time and attention to televisual media, scholastic performance, television advertising, violent entertainment, and two issues of current concern and interest—the development of codes warning parents about (and possibly luring young viewers with the promise of forbidden fruit) the violent, adult, or sexual content of media, and the role of new electronic media in the delivery of popular culture. Thus, we begin with the two fundamental requirements for media influence, time and attention, and conclude by examining the implications for time and attention of developing technology.

ALLOCATION OF TIME AND ATTENTION

Our first topic falls outside the usual parameters of child development but is essential not only to our theme—the influences of popular culture—but to the modern lives of American children and teenagers. It is the allocation of time and attention to the media. We draw on our own work: our analysis of the data on use of television and other film-related media (Comstock & Scharrer, 2001) and our analyses of the data on the content and themes of televisual entertainment media (Scharrer & Comstock, 2003).

Use of Television and Other Film-Related Media

There are five questions that are paramount in regard to the use of television and other film-related media by children and teenagers. How much do they view? What

makes television viewing different from other media consumption? What are the preferences of young people? Why do children and teenagers view? What changes in viewing occur as children grow up?

Time

Attention to the screen of an operating television set has been recorded as occurring as early as 6 months of age (Hollenbeck & Slaby, 1979). However, viewing on a regular basis usually begins between the ages of 2.5 and 3, with an average of about 1.5 hours per day (Huston et al., 1983). Viewing quickly rises to about 2.75 hours between the ages of 3 and 6 (Huston, Wright, Rice, Kerkman, & St. Peters, 1990), before declining about a half hour between the ages of 5.5 and 7, when the demands of initial school attendance reduce time available for viewing (Figure 20.1). Viewing then increases again until age 12.

The high school years see a sizable decline in viewing because of the greater freedom to be away from home and the greater competition from other activities, such as athletics, dating, and pursuits incompatible with viewing television. Viewing time remains lower for those who go on to college and, later, graduate school. When the years of education have ended, viewing time returns to about the same level as in the elementary school years, before increasing substantially for those in their mid-50s and older.

Based on a number of sources, including Roberts and Foehr (2004) and Robinson and Godbey (1997), we estimate the average amount of viewing for those age 2 to 11 to be 3 hours and 7 minutes a day, or 21 hours and 49 minutes a week. Our estimate for teenagers age 12 to 17 is 2 hours and 28 minutes a day, or 17 hours and 16 minutes a week. These estimates include three levels of viewing: *primary*, when viewing is reported as the sole or foremost activity; *secondary*, when viewing is said to be secondary to some other activity; and *tertiary*, when television is said to be subordinate to other activities but a set is operating (Comstock & Scharrer, 2001).

These averages mask a great deal of variability among individuals. Major factors that affect amount of viewing include *household characteristics*: socioeconomic status (inversely associated with television use), norms about viewing (which may promote or discourage television use), and availability of television sets, other media, and alternative leisure options (which will affect the ability to choose programs for oneself and the comparative attractiveness of the medium); *child attributes*,

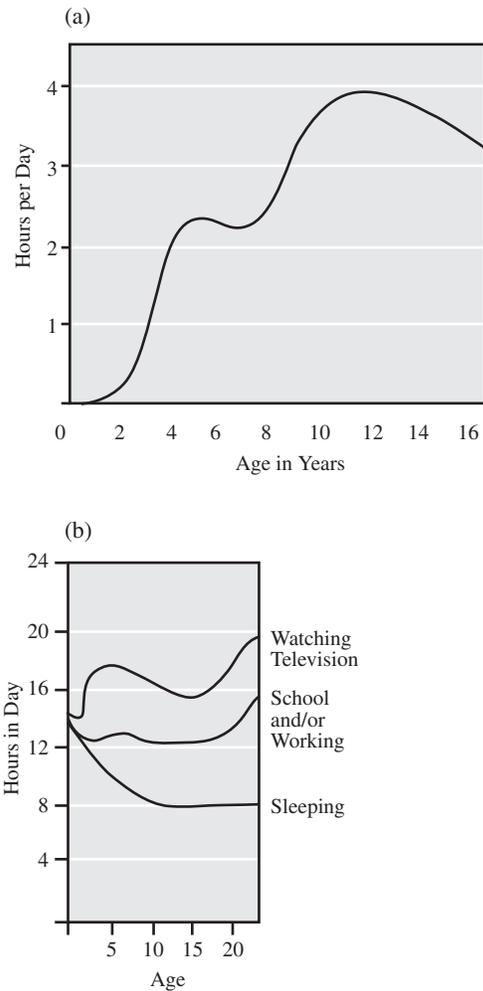

Figure 20.1 Television viewing, school or work, and sleep by age. *Source:* (a) Adapted from *Television and Human Behavior*, by G. Comstock, S. Chaffee, N. Katzman, M. McCombs, and D. such as age (as we have seen), mental ability (inversely associated with amount of viewing), and comprehension (a prerequisite for enjoying a televised narrative); *situational influences*, such as the presence and behavior of others (who might choose to turn a set on or direct attention to the screen by looking at it themselves), clock and calendar effects, such as hour of day, day of week, and season (the daily cycle of children's viewing rises when school lets out, is greatest during the week on Friday nights when there is no school the next day, and increases during the summer with more leisure time); and

states of mind (viewing often is engaged in to escape anger and stress).

What's Special

The ubiquity of media in the environment of young people sets the present era apart. The household of the 1950s typically had a single television set and sometimes one device that could play recorded music as well as one or more radios. Today's young person grows up surrounded by media and the options for diversion, learning, and play that they provide. Roberts and Foehr (2004) provide up-to-date data from a nationally representative sample of more than 3,000 children and teenagers between the ages of 2 and 18. They found that the typical home contained three television sets, three tape players, three radios, two videocassette recorders (VCRs), two compact disc (CD) players, one video game console, and one computer. When they inquired about direct and private access in the young person's bedroom, they found media in similarly impressive array. Among those age 2 to 7, 43% had radios, 38% had CD players, 32% had television sets, 16% had VCRs, 13% had video game consoles, and 6% had computers. Among those older (8 to 18), the figures were much larger: 88% for CD players, 86% for radios, 65% for television sets, 45% for video game consoles, 36% for VCRs, and 21% for computers. The result, undoubtedly surprising to some, has not been a diminishing of the time spent with television but an expansion of the total time spent with media, which Roberts and Foehr estimate as 3 hours and 38 minutes for those 2 to 7 and 6 hours and 17 minutes for those 8 to 18, with total exposure about 20% greater because of multiple use of more than one medium at a time. The greater the time available and the opportunity to be in the vicinity of an operable television set, the greater the amount of viewing that will be registered for an audience segment (thus, children's viewing increases in summer, and teenagers view less than those in elementary school).

Addressing the paucity of research regarding the role of media in the lives of very young children, the Kaiser Family Foundation sponsored a recent study entitled "Zero to Six: Electronic Media in the Lives of Infants, Toddlers, and Preschoolers" (Rideout, Vandewater, & Wartella, 2003). Random-digit dialing was used to secure survey data from a nationally representative sample of more than 1,000 parents of children ranging in age from 6 months to 6 years. Like their older counterparts, these youngsters live in media-rich homes; 50% contain

three or more TVs, 73% have a computer, and 49% a video game player. Media are not only present but accessed regularly by very young children. We concentrate our discussion on those 2 years old and younger, as this group is absent from the data reported earlier.

In a "typical" day, parents of these very young children report that 59% watch television, 42% view a videotape or DVD, 5% use a computer, and 3% play video games. Television's supremacy among media forms is apparent, again, in the first years of life. The average amount of time children 2 and under spend watching television per day is 2 hours and 5 minutes. About one in every four children 2 or younger has a television in their own bedroom.

Preferences

Program preferences develop surprisingly early. More than 3 decades ago, Lyle and Hoffman (1972b), in a pioneering study, asked a Los Angeles-area sample of 160 3-, 4-, and 5-year-olds to name a favorite program. About four-fifths of the 3-year-olds did so, and by age 5 almost everyone named a favorite.

Major predictors are gender and age. Both preschool boys and girls like animal characters such as appear on *Sesame Street*. Gender exerts an influence early, with 3 times as many boys as girls (17% versus 5%) naming a violent cartoon and twice as many girls as boys (39% versus 19%) naming a family cartoon (*The Flintstones*) among those 3 to 5 years old. Age makes a big difference. Lyle and Hoffman (1972a) again present pertinent data obtained from about 1,600 Los Angeles-area 1st-, 6th-, and 10th-grade students. Among the first graders, about one-fourth named a cartoon and about half a situation comedy. By the sixth grade, only 1 in 20 named a cartoon; situation comedies remained the most popular, but other general audience formats were gaining. By the 10th grade, drama, action adventure, soap operas, situation comedies, and talk, variety, and music (a category partly replaced now by MTV) were the most popular. *Sesame Street* provides an excellent example of the tyranny of age. Almost 33% of the 3-year-olds in the Lyle and Hoffman (1972b) data named it as a favorite; by age 5, that figure had declined to 12%, and 6- and 7-year-olds have almost wholly deserted the program as something for younger kids (Huston et al., 1990).

Why They View

The three major gratifications driving the use of television by children and teenagers as well as adults are (1)

diversion and escape from stress; (2) social comparison; and (3) keeping aware of what is transpiring in the world (Comstock & Scharrer, 1999). The first derives from the fact that those under stress, lonely, anxious, in negative mood states, or in conflict with others rank higher in their amount of viewing or other measures of attention to television (D. R. Anderson, Collins, Schmitt, & Jacobvitz, 1996; Canary & Spitzberg, 1993; Kubey & Csikszentmihalyi, 1990; Maccoby, 1954; R. Potts & Sanchez, 1994) as well as from the motives that people cite when asked why they view (Albarran & Umphrey, 1993; Bower, 1985). The second was advanced by Harwood (1997) and is consistent with the tendency of viewers to pay greater visual attention to screen personages like themselves, whether the characteristic is race (Comstock, 1991b), age (Harwood, 1997), or gender (Maccoby & Wilson, 1957; Maccoby, Wilson, & Burton, 1958; Sprafkin & Liebert, 1978). The third is based on the great frequency with which people cite learning something as a reason for viewing, though not referring specifically to the news or educational programming (Albarran & Umphrey, 1993; Bower, 1985), and we construe this motive to keep up with things as encompassing what is on television in the way of entertainment, sports, and news and the manner in which television covers events, as well as the events that make up the content of the news.

These motives find expression in two types of attention to the medium: ritualistic viewing and instrumental viewing. What separates the two is the degree to which the specific content of a program can be said to be responsible for viewing (Comstock & Scharrer, 1999; A. M. Rubin, 1983, 1984). The medium has primacy in ritualistic viewing, with the decision to watch television preceding the search for a satisfactory program. Instrumental viewing describes the more careful use of the medium to attend to particular programs. Most viewing is ritualistic, and most viewers are ritualistic most of the time in their attention to the medium. This holds true for children and teenagers as well as adults. The great attentiveness to favorite programs among younger children is certainly an example of instrumental viewing (but would account for no more than a fifth of their total television use). By age 10, they, like adults, have begun to see favorite programs less often (because their scheduling conflicts with other activities) but to spend more time with the medium (Comstock & Scharrer, 1999, 2001; Eron, Huesmann, Brice, & Mermelstein, 1983) and, at the same time, to begin to give less eye attention

to the screen (D. R. Anderson, Lorch, Field, Collins, & Nathan, 1986). Young people, like adults, are now usually *monitoring* rather than viewing television, paying enough attention to audio and visual cues to follow the narrative (whatever it might be) while giving less than full attention to the screen.

Developmental Changes

Viewing begins before the age of 3 and reaches a peak at about age 12. These 9 years begin with exposure to imagery that has very limited meaning to the young child, to monitoring television in the manner of an adult (although the inclusion of some of television's darker and morally complex offerings, such as *Law and Order*, *CSI: Crime Scene Investigation*, and *The Sopranos*, will usually wait until the middle or late teens).

Early instrumental use of educational programs such as *Sesame Street* often will have been the product of parental guidance and will lead to less viewing and greater instrumental use of the medium as a teenager (Rosengren & Windahl, 1989). In contrast, in households where print media are scarce and norms favor the constant use of television, children will view more than average, will largely confine their use of other media to audio or screen media, and will continue to do so as teenagers and adults (Comstock & Scharrer, 1999, 2001; Roberts & Foehr, 2004). Again, household characteristics play a large role in how much and in what ways television is consumed.

Attention to the screen represents involvement. Up to about 6 years of age, greater attention is confined to cartoons (Bechtel, Achelpohl, & Akers, 1972). Attention to television in general then increases up to about age 10, as more programs for general audiences become of interest (D. R. Anderson et al., 1986; Wolf, 1987); attention to the screen then declines, as the young have reached an adult orientation toward the medium. The increasing attention coincides with the shift, between the ages of 7 and 9, from Piaget's preoperational to his concrete operational stage. In the latter stage, children make greater use of verbal elements than appearances and action in interpreting television and become more open to subtleties of plot and character (Kelly & Spear, 1991; Van Evra, 2004). They now also need to give less rapt attention to the screen to follow a narrative, as exemplified by the decline in eye contact.

Most scholars agree that children's attention to the screen is also a function of the comprehensibility of the program (D. R. Anderson, Puzles Lorch, Field, &

Sanders, 1981; Campbell, Wright, & Huston, 1987), with comprehensibility explained, in part, by the age and cognitive-developmental level of the child (Calvert, Huston, Watkins, & Wright, 1982; Huston et al., 1990). These principles were demonstrated recently in data drawn by Valkenburg and Vroone (2004) via a home observation study with 50 6- to 58-month-olds. Examining attention paid to television segments that varied in content complexity, these researchers found that the youngest children (6 to 18 months) attended more to the least complex program (*Teletubbies*), whereas the oldest children attended more to the most complex program (*Lion King II*). Of particular importance, the two programs were similar in audio and visual features. Thus, a child dedicates attention to something perceived as within his or her cognitive grasp.

Content and Themes of Televisual Media

We begin our treatment of content and themes in the programming that children and teenagers watch with three fundamental parameters that establish the context for all else. We then turn to two forms of behavior depicted that have been the subject of controversy or concern because they present questionable guidance: violence and sexual intimacy. These portrayals and depictions attain importance given the potential for children and teenagers to take television as representative of the world or as a guide for emulation (Bandura, 1986; Comstock & Scharrer, 1999; DeFleur & DeFleur, 1967).

Entertainment Predominates

A large majority of the television viewed by those age 8 to 13 and a substantial proportion of that viewed by 2- to 7-year-olds is entertainment (Roberts & Foehr, 2004). Younger children particularly enjoy cartoons, and these have dominated the blocks of time set aside for children's programming on weekend mornings and after school for decades (Comstock, 1991a; Comstock & Scharrer, 2001), for animation signals to a child that the content is designed for a young viewer. However, children are also present in large numbers for general audience programming, which they will come to prefer. Because television earns most of its revenues from advertising, with some, for cable, coming from subscriber fees, popularity is the paramount goal (with audience demographics that will attract advertisers, such as children on Saturday mornings and young adults in general).

The most effective way to achieve popularity is with undemanding entertainment (Barwise & Ehrenberg, 1988). Thus, this type of programming is preeminent in all parts of the day every day of the week except weekend afternoons, when sports (another undemanding genre) predominate. Entertainment consequently is what children and teenagers mostly view.

Children's Programming: Popular but Limited Role

In a nationally representative sample of more than 3,000 young people in the late 1990s, about 85% of 2- to 7-year-olds, about 50% of 8- to 13-year-olds, and 16% of 14- to 18-year-olds said they watched entertainment created for young viewers the previous day (Roberts & Foehr, 2004). In recent years, children's programs on the three original networks (ABC, CBS, and NBC) have numbered in the high 50s, a decline from a high of 67 in 1979 to 1980 (Pecora, 1998). On cable, two channels, The Disney Channel (funded mostly by subscriber fees) and Nickelodeon (funded by both fees and advertising), use the same formula (Pecora, 1998): morning for preschoolers (who reach a peak of more than 20% at this time in their daily viewing cycle), an afterschool block for those older (who will reach a peak of 40% by 5 P.M. in this phase of their daily cycle), and entertainment for the family in prime time (when all audience segments peak in their daily viewing). The Disney Channel mostly programs its own characters, such as *Little Mermaid*, *Pooh Corner*, and *Mickey Mouse Club*; Nickelodeon features entertainment popular with older children, such as *Rugrats*, and educational preschool programs such as *Blues Clues*, *Bob the Builder*, and *Franklin*. However, the combination of children in the audience for general audience programming, the changing tastes of young people as they grow older, and the number and placement in the schedule of programs specifically designed for young people assign them a limited role despite their popularity among younger viewers.

Educational Programming: A Small Role

Educational programs have only a small role in the overall viewing of young people partly because of the small number of such programs in television schedules. The Public Broadcasting System (PBS) has offered the celebrated *Sesame Street* and *Mister Rogers' Neighborhood*. *Sesame Street* is of particular interest because regular viewing is associated with a number of favorable outcomes, such as the learning of letters and num-

bers, language learning, school readiness, and better grades years later, although many of these (other than the learning of letters and numbers) may reflect the superior parenting practices of those who also encourage their young children to watch *Sesame Street* rather than effects of viewing the program (Comstock & Scharrer, 1999; Cook et al., 1975; Fisch & Truglio, 2001; Huston et al., 1990; Rice, Huston, Truglio, & Wright, 1990; Wright & Huston, 1995; Zill, Davies, & Daly, 1994). Broadcast television abounds, of course, with advertising and merchandise tie-ins, but other channels are becoming more commercialized. Nickelodeon began without commercials, but after 4 years turned to advertising. Decreases in federal funding have led PBS to product tie-ins for such shows as *Barney and Friends* and *Lamb Chop's Play-Along*; backpacks, books, clothing, lunch boxes, and videotapes carry PBS characters for a price, and the corporate sponsorship announcements between programs resemble the advertising on commercial television. Thus, the experience of even educational fare has a substantial context of commercials and marketing.

In the Children's Television Act of 1990, Congress required commercial stations to offer educational programming as a condition for license renewal. The criterion eventually was set at 3 hours per week (or six half-hour shows), and programs were required by the Federal Communications Commission (FCC) to have a "significant purpose" cultural or educational benefit. Presumably, the latter phrase will end the initial response of broadcasters to the 1990 legislation of simply labeling a program already on the air as educational on the grounds that admirable behavior was sometimes portrayed (Kunkel, 1998; Kunkel & Canepa, 1994; Kunkel & Goette, 1997), making ostensible educators of *Yogi Bear* and *G. I. Joe*. Whether this definition will enlarge the scope of educational programming remains to be seen; some broadcasters are a hardy lot in pursuing profits and schedule educational programming at hours when children are unlikely to be in the audience because they can sell the time when children would be present to advertisers at a higher price with other offerings (Hamilton, 1998).

Violence

There has been a great deal of violence on television since its introduction in the late 1940s (Head, 1954; Smythe, 1954). This violence is often committed by at-

tractive characters who are typically White males, and usually occurs without inflicting great apparent harm or agony (Comstock & Scharrer, 1999). Flashy weapons are often used. These elements make it very attractive to emulate. The most violent television is children's programming because of the action-adventure cartoons (and this has been true for at least 3 decades), premium movie channels, cable channels that specialize in violence such as TNT, and theater movies shown on broadcast television (Hamilton, 1998; National Television Violence Study, 1998a, 1998b). Violence is best thought of as a staple that oscillates and sometimes migrates (from broadcast to cable channels) but does not change dramatically in frequency and is not at all likely to disappear, despite disapproving presidents and members of Congress.

Sexual Intimacy

There is plenty of sexual content on television reaching young people in the way of talk, allusions, and assignments, but comparatively little in the way of physical sexual contact other than kissing and a modest frequency of implied or depicted intercourse during the day and evening hours of viewing. The preschool educational programs and cartoons favored by young children obviously do not contain sexual references. However, the situation comedies, soap operas, and prime time programs popular with older children and adolescents do. For example, Kunkel, Cope, and Colvin (1996) examined 128 programs during what was once called the "family hour" (the first hour of prime time, beginning at 8 P.M. EST) and found that 61% contained some variety of sexual behavior (from kisses to the depiction of intercourse), 12% implied or depicted intercourse, and 59% contained talk about sex. Cope (1998) examined 95 episodes of programs favored by 12- to 17-year-olds: 67% included talk about sex, 62% depicted various sexual behavior, and 13% implied or depicted intercourse. The same pattern occurs in the comprehensive examination by Kunkel, Cope-Farrar, Biely, Farinola, and Donnerstein (2001) of 900 programs appearing between 7 A.M. and 11 P.M. on 11 channels (the four major broadcast networks, a WB affiliate, four cable channels, PBS, and HBO): Sexual messages occurred at a rate of 4.1 per hour and 66% of the programs contained sexual messages. Unfortunately, most of these depictions were devoid of any emphasis on or reference to the risks and responsibilities of sexual intimacy. Such references oc-

curred at the miserly rate of 6% (Kunkel et al., 1996) to 9% (Cope, 1998).

Applications

The great diversity of media use that occurs among young people is neatly captured by the statistical manipulations of Roberts and Foehr (2004). They performed a cluster analysis on their nationally representative sample of more than 2,000 8- to 18-year-olds and uncovered six groupings that could be aligned on the two dimensions of access to media (from low to high) and use of media (again, from low to high). The result is a very elegant typology because each group represents about one-sixth of the population (Figure 20.2):

1. *Enthusiast*: Highest use of media overall. High home and bedroom access. Uses all media more than others: print, television, computers, movies, video games. Home environment favorable to media.
2. *Vidkid*: Second-highest use of media, but focuses primarily on screen media, and especially television. Bedroom access medium, home access low, but media-favorable home environment.
3. *Interactor*: Moderate media use. Bedroom access low, home access medium to high. Focuses more than average on computer use and print media. Home environment on average neither favorable nor strict toward media.
4. *Restricted*: Low to moderate use of media. Home access high, bedroom access medium, but environment very strict about media use.
5. *Indifferent*: Comparatively low use of media. Bedroom and home access high. Home environment favorable to media.
6. *Media lite*: Lowest use of media overall. Bedroom and home access low. Environment very strict about media use.

Several factors are at work here. Access to multiple television sets and computers, especially access in the young person's bedroom, makes a significant difference. The home environment (whether there are rules restricting television use) makes a big difference. This was measured by three questions about television (how often the set is on, whether there is viewing during meals, and

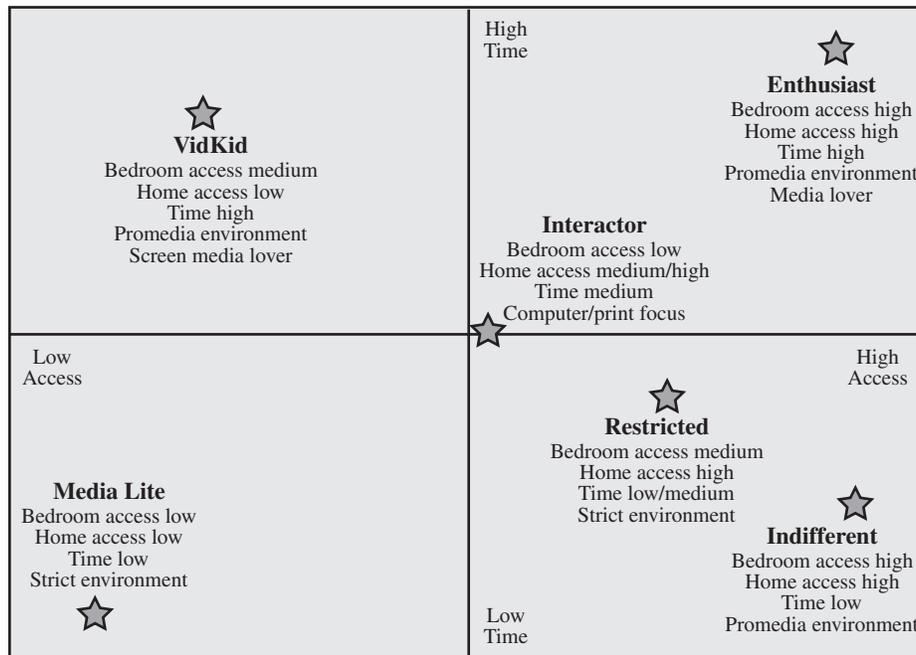

Figure 20.2 Typology of media use, 8- to 18-year-olds. *Source:* From *Kids and Media in America*, by D. F. Roberts and U. G. Foehr, 2004, New York: Cambridge University Press. Reprinted with permission.

whether there are rules about viewing), which turn out to be correlated with a variety of measures of media use as well as with greater television use. Personal interests then enter, with one group (Interactor) emphasizing computer use and print media more than average and another (Indifferent), despite easy access, ignoring media to a large degree, in favor, presumably, of other activities that are engaged in outside the home.

The survey by Roberts and Foehr (2004) leads to four important conclusions:

1. Television remains preeminent among the media in use by young people and has not been diminished by the Internet or computer use, which is mostly employed outside of school work for e-mail with friends.
2. This dominance of television, which is the most used of all the media by each of the six groups, means that it is the somewhat lower-than-average use of television or greater-than-average use of other media that distinguish those who are not among the two high media use groups and not the desertion of the medium.
3. Use of one medium by a young person is correlated with use of other media, so that at the present time, media do not crowd each other out but share a stage that is larger or smaller depending on the favorableness of individual and household toward media.
4. Media are very prominent in the lives of young people by three measures: the variety and number of media available in the home, the variety and number of media to which the young person has direct and private access in his or her bedroom, and the amount of time and attention allocated to media.

PERFORMANCE IN SCHOOL

Since the introduction of television in the late 1940s, evidence has accumulated on the influence of television on the scholastic performance of children and teenagers. Schramm, Lyle, and Parker (1961), in their large-scale examination of the effects of the introduction of television on young persons in the United States, concluded that outcomes related to knowledge and schooling were mixed. Children higher than average in mental ability who watched a great deal seemed to be somewhat impeded; children below average in mental ability who did the same seemed to be helped; and, for most—those average in mental ability—viewing made no difference. The implication that what counted was the quality of the experience for which television substituted would find support in later studies. Similarly bright children who viewed very selectively might be helped; this, too, has

found support in later studies. However, on vocabulary tests, first graders in communities with television scored about a year ahead of those in communities without television, although by the sixth grade this advantage had vanished. Future research would fail to confirm optimism over the effects of television on vocabulary.

The data are now rich on a large number of questions about television and school-related performance, and there are some definitive answers. Still, certain aspects of this early pattern have remained in place. Amount of viewing has been identified as a critical variable, but there also is evidence that the content viewed makes a big difference, and this applies to several different types of content with diverse implications. There has been a continued interest in specialized areas where television might make a positive contribution, as exemplified by the early findings on vocabulary.

We divide the literature into two broad areas. The first covers a range of quite specific hypotheses about the relationships between viewing and school-related performance. The second covers the evidence on the relationships between viewing and achievement on standardized tests and the interpretation of that evidence.

Specific Hypotheses

We begin with two hypotheses proposing positive contributions by television. We then turn to four hypotheses offering mixed expectations.

Favorable Outcomes

Television viewing increases vocabulary. Television viewing increases visual skills. These are the two well-tested hypotheses that have proposed positive contributions by television to scholastic achievement.

Vocabulary. On the basis of the findings by Schramm et al. (1961), Williams (1986) and colleagues hypothesized in their three-community quasi-experiment (Cook & Campbell, 1979) that the vocabularies of young persons in Notel (the community to which television was being introduced) would increase compared to earlier cohorts or those in Unitel (with one Canadian channel) or Multitel (with American as well as Canadian channels). At no grade level and on none of three standardized tests—the Stanford-Binet vocabulary subtest, the vocabulary subscale of the Wechsler Intelligence Scale for Children, and the Peabody Picture Vocabulary Test—was there any evidence of a change in vocabulary.

Our interpretation is twofold. First, television may have increased vocabularies when it was introduced, but viewing itself no longer mattered because any contributions traceable to the medium had now become disseminated through the interaction of young people with peers, teachers, and parents. Second, much of what young people might take away from television in vocabulary would pertain to entertainment, sports, news, and commercials and would elude those standardized measures of vocabulary. The exception would be educational television, for which research has supported lexical gains (Naigles & Mayeux, 2001).

Visual Skills. Gavriel Salomon (1979) proposed that the visual imagery and forms of television depictions (such as pan shots, close-ups, cut-aways, and montages) increase skills of recalling, interpreting, and comprehending visual stimuli. An analogy would be exercise, which builds muscles and strength.

The research is quite clear. There are no measurable effects among preschool children (Hofman & Flook, 1980; Salomon, 1979) except for video instruction in serial ordering by height or size (Henderson & Rankin, 1986). Older children improve after seeing video examples in their ability to link portions of a complex painting with the whole and to understand perspective (Rovet, 1983; Salomon, 1979). Visual tasks such as ordering pictures logically and discerning an embedded figure were slightly improved by watching an entertaining educational program, *Sesame Street* (Salomon, 1979). All demonstrated effects were confined to educational videos, with the greatest effects occurring when the pedagogy was most focused. Our conclusion is that ordinary viewing at most would have only minor effects very early in children's lives because of the limited variety of the forms and devices used on the screen and their organization as entertainment (or news and sports) rather than focused video instruction.

Mixed Outcomes

Fantasy play, daydreaming, creativity, and mental ability are four topics where a variety of possible relationships with television viewing have been examined.

Fantasy Play and Daydreaming. Fantasy play occurs when young children pretend to take on a role apart from their actual selves and is generally confined to those between the ages of 3 and 7 (Fein, 1981; D. G. Singer & Singer, 1990). Daydreaming, in contrast, is lifelong, doesn't involve physical activity, and, unlike

play, is not always voluntary. Both are developmentally important because they permit young people to experiment with different roles and encourage inventiveness (Valkenburg & van der Voort, 1994).

Several hypotheses have been offered:

- Viewing decreases play and daydreaming by substituting for them.
- Viewing increases play and daydreaming by supplying stimulating ideas.
- Viewing shapes play and daydreaming by providing examples and subject matter.
- Viewing decreases play by some mechanism other than displacement (such as mental exhaustion, arousal, or anxiety and fear).
- Unpleasant thoughts and daydreams increase viewing because it serves as an escape from them.

The evidence on fantasy play is extensive and includes surveys of everyday experiences (Lyle & Hoffman, 1972a, 1972b; J. L. Singer & Singer, 1976, 1981; J. L. Singer, Singer, & Rapaczynski, 1984), quasi-experiments (Gadberry, 1980; Maccoby, 1951; Murray & Kippax, 1978; Schramm et al., 1961), and laboratory-type experiments (D. R. Anderson, Levin, & Lorch, 1977; Friedrich-Cofer, Huston-Stein, McBride Kipnis, Susman, & Clewett, 1979; Noble, 1970, 1973; W. J. Potts, Huston, & Wright, 1986; Silvern & Williamson, 1987; Tower, Singer, Singer, & Biggs, 1979). We find no convincing evidence that television decreases or increases play, except for an increase for educational programs designed to enhance imaginative activity. There is ample evidence that television shapes play. French and Penna (1991), for example, found that adults who had grown up in communities with television recalled more superhero play than those who grew up in communities without television. The viewing of violent programs clearly decreases fantasy play, but the causal mechanism is unclear (Huston-Stein, Fox, Greer, Watkins, & Whitaker, 1981; Noble, 1970, 1973; J. L. Singer & Singer, 1976).

The literature is less extensive for daydreaming. There is a full range of methods and subjects, and respondents largely were 7 years of age and up because, unlike play, daydreaming cannot be observed and information must be elicited by interview or questionnaire, methods that are not feasible with those younger (Feshbach & Singer, 1971; Fraczek, 1986; Hart, 1972; Hues-

mann & Eron, 1986; McIlwraith, Jacobvitz, Kubey, & Alexander, 1991; McIlwraith & Josephson, 1985; McIlwraith & Schallow, 1982–1983; Schallow & McIlwraith, 1986–1987; Sheehan, 1987; Valkenburg & van der Voort, 1995; Valkenburg, Voojij, van der Voort, & Wiegman, 1992; Viemero & Paajanen, 1992). We find no evidence that viewing in general decreases or increases daydreaming (neither does exposure to any mass medium, including books, movies, and compact discs). However, the hypothesis that viewing shapes daydreaming receives some support. Consistently, there are correspondences between what has been viewed and the content of daydreams. Pleasant fantasies are correlated with general drama and comedies and to a somewhat lesser degree with music videos and entertainment. Thoughts about how things work are correlated with science fiction. “Positive-intense” daydreams (in the language of Valkenburg and van der Voort) are correlated with nonviolent children’s programs. “Aggressive-heroic” daydreams are positively correlated with violent drama and negatively correlated with nonviolent programs. Although these correlations may be partially explained by the viewing choices of those in these varied states of mind, it is likely that, at least in part, they represent the influence of what has been viewed. This is because they persist when other variables are statistically taken into account that would be correlates of interests, such as gender and age (thus reducing the likelihood of artifactuality), and because Valkenburg and van der Voort were able to trace the daydreams of about 780 third- and fifth-grade children to differences in the television programs viewed in an earlier period.

The most pronounced correspondences were for heroic-aggressive daydreaming and violent drama. For example, Viemero and Paajanen (1992) found that the mental replaying of violent scenes and fantasies about behaving aggressively was predicted by viewing greater numbers of violent programs in a large sample of 8- and 10-year-old Finnish boys and girls.

Finally, fantasies of failure and guilt predict purposeful use of television to counter negative moods and more frequent switching of channels (but not greater viewing, which would be governed by the time available). Thus, the proposition that television serves as an escape receives some support.

Creativity. The hypothesis that has been advanced most often is that viewing would decrease creativity because of the medium’s concreteness and set pace (as

compared, say, with reading), which might squash ruminative and inventiveness, and the conventionality of its portrayals (Comstock & Scharrer, 1999; Valkenburg, 1991). Evidence comes from three sources: experiments testing the effects of viewing television on the retelling or construction of stories (Greenfield & Beagle-Roos, 1988; Greenfield, Farrar, & Beagle-Roos, 1986; Kerns, 1981; Meline, 1976; Runco & Pedzek, 1984; Stern, 1973; Valkenburg & Beentjes, 1997; Vibbert & Meringoff, 1981; Watkins, 1988), correlational studies comparing measures of creativity for those higher or lower in television use (Childs, 1979; Peterson, Peterson, & Carroll, 1987; J. L. Singer et al., 1984; Williams, 1986; D. M. Zuckerman, Singer, & Singer, 1980), and the three-community British Columbia quasi-experiment (Williams, 1986).

The experiments convincingly demonstrate that exposure to television in the short run diminishes the creative inventiveness of retold or newly constructed stories compared to being read to by an adult. However, this is evidence of a transient state and the greater or lesser immediate facilitation of creativity, and not an alteration in a trait (the children scoring higher or lower would have done the opposite had they been assigned to the other treatment condition). We find no convincing evidence of positive or negative correlations between amount of everyday television use and the ability to generate new ideas (as exemplified by the Alternate Uses test), to think about things in different ways (as exemplified by the Pattern Meanings test), or to elaborate on a theme (as measured by storytelling). However, there is some evidence (Watkins, 1988) that young people who view a lot of television tend to draw on its plots and characters when storytelling, and their stories are more complex but decorated with the conventions of television programs.

Mental Ability. Schramm et al. (1961, p. 79) designated mental ability as “one of the great building blocks (along with personal relationships and social norms, and of course, age and sex) that go into the structure of a child’s television viewing patterns.” The model they offered remains essentially valid today.

Very early, very bright children viewed large amounts of television, just as they engaged in many activities with enthusiasm. Between the ages of 10 and 13, viewing by most young people declined; this was the now familiar adolescent downward slope. Print use increased. Today, it would be print and computer use. This shift began earlier

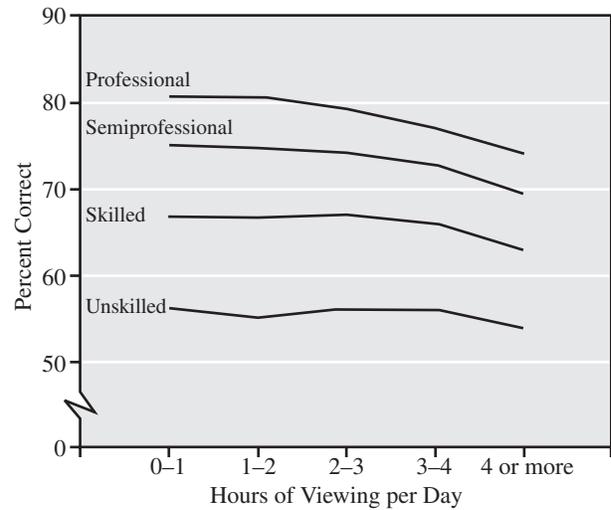

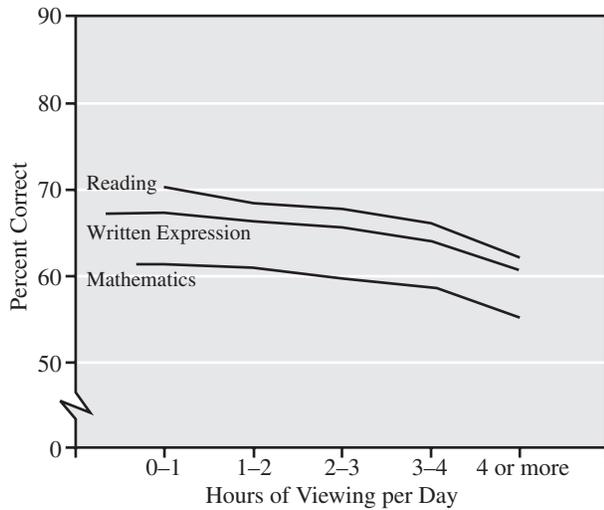

and was much more pronounced among brighter children. The authors conclude:

Both the high and low groups, in mental ability, are settling into adult patterns. The high group will use television less, and more selectively, and will turn to other media for much of its serious information needs. The low group will use television more, and printed media less. (Schramm et al., 1961, pp. 46–47)

More recent data confirm that amount of viewing after the early years of childhood is inversely associated with mental ability (Gortmaker, Salter, Walker, & Dietz, 1990; Morgan & Gross, 1982; Williams, 1986). This occurs independently of the inverse association between viewing and family socioeconomic status (although socioeconomic status is a strong positive predictor of mental ability). Schramm et al. (1961) also were correct to identify these early patterns as lifelong. Heavy use of television in early childhood is associated with heavy use when older, and there is evidence that early preferences for particular types of content are likely to still be in place years later (Huston et al., 1990; Kotler, Wright, & Huston, 2001; Tangney & Feshbach, 1988; Wright & Huston, 1995).

Viewing and Achievement

There is no question that amount of television viewing and performance on standardized tests are inversely associated. Our preference is to draw on the 1980 California Assessment Program (CAP) data because it was a census of enormous size rather than a sampling (282,000 in the sixth-grade and 227,000 in the 12th grade on the day of data collection). The same pattern appeared for both the sixth and 12th grades, although the negative slope of the curves was more pronounced in the 12th grade (probably because anything taking a toll on scholastic performance would have a greater effect where the demands on performance are greater, which would be at the higher grade). As can be seen in the sixth grade data (Figure 20.3), the slope of the curves is negative for reading, writing, and mathematics and for all four social strata. However, the slope of the curve becomes steeper as socioeconomic status increases, and the data of Gaddy (1986) provides the explanation. He divided households into those high, medium, and low in regard to educational resources: newspapers, books, magazines, and in the present day, we would include

Viewing and Achievement by Socioeconomic Status—Reading

Number of Students by Socioeconomic Status
Hours of Television Viewed per Day

| Occupation of Head of Household | 0-1 | 1-2 | 2-3 | 3-4 | 4 or more | Non-response | Total | Percent |
|---------------------------------|--------|--------|--------|--------|-----------|--------------|---------|---------|
| Professional | 15,731 | 11,176 | 7,022 | 3,787 | 4,976 | 337 | 43,029 | 15 |
| Semiprofessional | 15,634 | 12,927 | 9,449 | 5,812 | 9,631 | 495 | 53,948 | 19 |
| Skilled | 23,713 | 21,283 | 16,966 | 11,301 | 21,795 | 1,189 | 96,247 | 34 |
| Unskilled | 10,408 | 9,391 | 7,591 | 5,211 | 11,451 | 769 | 44,821 | 16 |
| Nonresponse | 11,505 | 9,866 | 7,266 | 4,627 | 9,481 | 1,173 | 43,918 | 16 |
| Total | 76,991 | 64,643 | 48,294 | 30,738 | 57,339 | 3,963 | 281,968 | 100 |
| Percent | 27 | 23 | 17 | 11 | 20 | 2 | | |

Reprinted with permission.

computers and Internet access. His negative coefficients between viewing and performance in school were consistently larger in the high-resource households. The implication, again, as in the conclusions of Schramm et al. (1961), is that the role of viewing depends on the quality of experience for which it substitutes. Thus, the curves are steeper where resources that would have some usefulness for in-school performance are present.

These 1980 CAP data do not stand alone. The same pattern appears in two CAP follow-ups (1982, 1986), in the sample of 28,000 seniors from the data collected by the National Center for Educational Statistics (Keith, Reimers, Fehrmann, Pottebaum, & Aubey, 1986), in the sample of 70,000 in three grades collected for the National Assessment of Educational Progress (B. Anderson, Mead, & Sullivan, 1986), and in Neuman's (1988)

pooled data from eight statewide evaluations (California, Connecticut, Maine, Illinois, Michigan, Pennsylvania, Rhode Island, and Texas). We are on firm and confident ground in the conclusion that viewing and achievement are inversely associated. In the earlier grades, here and there are occasional signs of a slight curvilinearity (Fetler, 1984; Neuman, 1988, 1991), but none at all in the later grades, and nowhere does it constitute more than a small portion of a curve that is almost totally negative in slope. The exception may arise among immigrants or ethnic minorities, in which higher levels of television exposure in conjunction with parental communication have been found to positively predict children's educational aspirations (Tan, Fujioka, Bautista, Maldonado, Tan, & Wright, 2000). Tan and colleagues explain that in this context, television view-

ing may help to acquaint children with the dominant American culture, knowledge of which is instrumental in American schools.

Our interpretation is that the inverse associations represent both the selective media use of young persons less likely to do well in school and some influence of television on scholastic achievement. We would divide the variance about equally, with slightly more allocated to the former than to the latter. We constructed a mock path analysis synthesizing the outcomes of many studies (Figure 20.4).

There have been two analyses of data (Gaddy, 1986; Gortmaker et al., 1990) that seemingly cast doubt on these conclusions, in which a decidedly negative association between amount of viewing and achievement appears to vanish when other variables are controlled. Yet, in both cases, the dependent variable is so truncated in the potential for an association with viewing that none could be expected. In Gaddy's case, it is the use of a change in grades over the last 2 years of high school and an earlier measure of viewing. In the case of Gortmaker

and colleagues, it is the use of measures of intelligence and achievement that are so high in test-retest reliability that they represent traits rather than a changeable state of scholastic achievement.

Selective Media Use

Socioeconomic status and mental ability are both inversely associated with viewing and positively associated with scholastic performance (notice the rankings by socioeconomic status in Figure 20.3). This leads to the expectation that those who view greater amounts of television will perform less well in school. Stressful circumstances and lack of mental and physical well-being predict greater use of television, and these same factors predict lower achievement in school. These patterns have persisted for more than 5 decades, and their present-day validity is attested to by the recent large-scale national survey of Roberts and Foehr (2004), where television viewing on the part of young people was inversely associated with academic achievement and positively associated with psychological and social discontent.

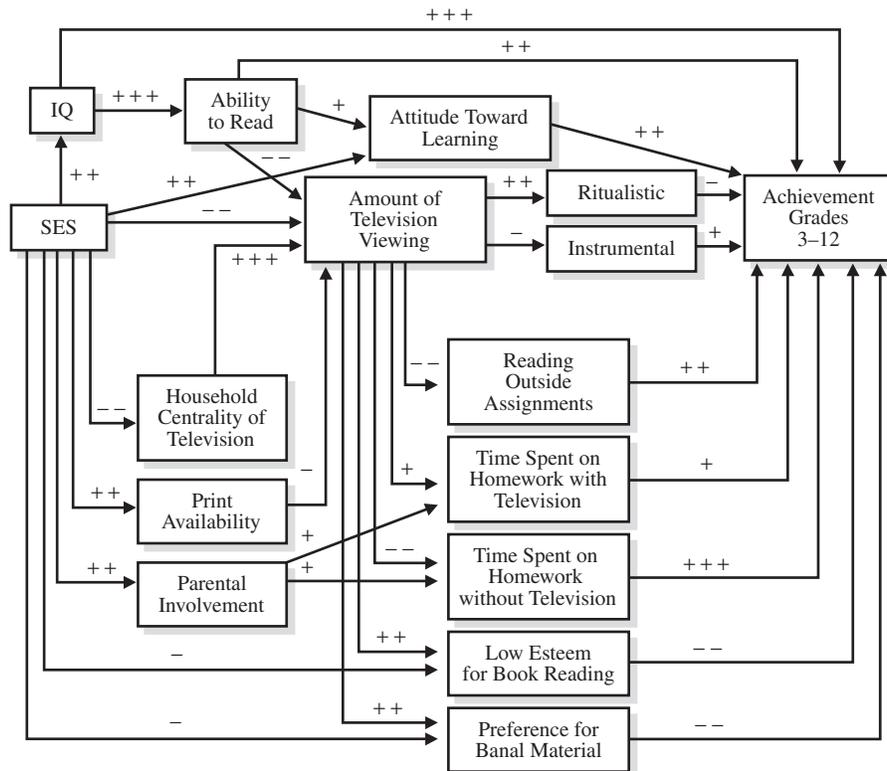

Figure 20.4 Path model: viewing, household and individual variables, and scholastic performance. *Source:* Adapted from *Television: What's On, Who's Watching, and What It Means*, by G. Comstock & E. Scharrer, 1999. San Diego, CA: Academic Press. Reprinted with permission.

Television's Contribution

We conclude that there are three processes by which viewing affects scholastic performance: interference, displacement, and the nurturing of self-defeating tastes and preferences.

Interference. The undertaking of homework, assigned reading, or reading for pleasure while monitoring television programming may somewhat debase these experiences. Several experiments document that homework-like cognitive processing tasks are performed with lower quality or at longer times to completion when there is an operating television set in the background, and this seems to be particularly so for television that presents an interesting narrative (Armstrong, 1993; Armstrong, Bojarsky, & Mares, 1991; Armstrong & Greenburg, 1990; Pool, van der Voort, Beentjes, & Koolstra, 2000). Fetler (1984), in a large CAP follow-up, found a small negative association between homework regularly done in front of an operating television set and scholastic achievement: about one-fourth that for amount of viewing (negative) and one-seventh that for amount of homework (positive). In a Dutch sample of more than 1,000 second and fourth graders, Koolstra and van der Voort (1996) found that greater viewing resulted in lower mental effort when reading, after statistically controlling for mental ability (which could have offered an alternative explanation for both greater viewing and lower effort). The tendency for viewing and reading to become positively correlated as young people grow older (CAP, 1980; Morgan, 1980) is thus actually somewhat ominous, because it implies less concentration and less demanding reading material. Finally, the sample of more than 28,000 seniors examined by Keith et al. (1986) suggests that for those who view for average amounts of time, there is no serious conflict between the blocks of time that could be allocated to homework and television viewing. This is because only modest amounts of homework typically were assigned. Nevertheless, time spent on homework was a predictor of scholastic performance, and parental interest and involvement was a predictor of greater time spent on homework (which may merely indicate that those with discipline and motive do better in school, with time spent on homework an outcome rather than a cause).

The more wide-sweeping and damning allegation that television viewing interferes not just at the moment that homework is being done but in a more insidious and

long-term manner by generally reducing children's ability to concentrate and focus their attention has received less research support. One of the few studies to bring data to bear on this frequent complaint was published recently in *Pediatrics* and uses the National Longitudinal Survey of Youth to examine hyperactivity and television viewing (Christakis, Zimmerman, DiGiuseppe, & McCarty, 2004). Hyperactivity was measured using a subscale of the Behavioral Problems Index (covering such indicators as difficulty concentrating, impulsivity, obsessiveness, confusion, and restlessness) among 7-year-olds in the data, and estimates of their television exposure when they were toddlers (1 and 3 years of age) were obtained from the reports of their mothers. Employing numerous covariates (including, but not limited to, demographic characteristics, number of parents and siblings in the home, measures of cognitive stimulation such as reading and playing, and parental emotional support such as communication with parents), number of hours of television viewing at ages 1 and 3 was a significant predictor of attention problems at age 7. However, the lack of additional research to join this investigation, as well as limitations to the present study pointed out by both its authors (Christakis et al., 2004) and others in letters to the editor of *Pediatrics* (Bertholf & Goodison, 2004; Obel et al., 2004)—including the classification of those 1.2 standard deviations above the mean and higher as having attentional difficulties, failure to account for television content viewed, and the possibility of reverse causation—suggest that advancing this claim with conviction is premature.

Displacement. The displacement hypothesis in its more general version proposes that television may consume time and attention that could be better spent on acquiring the three basic skills of reading, writing, and mathematics, although the most attention has been given to the displacement of time that should have been spent acquiring the rudimentary skills of reading between the second and third grades (Chall, 1983; Comstock & Scharrer, 1999; Williams, 1986). Reading achievement is inversely associated with amount of time spent viewing (the downward sloping curve in the CAP data is a good example). Both reading and viewing are sedentary, so they compete for the same blocks of time (Heyns, 1976; Medrich, Roizen, Rubin, & Buckley, 1982), and television would be an enticing alternative to the effort required during the 2 years when reading is not for pleasure (as it will become in the fourth grade) but the

tiresome learning of a skill. The 4 or more hours spent with television by 20% of young people (we use the CAP data as an estimate) would place these children at high risk. Similarly, the same argument would apply to writing and mathematics. In our view, the displacement hypothesis should be expanded to a more general proposition (Comstock & Scharrer, 1999, p. 259).

Television viewing is inversely related to achievement when it displaces intellectually and experientially richer stimuli. Viewing is positively related to achievement when the stimuli it supplies are intellectually and experientially richer than the available alternatives.

We view displacement as having two distinct aspects. The first is the usurpation of time that should be spent acquiring the three basic skills, and will have lifelong consequences for most. The second is the consumption of time at any age that might be spent on activities that are scholastically more productive, from reading to visiting a museum (or, for that matter, going to a movie that has aesthetic claims beyond the daily fare of television).

Tastes and Preferences. Television often has been described as a teacher, but unhappily, primarily of the ways of entertainment, news, sports, and commercials. The evidence now goes quite a bit beyond this. Koolstra and van der Voort (1996) collected data over a 2-year period between the second and fourth grades from a Dutch sample of more than 1,000 boys and girls. They found that greater amounts of television viewing in the earlier grade predicted greater reading of comic books and attitudinal dispositions flagrantly and decidedly hostile to the reading of books as dull and boring in the later grade. In a similar 3-year undertaking in the United States that ended with the students in high school, Morgan (1980, p. 164) found that greater amounts of viewing earlier predicted a greater liking for television-like content, “stories about love and families, teenage stories, and true stories about stars.” These two sets of data make a strong claim on behalf of a causal disruption of the use of print (and by extension, we argue, other demanding media, such as computers and the Internet) because the findings survive statistical controls for numerous other variables, including mental ability (crucial in this case because mental ability predicts greater viewing and lower reading ability and thus would be the prime candidate as an alternative explanation). Our conclusion is that television socializes young people in regard to tastes and preferences in ways that are self-defeating in regard to scholastic achievement.

Our model (Figure 20.4) assigns large roles to socioeconomic status, mental ability, and the household norms about television use. We see greater amounts of television use as having a negative effect on achievement by reducing reading outside of assignments, by lowering the quality of homework done in the company of an operating television set (while acknowledging that homework with television is better than none at all), and by the socialization of tastes and preferences that disdain books that are perceived as challenging and favor the banal. We see television viewing that is selective—that is, instrumental viewing—as having positive consequences for achievement.

TELEVISION ADVERTISING

Television advertising directed at children and teenagers is an excellent example of an area in which empirical research was called on to help settle a policy issue. It has the requisite properties to be representative in many ways of what often transpires in the attempt to translate science into action. These include a series of questions on which there are disparate opinions, contentious debate, and scant evidence (or even, in many cases, the criteria by which to evaluate evidence); a government agency committed to the possibility of regulatory action; advocacy groups calling for reform confronting an industry defending the status quo; the clear enhancement of knowledge by social research about the responses of children and teenagers to commercials; a disconnect between the interest of the agency in formulating policy based on research and its ability, in the existing political context, to do so; and, finally, the emergence of some real reforms despite the absence of new regulatory initiatives. This sequence—debate and contention, the collecting of data, the political obfuscation of the application of research, and some salutary changes—is quite typical of the oblique but important role of social and behavioral science in the arena of practice.

Background

Television, introduced in the United States in the late 1940s, enjoyed its first 2 decades (during which households with television increased from essentially zero to 96%) with almost no attention given by parents, the public, or regulatory agencies to television advertising directed at children. Children, of course, have always been

a central element in various strategies for marketing television. Very early, programming for children was considered to be an effective means of encouraging parents to purchase sets; similar strategies are operating today, with cable systems and premium channels offering programming with special appeal to parents and children. Children also were thought to be particularly influential in what the family watched before their bedtime (by 1960, only 12% of households had more than one set; by the end of the decade, this figure had increased, almost robustly, only to about 33%), and in the 1960s, ABC used situation comedies with characters designed to be appealing to teenagers to compete successfully with CBS and NBC. Les Brown in his 1977 *New York Times Encyclopedia of Television* (still quite useful for the programs, controversies, and personalities that marked the medium's first 3 decades) tells the story:

Although children helped to build circulation for stations, and good will for the new television medium, they were not initially perceived as a major marketing group for products. Television was considered too high-priced for child-oriented products in the 50s and early 60s when the single or dual sponsorship of programs was the rule. But a number of factors converged around 1965 to make children's programs a major profit center of networks: first, the proliferation of multiset households, which broke up family viewing and loosened the child's control over the program his or her parents would watch; second, the drift to participation advertising as opposed to full sponsorships, which encouraged more advertisers to use the medium; and third, the discovery that a relatively "pure" audience of children could be corralled on Saturday mornings (and to a lesser extent on Sundays) where air time was cheaper, advertising quotas were wide open and children could be reached by the devices used years before by comic books.

By the late 60s television programming aimed at children was confined, with few exceptions, to Saturday mornings in the form of animated cartoons. Moreover, the animation studios developed a form of limited animation for the indiscriminating youngsters, involving fewer movements per second, which was cheaper than standard animation. Recognizing that children enjoy the familiar, the networks played each episode of a series six times over 2 years, substantially reducing costs. And while prime time programs, under the Television Code, permitted 9.5 commercial minutes per hour, Saturday morning children's shows carried as many as 16 commercial minutes per hour. Citizens groups did not become aroused, however, until the networks began to deal excessively—in their competitive zeal—with monsters, grotesque super-

heroes and gratuitous violence to win the attention of youngsters. Advertisers, by then, were making the most of the gullibility of children by pitching sugar-coated cereals, candy-coated vitamins and expensive toys. (pp. 82–83)

Commercials directed specifically at children . . . became a highly controversial aspect of television, raising questions of the morality of subjecting children to sophisticated advertising techniques. In the 70s consumer groups began protesting the differing commercial standards for children and adults, as well as other allegedly abusive practices, among them promoting nutritionally inadequate foods, using program hosts as salesmen, tempting purchases by offering premiums, and advertising expensive toys in a deceptive manner. (pp. 81–82)

The best known of the advocacy groups was Action for Children's Television, led by the indefatigable Peggy Charren and headquartered in a suburb of Boston. ACT, now disbanded (but hardly yet forgotten), asserted that advertising to children distorted and lowered the quality of programming aimed at them by making audience attractiveness to advertisers rather than child development the foundation on which programs were designed; these commercially attractive shows undeniably would seek large audiences varying in age rather than the smaller audiences that programs tailored to the narrower interests and needs of specific age groups would attract. ACT also argued that young children could not understand the self-interest behind commercials, making them by definition deceptive. Press coverage, complaints to broadcasters, and petitions to the FCC and the Federal Trade Commission (FTC) created an atmosphere favorable to some conciliatory response by broadcasters and advertisers fearful of government regulation or public hostility.

One of the effects of this activity was the nurturing of a considerable amount of research on television advertising directed at children and teenagers. Another, eventually, was a series of hearings by the FTC in conjunction with the FCC on the possibility of rule making.

Three Topics

It is no accident that the voluminous citations of research articles bear dates almost wholly subsequent to the public emergence of the controversy. This is an instance in which research on questions of child development sought to answer questions of public policy and industry practice. Although many issues were pur-

sued, most of the research addressed three broad topics (Comstock, 1991a):

1. Recognizing and understanding commercials
2. Degree of persuasion achieved by commercials
3. Exchanges between parents and offspring

In effect, the issues were deception, influence, and the disruption of parental authority or, at least, comfort.

Recognition and understanding present a clear picture. Several studies document that very young children, as young as 3 years of age, usually can recognize that a commercial is different from or at least not a seamless part of the accompanying program (Butter, Popovich, Stackhouse, & Garner, 1981; Levin, Petros, & Petrella, 1982; P. Zuckerman & Gianinno, 1981), although it is probably not until about age 5 that most children can make this distinction without some confusion, such as correctly applying the term “commercial” but thinking of the commercial as a part of the program (Kunkel, 2001). Performance is similar on another measure of recognition in these same studies: matching characters from commercials with the products they advertise. For example, P. Zuckerman and Gianinno showed 64 4-, 7-, and 10-year-olds photos of animated characters from either commercials or programs. Most at all ages could identify those associated with products and match the characters with the products they represented. However, understanding is a very different matter.

Under the age of 8, a majority do not fully understand the motivated purpose of a commercial as a self-interested vehicle intended to benefit the advertiser by gaining the compliance, eventually if not immediately, of a consumer. Blosser and Roberts (1985) present the definitive evidence. They showed 90 children varying in age from preschool to fourth grade five different kinds of televised messages: commercials aimed at children and at adults, news, educational programming, and public service announcements. The researchers then applied three measures of understanding: comprehending the content, labeling the message correctly, and articulating accurately the message’s purpose and character. When the criterion for commercials was the recognition that they presented items that could be purchased, more than half under the age of 7 “understood” what a commercial was. When the criterion was articulating self-interested persuasive intent, it was not until age 8 that a majority could be said to understand commercials. News was correctly described earliest across all mea-

asures; this makes the important point that it is not a matter of exposure, which would be greater for commercials, but the cognitive concept of self-interested persuasion that is the problem.

The brilliant experiment by Gentner (1975) provides insight into why this is the case. She inventively asked children varying in age from 3.5 to 8.5 to dramatize a series of verbs using two puppets from *Sesame Street*: have, give, take, sell, buy, and spend. “Give” and “take” were largely understood by even the youngest, but these same youngest did not comprehend “buy” and “sell.” Comprehension of “buy” and “sell” of course increased with age, and for those between 7.5 and 8.5 reached 95% for “buy” and 65% for “sell.” Gentner’s interpretation, with which we concur, is that selling is too complicated, with its many steps culminating in an exchange of goods, for early comprehension, whereas buying is something children typically see their parents engage in often (and often enjoy the benefits of), and giving and taking are experienced quite early, in both cases with toys and food.

The evidence on persuasiveness is equally clear. Commercials are quite effective in directing children’s choices of products within a category but less effective in switching preferences from one genre to another. Product choices have been shown to be influenced by endorsements by liked or respected figures quite apart from any other aspect of a commercial (Ross et al., 1984). The heavy toy and game advertising leading up to Christmas by the end of the shopping season was found to shift choices toward the advertised products, in effect eroding defenses against persuasion (decreasing critical attitudes toward advertising) and preferences for other items among 290 first-, third-, and fifth-grade children (Rossiter & Robertson, 1974). A dissertation (R. S. Rubin, 1972) even queried 72 first-, third-, and sixth-grade children about their recall for products and premiums and found that at all ages the premium was better recalled than the product name and vied quite successfully with the product in being perceived as what the viewer was supposed to want. Later, Shimp, Dyer, and Divita (1976) would report a modest but positive correlation between brand choice and liking for a premium, and Atkin (1975a, 1975b, 1978) reported that a large majority (about three-fourths) of a sample of mothers of children from preschool to fifth grade said that premiums had been specifically mentioned by their children in asking for cereals. One out of 10 children’s product requests recorded

surreptitiously in supermarket aisles included specific mention of a premium.

Food selections have repeatedly been demonstrated to be influenced by exposure to commercials at all ages (Galst & White, 1976; Goldberg, Gorn, & Gibson, 1978; Gorn & Goldberg, 1982; Meringoff, 1980; Stoneman & Brody, 1981; Story & French, 2004). Between half and two-thirds of commercials directed at children are for food-related products (Kotz & Story, 1994; Taras & Gage, 1995). An effect on selection holds primarily for selections within a genre, exemplified by the selection of one brand or option rather than another. For example, Gorn and Goldberg found among 288 children ranging in age from 5 to 8, exposure over a 2-week period to commercials for orange juice or candy could shift choices away from Kool-aid or fruit, but Galst (1980) found among 3- to 6-year-olds that commercials for nutritional foods did not shift choices unless followed by advice from a live adult. Thus, children can be persuaded to change the means by which they satisfy a preference but not the preference.

The data on parent-child interaction are not quite so clear. There are two reasons. The data focus on three topics: children's requests for products, parental yielding, and intemperate responses from the child when yielding does not occur. These do not lend themselves to straightforward measurement, as do recognizing or understanding commercials and the shift of product choices toward an advertised item, and we are largely left with proportions of children or parents saying requests, yielding, or displays of temper occur often, sometimes, or seldom, so that precise estimates are not available. Furthermore, for none of these three measures is there a recognized criterion or threshold that signals trouble or pathology other than that most would agree that repeated tantrums by the same child probably deserves some attention. Yet, these very concerns are at the heart of any interest in parent-child interaction in regard to television commercials—that they disrupt the orderly process of parenting and make it less effective (by widening children's options while limiting those of parents) or tranquil (by contributing to the dissatisfaction of children and disputes between parents and children).

However, the data do permit some conclusions. Children certainly do regularly ask for products as a consequence of seeing them advertised on television. Atkin (1975b) reported that among 440 children ranging from preschool to fifth grade, those who were classified as heavy viewers said they asked for products "a lot," whereas the figure for light viewers was about half the

frequency of requests. Isler, Popper, and Ward (1987) found that one-sixth of the purchase requests of children between 3 and 11 were attributed to television advertising by a sample of 260 mothers, although the requests declined decidedly as children grew older. Yielding also is highly frequent. Parental reports of yielding to cereal requests ranged from 87% to 62% in different samples (Atkin, 1975b; Ward & Wackman, 1972; W. D. Wells & LoScuito, 1966) and decline as the purchase from the genre becomes less obligatory or of less direct interest to the child. For example, Ward and Wackman found that yielding declined steadily as a function of those two variables: from cereal (87%), snack foods (63%), games and toys (54%), candy (42%), toothpaste (39%), shampoo (16%), to a mere 7% for dog food. This descending order represents children's interest in the product and the recognition by parents of the legitimacy of that interest. Both would increase with greater efforts to market products to children, so we would expect toothpastes and shampoos to rank higher today, with their packaging emblazoned with television characters popular with children. We think the best data on yielding are those of Atkin's (1978) supermarket aisle study of 516 sets of parents and children ages 3 to 12 because they trace the process from purchase initiatives by both children and parents (Figure 20.5). The child initiated interactions two-thirds of the time, and more than two-thirds of these were classified as demands. About two-thirds of the time a parent yielded to a demand or request; the figure for rejecting was less than half that.

Disputes between parents and children and the anger of children at the refusal of a request are plagued by the same problems of measurement and interpretation. Nevertheless, we can say that such occurrences are not rare. For example, Atkin (1975a, 1975b) found in one sample of children that one out of five said they became angry "a lot" when toy requests were denied, and one out of six said they argued "a lot" in response to such denials. In his observational study of parents and children in supermarket aisles, Atkin recorded that two-thirds of denials (occurring at a rate of 18%) evoked anger, and one-half induced disappointment.

Enter the National Science Foundation and the Federal Trade Commission

In the late 1970s, the National Science Foundation (NSF) took the extraordinary step of commissioning a review of this burgeoning literature to serve as the evidentiary foundation for possible rule making by the FCC

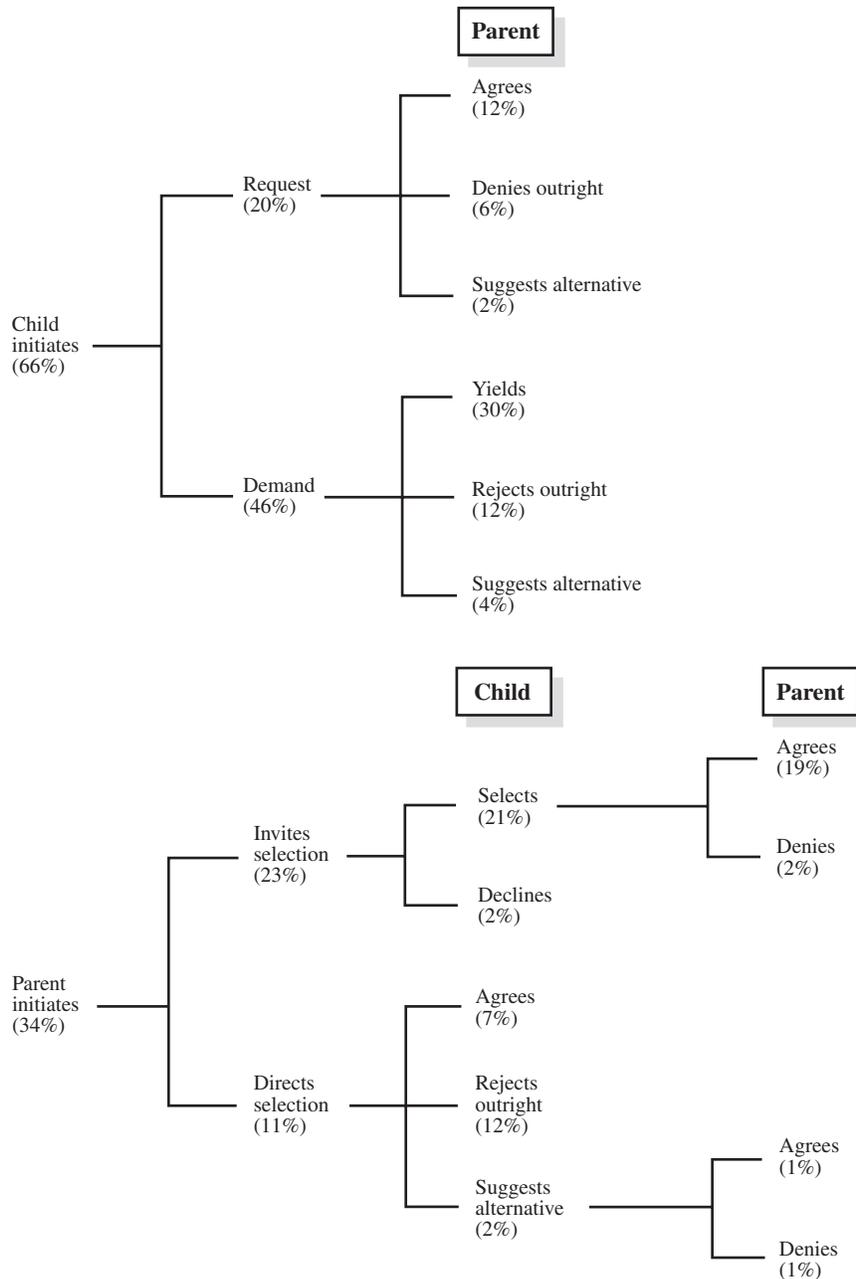

Figure 20.5 Parent-child supermarket aisle interaction over breakfast cereal. *Source:* Adapted from “Observations of Parent-Child Interaction in Supermarket Decisionmaking,” by C. K. Atkin, 1978, *Journal of Marketing*, 42, pp. 41–45. Reprinted with permission.

and the FTC. This was a brave attempt to resolve the conjunction of new issues and new science. This painstaking effort, under the direction of Richard P. Adler, stands as a landmark in the literature on television advertising and children and eventually was published commercially in 1980 as *The Effect of Television Advertising on Children* (Adler et al., 1980), although an earlier version first appeared from the U.S. Government

Printing Office in 1977. Its major conclusions matched those we have reported:

- Children at a very early age can recognize that a commercial is different from the program accompanying it, but it is not until much later that they can articulate—and, in our view, be said to understand—the nature of commercials.

- The techniques employed by commercials are very successful in persuading children to desire advertised products, and this is particularly so for foods.
- Purchase requests are common, yielding is typical, and dissatisfied children and parent-child disputes are not rare.

In response to the report, in 1978 the FTC proposed to ban or limit advertising to children. This raised some interesting questions. Would children's entertainment disappear from the air if it were not supported by advertising? Would the FCC be willing to require such programming without supportive advertising, in effect placing a "children's tax" on broadcasters (as ACT advocated)? If limits rather than a ban were imposed, what would be the parameters (in the sense of what would qualify as a consumer product or slice of the broadcast schedule for targeting)? Extensive hearings followed, but economic power and political influence eliminated the need to address these issues. Kunkel (2001, pp. 387–388) tells the story succinctly:

The painstaking level of detail the FTC pursued in marshaling its supporting evidence contrasted sharply with a serious miscalculation about the extent of the political opposition to its proposal (Kunkel & Watkins, 1987). The broadcasting and advertising industries were joined by many of America's largest corporate conglomerates in opposing the ban. These businesses owned subsidiaries producing toys, sugared cereals, and numerous other types of child-oriented merchandise. Fearing adverse impacts on their profits, these industries initiated campaigns to influence the public to oppose the ban. A key element of their strategy was the claim of First Amendment protection for the right to provide "information" about products to America's budding consumers.

The FTC's formal rule-making process for implementing the proposed ban moved forward. Open hearings were held. Elaborate briefs assessing the research evidence regarding children's comprehension of advertising were submitted by all sides. On this front, the forces seeking regulation fared reasonably well. Although some inevitable qualifications were lodged, a consensus emerged among researchers that young children were indeed uniquely vulnerable to television's commercial claims and appeals.

At the same time, however, a much different outcome was occurring on other fronts of the political battle. Using their influence with elected officials, the FTC's corporate opponents succeeded in derailing the agency's proposal, employing an innovative strategy. Responding to corporate pressure, Congress rescinded the agency's authority to re-

strict advertising deemed unfair by enacting legislation ironically titled the FTC Improvements Act of 1980. Besides removing this aspect of the FTC's jurisdiction, the act specifically prohibited any further action to adopt the proposed children's advertising rules. The agency soon issued a final ruling on the case formally implementing the congressional mandate (FTC, 1981), and since then there has been no further effort to resurrect this initiative.

Reforms and Subsequent Research

The consequences of these events—public displeasure, the rise of advocacy groups, new research in child development, the NSF review, the FTC rule-making hearings—were a series of significant reforms (Comstock, 1991a). The discrepancy between amount of nonprogram material on children's and primetime television was eliminated (and more recently was set by the Children's Television Act of 1990 at no more per hour than 10.5 minutes on weekends and 12 minutes on weekdays). Advertising of vitamins branded and packaged to appeal to children as if they were breakfast cereals was ended. Restraints were placed on the use of television storyline characters in advertising (although only halfheartedly; so-called host-selling was barred accompanying the program in which the character appeared but permitted in commercials accompanying other programs; hosts only had to take a hike). Industry codes were strengthened. "Bumpers" or separators before and after commercials were adopted to aid identification, although research indicates these have been largely ineffective (Comstock, 1991a; Kunkel, 2001).

Subsequent research has turned away from these issues of possible harm toward a topic that also was pursued earlier: the cognitive processing of commercials, and in particular, the characteristics of commercials that lead to a favorable response from a child (Greer, Potts, Wright, & Huston, 1982; John, 1999; Macklin, 1988; Wartella & Ettema, 1974; Wartella & Hunter, 1983). John neatly summarizes the cognitive changes that take place in young people as they mature (Table 20.1), using a Piagetian schema (we have substituted adjacent years for the overlapping ones in the original but have retained the somewhat earlier transition to a more advanced stage because we agree that advertising, while certainly involving many subtleties in its messages, does not impose as severe demands on formal reasoning as occurs in many other topics where cognitive stages predict—and constrain—success at a task). Examples include the shift from approval to skepticism without much in the

TABLE 20.1 Responses to Advertising by Cognitive Stage

| Topic | Perceptual Stage, 3–7 Years | Analytical Stage, 8–11 Years | Reflective Stage, 12–16 Years |
|---|---|---|---|
| Advertising knowledge | Can distinguish ads from programs based on perceptual features Believe ads are truthful, funny, and interesting Positive attitudes toward ads | Can distinguish ads from programs based on persuasive intent Believe ads lie and contain bias and deception—but do not use these “cognitive defenses” Negative attitudes toward ads | Understand persuasive intent of ads as well as specific ad tactics and appeals Believe ads lie and know how to spot specific instances of bias or deception in ads Skeptical attitudes toward ads |
| Transaction knowledge: Product and brand knowledge | Can recognize brand names and beginning to associate them with product categories Perceptual cues used to identify product categories Beginning to understand symbolic aspects of consumption based on perceptual features Egocentric view of retail stores as a source of desired items | Increasing brand awareness, especially for child-relevant product categories Underlying or functional cues used to define product categories Increased understanding of symbolic aspects of consumption Understand retail stores are owned to sell goods and make a profit | Substantial brand awareness for adult-oriented as well as child-relevant product categories Underlying or functional cues used to define product categories Sophisticated understanding of consumption symbolism for product categories and brand names Understanding and enthusiasm for retail stores |
| Shopping knowledge and skills | Understand sequence of events in the basic shopping script Value of products and prices based on perceptual features | Shopping scripts more complex, abstract, and with contingencies Prices based on theories of value | Complex and contingent shopping scripts Prices based on abstract reasoning, such as input variations and buyer preferences |
| Decision-making skills and abilities: Information search | Limited awareness of information sources Focus on perceptual attributes Emerging ability to adapt to cost-benefit trade-offs | Increased awareness of personal and mass media sources Gather information on functional as well as perceptual attributes Able to adapt to cost-benefit trade-offs | Contingent use of different information sources depending on product or situation Gather information on functional, perceptual, and social aspects Able to adapt to cost-benefit trade-offs |
| Product evaluation | Use of perceptually salient attribute information Use of single attributes | Focus on important attribute information—functional and perceptual attributes Use two or more attributes | Focus on important attribute information—functional, perceptual, and social aspects Use multiple attributes |
| Decision strategies | Limited repertoire of strategies Emerging ability to adapt strategies to tasks—usually need cues to adapt | Increased repertoire of strategies, especially noncompensatory ones Capable of adapting strategies to tasks | Full repertoire of strategies Capable of adapting strategies to tasks in adult-like manner |
| Purchase influence and negotiation strategies | Use direct requests and emotional appeals Limited ability to adapt strategy to person or situation | Expanded repertoire of strategies, with bargaining and persuasion emerging Developing abilities to adapt strategy to persons and situations | Full repertoire of strategies, with bargaining and persuasion as favorites Capable of adapting strategies based on perceived effectiveness for persons or situations |
| Consumption motives and values: Materialism | Value of possessions based on surface features, such as “having more” of something | Emerging understanding of value based on social meaning and significance | Fully developed understanding of value based on social meaning, significance, and scarcity |

way of effective defenses against appeals (top), the adoption of a stance of sophisticated (if hooked) consumption (middle), and the eventual awareness of the symbolic role of products and brands (bottom).

Children certainly are exposed to a large quantity of commercials (Comstock & Scharrer, 1999). The average child ages 2 to 11 sees almost 40,000 commercials a year. Discounting for no interest in many product categories, we estimate these children would see at least 12,500 commercials for products in which they might take an interest, with about 90% appearing outside of children's programming. Cereals and candies top the list for children's programming, followed by toys and fast foods; in general audience programming, these are joined by soft drinks, shoes, and clothing. Toys are the crown princes of pre-Christmas advertising, accounting for at least half of the commercials in children's programming. Teenagers 12 to 17 watch less television but would find more products of interest (comparable figures are 27,000 commercials with an estimated 16,000 of possible interest). Thus, advertising likely will remain a fertile area for research, although at a slower pace than during the heated 1970s.

VIOLENT ENTERTAINMENT

Entertainment is the type of television content most often attended to by children and teenagers. Unambiguously, the topic that has received the most attention in child development research in regard to entertainment (with the exception, of course, of the continuing and repeated measurement of audience demographics to satisfy the informational needs of those who buy and sell time slots for commercials, which unavoidably produces data of some interest in regard to child development but is motivated by and designed to serve the needs of marketing) is violent entertainment and its effects on aggressive and antisocial behavior.

Although the investigation of the influence of audiovisual entertainment media on antisocial behavior traces to the Payne Fund movie studies of the early 1930s (Charters, 1933), the contemporary inquiry into this issue dates from the early 1960s. We have constructed a timeline displaying significant events in the empirical examination of the possible influence of violent television and film entertainment on aggressive and antisocial behavior (Figure 20.6). In 1963, two pioneering experiments were published in the *Journal of Abnormal and*

Social Psychology. In one, Bandura, Ross, and Ross (1963a) demonstrated that nursery school children would imitate the aggressive antics of those observed on a television screen, including a young adult female clothed in a cat costume intended as a faux representation of a character that might appear in children's entertainment. In the other, Berkowitz and Rawlings (1963) demonstrated that college students would increase their aggressiveness after exposure to an example of justified aggression observed on a television screen. These two investigations began an experimental literature now numbering more than 100 exploring the various factors on which an effect of violent television or film portrayals on behavior are contingent. For example, Bandura, Ross, and Ross (1963b) quickly enlarged the range of variables in their studies of nursery school children to include positive reinforcement or punishment of the portrayed behavior, with positive reinforcement on screen increasing the likelihood of imitation. Berkowitz and colleagues later found in their studies of college students that cues in a portrayal matching real-life circumstances (Berkowitz & Geen, 1966, 1967) and portrayals that depict malevolent motives for aggression (Berkowitz & Alioto, 1973; Geen & Stonner, 1972) enhanced the likelihood of aggressive behavior.

Enter the Surgeon General

By the end of the decade, there was enough evidence from experiments and other research methods to lead the National Commission on the Causes and Prevention of Violence (1969) to conclude that there was a causal link between exposure to violent portrayals in television entertainment and aggressive and antisocial behavior. This commission had been established by President Lyndon Johnson as a result of the assassinations of John and Robert Kennedy and Martin Luther King and widespread urban rioting in Black neighborhoods. Its judgment about the media was not considered particularly credible or important; however, the compilation of commissioned papers on media effects (Baker & Ball, 1969) in academic circles was considered something of a landmark (and a valuable reference) for many years. Senator John Pastore of Rhode Island then extended the concern with the media to an investigation focused exclusively on television. The result was the 1972 federal report *Television and Growing Up: The Impact of Televised Violence* by the Surgeon General's Scientific Advisory Committee on Television and Social Behavior, accompanied by

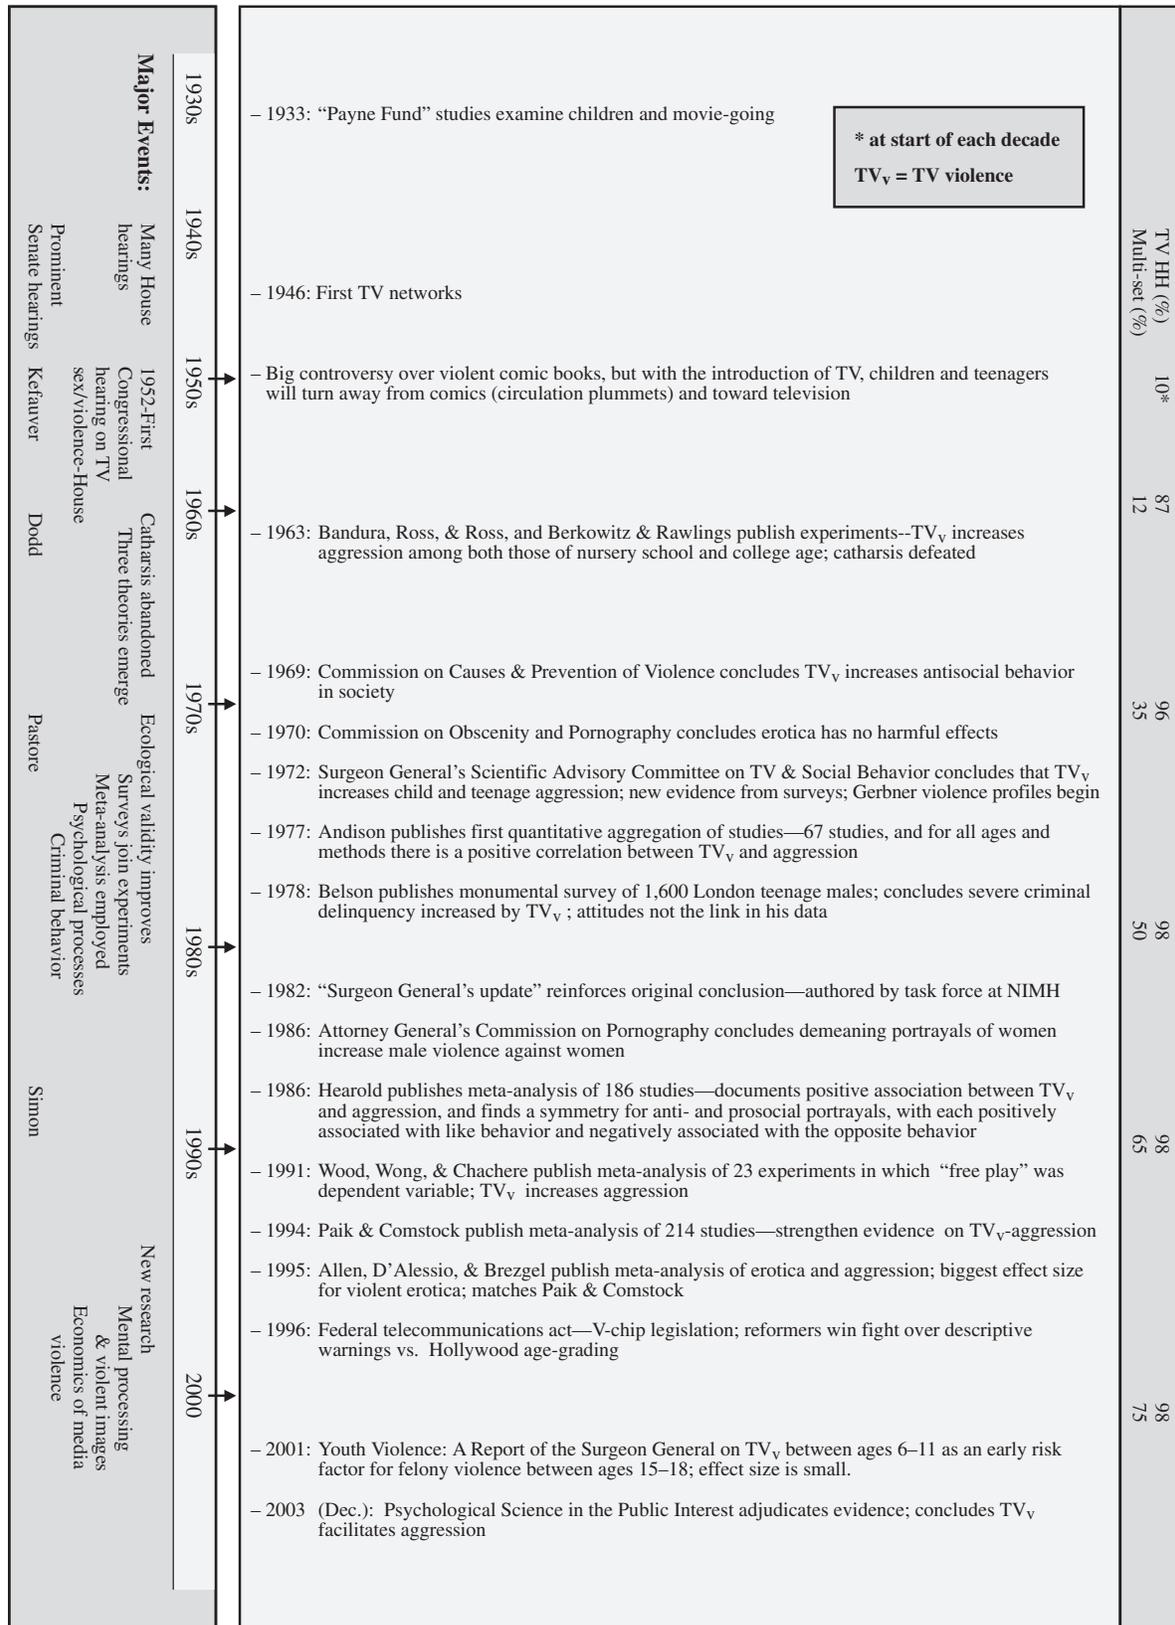

Figure 20.6 TV violence through the ages.

five volumes (Comstock, Rubinstein, & Murray, 1972a, 1972b, 1972c, 1972d, 1972e) representing \$1 million in new research. This enterprise substantially enlarged the research literature. More significant, the surgeon general's committee concluded in its report that, at least for some children, there was a causal link between exposure to television violence and aggressive behavior.

Ten years later, the National Institute of Mental Health assembled a special committee of social and behavioral scientists expert in regard to research on television on the 10th anniversary of the original surgeon general's report. This undertaking, known as the "surgeon general's update," produced a committee report accompanied by a volume of commissioned papers covering recent research (Pearl, Bouthilet, & Lazar, 1982a, 1982b). The focus was largely on children and teenagers, and the range of topics in regard to television was now quite broad: cognition and affect, social beliefs and social behavior, and family and social relations, as well as violent portrayals and aggression. This select committee concluded that the research of the past decade had strengthened and reinforced the evidence on which the original surgeon general's committee drew in concluding that there was a causal link between exposure to television violence and aggressive behavior.

In 2001, the surgeon general's report on youth violence (U.S. Department of Health and Human Services, 2001) again raised the issue of effects on aggressive and antisocial behavior, but in a more pronounced way. Accompanied by a judicious evaluation of the evidence for some effect of violent television and film portrayals on behavior (the conclusion is that the evidence supports such an effect, and there is speculation that newer media, with interactivity, greater graphicness, and availability on demand, may have stronger effects), the report incorporates television violence as among the factors empirically documented as causally predictive of seriously harmful antisocial behavior. Specifically, it identifies exposure to television violence as one of 20 early risk factors for the committing of felony violence. The early period of exposure encompassed ages 6 to 11, with the seriously harmful criminal violence occurring between 15 and 18 (p. 58, Box 4.1). The effect size of $r = .13$ would be classified as small (by the widely used criteria of Cohen, 1988). However, so too were three-fourths of the factors said to pose an early risk (Figure 20.7), none of which on the surface would seem to be inconsequential for the welfare or constructive social functioning of a child or teenager.

This is an important conclusion in the debate over the effects of television and film violence, for it both escalates the degree of social harm and heightens the standards of evidence. The effect is now felony violence, and not the more vague and quite encompassing aggressive or antisocial behavior. It also has particular credibility because the authors insisted on data either from meta-analyses quantitatively aggregating the results of a group of studies or data from at least two independent studies. The ignoring of this indictment by the press and

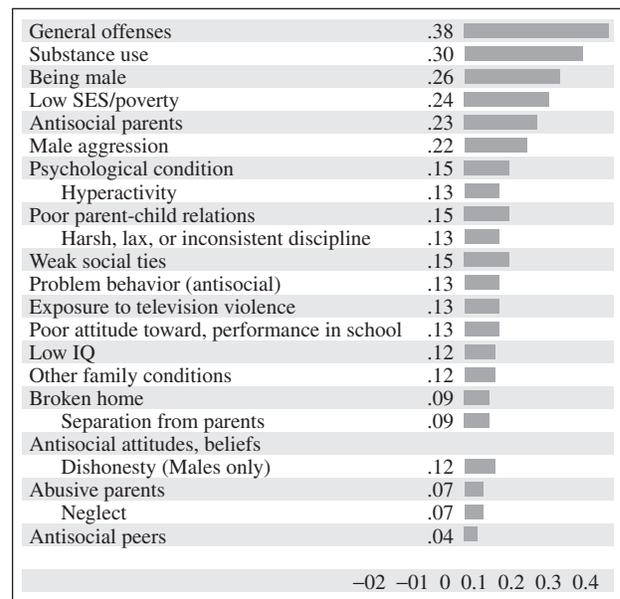

Figure 20.7 Effect sizes for early risk factors (ages 6 to 11) for serious violence at ages 15 to 18. *Source:* From "A Review of Predictors of Youth Violence" (pp. 106–146), by J. D. Hawkins, T. L. Herrenkohl, D. P. Farrington, D. Brewer, R. F. Catalano, and T. W. Harachi, in *Serious and Violent Juvenile Offenders: Risk Factors and Successful Interventions*, R. Loeber and D. P. the public almost certainly has less to do with the substance of the charge or the quality of the evidence than the issuing of the report at the beginning of the inaugural week of George W. Bush (see Figure 20.8).

Aggregating the Evidence

At the time of the original surgeon general's inquiry, about 50 experiments had been published with nursery school children or college students as subjects, with most recording increased aggressiveness as a consequence of exposure to a violent television portrayal. However, these outcomes are problematic for generalizing to everyday viewing; in the jargon of social science methodology, they are weak in external validity (Cook & Campbell, 1979) because of the contrived conditions of the experience, with viewing brief and attenuated rather than continuous, as it would be in ordinary circumstances, and zero likelihood of retaliation from the victim. Today, with the contributions of the research undertaken for the surgeon general's 1972 inquiry and the extensive subsequent research, there are more than twice as many experiments (thereby increasing the credibility, what Cook and Campbell call internal validity, of this body of studies), and many that incorporate elements of everyday viewing (increasing their external validity), as well as evidence from a variety of methods, such as the survey (which does not suffer from the weak external validity of the experiment). Thus, it is possible now to answer the question of whether exposure to violent television portrayals increases aggressive and antisocial behavior with much greater confidence than in the past (in effect, we can test the validity of earlier inferences by asking whether more recent research, more varied in approach and sometimes employing different methods, strengthens or weakens the evidentiary trail).

Happily, we can effectively describe the evidence through a series of seven quantitative aggregations of study outcomes, with most using the techniques of meta-analysis (which, using the standard deviation as a criterion, leads to an effect size, or statistical coefficient, representing the difference across studies between those experiencing or not experiencing a stimulus, or what in an experiment would be the treatment versus the control conditions; Hunt, 1997). These aggregations are more reliable and valid than a single study because the outcomes rest on a much larger number of subjects or respondents and they do not suffer much from the singular weaknesses of a particular study.

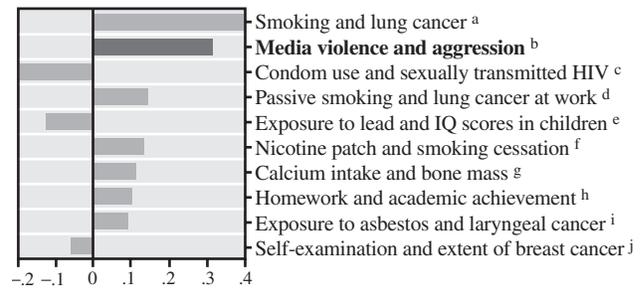

Figure 20.8 Effect size for media violence and aggression compared with effect sizes for other domains. Note: A correlation coefficient can range from -1 (a perfect negative linear relation) to $+1$ (a perfect positive linear relation), with 0 indicating no linear relation. The effect of smoking tobacco on lung cancer was estimated by pooling the data from Figures 1 and 3 in Wynder and Graham's (1950) classic article. The remaining effects were estimated from meta-analyses. Sources: (a) Adapted from "Tobacco Smoking as a Possible Etiological Factor in Bronchiogenic Carcinoma," by E. L. Wynder and E. A. In a pioneering aggregation of results (and the one instance in which the techniques of meta-analysis were not employed), Andison (1977) scored the outcomes of 67 experiments and surveys as to direction and magnitude. Hearold (1986) examined 168 studies to estimate effect sizes between exposure to either antisocial or prosocial portrayals and both antisocial and prosocial outcomes. Wood, Wong, and Chachere (1991) focused on 23 experiments with children and teenagers as subjects in which the dependent variable was “unconstrained interpersonal aggression” such as would occur in everyday play. In contrast, M. Allen, D’Alessio, and Brezgel (1995) focused on 33 experiments in which the treatment was exposure to sexually explicit portrayals, including those that combine violence with erotica. Hogben (1998) avoided experiments altogether and confined himself to 56 coefficients from studies where the independent variable was everyday viewing. Bushman and Anderson (2001) calculated effect sizes at 5-year intervals over 25 years for both experimental and nonexperimental designs. Paik and Comstock (1994) updated Hearold’s examination of the link between television violence and aggression by including 82 new studies for a total of 217.

This is a challenging body of data because meta-analysis, though increasing reliability and validity, does not absolve the analyst from the anxiety-ridden task of interpretation. It is still necessary to assign meaning to the data: what to make of positive correlations in survey designs where causal inference is ambiguous, whether experimental findings can be generalized to other settings, and how large an association should be to qualify as socially important.

In our view, these aggregations, qualified and amplified by information from individual studies that escapes the broader net of the aggregations, lead to several important conclusions:

1. Because the aggregations *all* produce positive and (when put to this criterion) statistically significant effect sizes between exposure to the portrayals under scrutiny and the dependent variables of aggressive or antisocial behavior, they make it irrefutably clear that there is a positive association between exposure and behavior.

2. This positive association occurs for both experimental and nonexperimental designs (most of which are surveys). These parallel outcomes would produce a strong case for causation should one condition be met: that the positive coefficients in the nonexperimental designs cannot be wholly explained by the influence of

something, a so-called third variable, other than exposure to violent portrayals. In fact, this is precisely what occurs. When the studies in the meta-analyses are examined individually, the positive correlations persist when every other measured variable is taken into account (Comstock, 2004; Comstock & Scharrer, 2003). Thus, the case for causation rests on the demonstration of causality in the experiments, which unambiguously permit such an inference, and the documentation of a positive association not otherwise wholly explainable in everyday circumstances. In effect, the surveys, drawing on data representing viewing and behavior outside of the laboratory, confirm the generalizability of the experimental outcomes. This interpretation is strongly reinforced by the failure of the “reverse hypothesis” to provide an explanation. This is the hypothesis that the positive correlations between exposure to violent portrayals and aggression are attributable to the preference on the part of aggressive youths for violent entertainment. There is some evidence that such a phenomenon occurs (Huesmann, 1986, 1998; Slater, Henry, Swaim, & Anderson, 2003), but not on a scale sufficient to absolve television of complicity in television violence-aggression causation. For example, in examining a series of correlations between earlier aggression and later viewing and later viewing and earlier aggression, Kang (1990) found twice as many statistically significant viewing-to-behavior as behavior-to-viewing coefficients, and Belson (1978), in his survey of about 1,600 London male teenagers, reported only a minute link between prior aggression and violence viewing but a link of substantial magnitude between prior viewing violence and aggression. Thus, data are highly supportive (by what they don’t provide: an alternative explanation that eliminates the possibility of violence viewing playing a causal role) of violent portrayals in television and film entertainment contributing to aggressive and antisocial behavior.

3. Effects are surprisingly similar for males and females. The early experiments of Bandura (1965; Bandura et al., 1963a, 1963b) with nursery school children so clearly recorded greater aggressiveness by males that this has become almost axiomatic in the child development literature. However, the Paik and Comstock (1994) meta-analysis makes it equally clear that this is an untenable position. As more findings accumulated, outcomes for males and females became more similar and are almost identical in the nonexperimental designs that best represent everyday viewing and behavior.

4. There is definite evidence of a longitudinal influence, with earlier violence viewing contributing to later aggressive or antisocial behavior. One prominent example, of course, is the conclusion of the 2001 surgeon general's report on youth violence that violence viewing between the ages of 6 and 11 heightens the risk of serious violence between the ages of 15 and 18 (U. S. Department of Health and Human Services, 2001). However, there are many examples in the literature in which earlier viewing affects later behavior. These include Eron and colleagues (Eron & Huesmann, 1987; Huesmann, Eron, Lefkowitz, & Walder, 1984), who report positive correlations between violence viewing and aggression not only at 10-year but also at 20- and 30-year intervals; Cook and colleagues (Cook, Kendzierski, & Thomas, 1983) and Kang (1990), who both reported coefficients of increasing size with extended time spans in the 3.5-year panel study of Milavsky and colleagues (Milavsky, Kessler, Stipp, & Rubens, 1982) and with different segments of the panel population; and the very recent analyses by Johnson and colleagues (Johnson, Cohen, Smailes, Kasen, & Brook, 2002) and Huesmann and colleagues (Huesmann, Moise-Titus, Podolski, & Eron, 2003), with the former finding young adult aggression predicted by adolescent television viewing, and the latter finding violence viewing between the ages of 6 and 10 predicting aggression 15 years later, both with samples of several hundred and after numerous potentially contaminating variables had been statistically controlled.

5. When the nonexperimental studies are examined individually, it becomes clear that the recorded effects do not represent outcomes that most people would consider particularly tolerable. The most common dependent variable has been interpersonal aggression, and although this may escape the attention of the law, the hitting, fighting, stealing, and name-calling encompassed would hardly be found pleasant by anyone. In other cases, the dependent measure has been delinquency against property, teachers, or the use of physical violence in an encounter (Cook et al., 1983; Thornton & Voigt, 1984). In fact, one investigator found a convincing causal link between violence viewing and the committing of crimes: using a knife or gun in a fight, rape, or torturing a victim with a lit cigarette (Belson, 1978).

6. The size of effects is not trivial by social standards. Bushman and Anderson (2001) and Bushman and Huesmann (2001) compiled a catalogue of effect sizes for other variables and outcomes, and the overall effect

size ($r = .31$) recorded by Paik and Comstock (1994) is among the largest (Figure 20.2). Of course, effect sizes in Paik and Comstock and in other meta-analyses vary for each specific pairing of an independent variable and an outcome, and range (by Cohen's criteria) from small to large. However, even small effect sizes can have social consequences if the behavior in question is of importance because, as Rosenthal and colleagues (Rosenthal, 1986; Rosenthal, Rosnow, & Rubin, 2000) have persuasively argued, a small effect size masks a sizable number of people being shifted above or below the mean by the treatment.

7. The link between exposure to television or film portrayals and behavior applies to a wide variety of circumstances: prosocial behavior (defined to encompass altruism, acceptance of others, and engaging in social interaction, the three most frequent in a much longer list, as would have been seen on *Mister Rogers' Neighborhood*, *Big Blue Marble*, and, more recently, *Blue's Clues*), which declines after exposure to violent portrayals and increases after exposure to prosocial portrayals (Hearold, 1986); when the experimentally measured behavior is naturally occurring spontaneous aggression on the playground or similar settings (Wood et al., 1991); and when the measure of viewing occurred in everyday circumstances rather than the contrived environment of an experiment (Anderson, 1977; Bushman & Anderson, 2001; Hearold, 1986; Hogben, 1998; Paik & Comstock, 1994). This favors the view that the exposure-behavior link is robust across circumstances.

8. There is a stunning symmetry between outcomes for violent and prosocial portrayals (Hearold, 1986). Effect sizes are positive for violent portrayals and aggressive behavior but negative for violent portrayals and prosocial behaviors, and positive for prosocial portrayals and prosocial behavior and negative for prosocial portrayals and aggressive behavior.

The inferences in regard to violent media receive strong endorsement from the recent review in *Psychological Science in the Public Interest* (Anderson et al., 2003), the American Psychological Society journal whose mission is to adjudicate the empirical evidence on issues of significant public concern. The authors conclude that (a) exposure to violent television or film entertainment facilitates aggressive and antisocial behavior, that (b) this facilitation extends to seriously harmful behavior, and that (c) there is a developmental pattern in which earlier viewing nurtures one or more

traits that will be expressed in aggressive and antisocial behavior in a later time period.

Other Violence-Related Hypotheses

Three other hypotheses have seen considerable attention in regard to television and film violence. These include the expectation that media portrayals may induce, as well as temporarily invoke, anxieties and fears (Cantor, 2001), the possibility that media portrayals may desensitize audience members to future displays of violence (Drabman & Thomas, 1974), and the proposition that television cultivates beliefs and impressions that are in accord with the emphases of its programming (Gerbner, Gross, Morgan, Signorielli, & Shanahan, 2002).

Fear

Cantor (1998a, 2001) and her colleagues (Cantor, 1994a, 1994b; Cantor & Hoffner, 1990; Cantor & Nathanson, 1996; Cantor & Reilly, 1982) have explored the relationships between the anxieties and fears of children and teenagers in relation to television and films. Almost half have been frightened at one time and will recall this many years later. Young children are particularly disturbed by visual manifestations of danger, including monsters and transformations such as *The Incredible Hulk* used to undergo. Older children are less frightened by the impossible than by the possible if improbable: kidnappings, abuse, threats to pets. Cataclysmic events such as wars and natural upheavals such as hurricanes and earthquakes are not of much significance to young children (until experienced), although they are quite frightening to older children who are better prepared to imagine the harm and destruction and threat to life that such an event might bring. A highly dramatic portrayal may be particularly powerful; the movie *Jaws* left many young people and particularly teenagers, who would be more apt to venture into deeper waters, avoiding the beach, an effect that would be expected today when reports of shark attacks are prominent in the media (although their effect would certainly be diminished without graphic video).

Desensitization

The evidence is quite convincing that media portrayals of violence may lessen the subsequent responsiveness of children and teenagers to violent stimuli. Drabman and Thomas (1974) and Thomas, Horton, Lippencott, and Drabman (1977) found that third- and fourth-grade chil-

dren who viewed a violent film were slower to respond to a signal that children they had been assigned to watch over had become engaged in a physical melee. Cline, Croft, and Courrier (1973) found that children between the ages of 5 and 12 who had a history of viewing violent television were emotionally less aroused by new violent television scenes. Donnerstein, Linz, and Penrod (1987) and Linz, Donnerstein, and Adams (1989) report that continuous exposure to violent erotica reduces the readiness of college students to label similar new stimuli as violent or pornographic, and increases the likelihood that they will perceive the female victim of a rape as somehow responsible. It would be far too much to conclude that this desensitization extends to bloody violence witnessed in real life, for all of the studies we have described used television or film to convey the new stimuli that evoked a lessened response (the children in the experiments by Drabman and colleagues were responding to video coverage of their wards' play area). However, media portrayals inevitably figure prominently in the reactions of children and teenagers, as well as adults, to the larger world. Media are the principal means by which children and teenagers, as well as adults, learn of distant events. What media depict impinges on viewers' interpretation of what is transpiring in the world and critically affects the picture that people have of reality. These events often include human suffering, distress, and death. The media also have long been used by nations to justify the retribution imposed on an enemy; this is the process of dehumanization (Bandura, 1986), by which the suffering of others is made more tolerable by the media. The implication is that desensitization to media portrayals may encourage a callous indifference to suffering and a curtailment of empathy (this is, of course, speculation because such outcomes in regard to the news have not been investigated for either young people or adults).

Cultivation

Gerbner and colleagues (Gerbner, Gross, Morgan, & Signorielli, 1980; Gerbner et al., 2002; R. P. Hawkins & Pingree, 1990) have proposed what has become known as "cultivation theory." This formulation takes its name from the notion that television cultivates beliefs and perceptions, with the emphasis on the subtlety and generally small scale of the influence rather than the larger impact connoted by its synonym, effects. Two initial assumptions were that television is homogeneous enough in its presentations—as exemplified by such perennials

as ubiquitous violence, preeminence in news, sports, and entertainment of the White male, and a focus on the middle and upper-middle classes—that amount of viewing is a reasonable index of exposure to the emphases of the medium, and that the cultivation effect will be a function of amount viewed.

The first proposition offered by cultivation theory is that those who view more will be more likely to perceive the world as resembling what has been portrayed on television. Morgan (1989) catalogues a large number of such correlations; for example, heavier viewers perceive the world as racially and occupationally more like the demographics of television casts. The two propositions that have been offered in regard to violent entertainment is that heavier viewers will perceive the world as a mean and dangerous place, and that they are more likely to be fearful of falling victim to an attack. The first finds considerable support; after controlling for a large number of other variables, including those that are correlates of both amount of viewing and such pessimistic views (lower socioeconomic status, senior citizen status, or being female) that might artifactually create correlations between viewing and perceptions, the viewing-pessimism correlations hold up stoutly (Hughes, 1980). The second has fared less well (Hughes, 1980; Tyler, 1980, 1984); television viewing in general, as contrasted with the viewing of terrifying or frightening portrayals, is unrelated to fearfulness when the influence of other variables is statistically controlled. The analysis by Hughes presents critical evidence in what is essentially a match-up of mean world and fearfulness responses. In a nationally representative sample of about 2,000 (and thereby particularly credible), he found that after controlling for crucial variables such as age, sex, and race (because they are positively correlated with both amount of viewing and mean world and fearfulness responses), three out of four mean world items were positively associated with amount of viewing to a statistically significant degree; the one item representing fearfulness, after controlling for those same items, reversed in direction, with scores increasing as amount of viewing decreased—exactly the opposite of what cultivation theory would predict.

Thus, the two initial assumptions have held up well enough for data collected under their rubric to support the theory, but on closer examination they do not accurately convey the whole story. There is enough variation in the makeup of television programs for those who watch a particular genre a great deal to display stronger effects for the emphases of that particular genre, and as

a consequence measuring exposure to particular types of programming produces larger correlations between program emphases and beliefs than occur for viewing in general and the overall emphases of programming (R. P. Hawkins & Pingree, 1980, 1982). Ironically, these both follow logically from the initial assumptions, because effects, if present, surely should increase with more specific measures of program emphases and more precise measures of exposure to those emphases.

The data supporting the cultivation perspective mostly has represented adults, but the few instances where children or teenagers have been examined show the same pattern (R. P. Hawkins & Pingree, 1982; R. P. Hawkins, Pingree, & Adler, 1987; Pingree & Hawkins, 1981). In addition, children and teenagers are particularly likely to rely on the media when firsthand knowledge is absent (DeFleur & DeFleur, 1967), and so it is a reasonable speculation that they would be particularly affected by portrayals that take them away from their own world, which would account for a good amount—although certainly not all—of their television exposure.

Theory, the V-Chip, and the Surgeon General

Child development as a field has profited from research on the influence of violent portrayals on aggressive and antisocial behavior. The data identify a developmental pattern in which viewing violence during the elementary school years nurtures a trait of aggressiveness that will persist well into and perhaps throughout adulthood, and large amounts of violence viewing during the teenage years will promote enhanced aggressiveness (but not necessarily a lasting trait) whatever the history of prior viewing (Anderson et al., 2003; Comstock & Scharrer, 1999; Huesmann, 1986). The two theories that guided so much of the research—Bandura's (1986) social cognition and Berkowitz's (1984, 1990) neo-associationism—have certainly benefited by the support from myriad findings, and we have all benefited by being able to apply these explanations of behavior with greater confidence. Social cognition, of course, holds that what children and teenagers see—in the media as well as the real world—is a source for the acquisition (and subsequent performance) of behavior; neo-associationism emphasizes the influence on behavior of the thoughts, semantically linked in the brain, triggered by what is observed. Both predict that media portrayals under some circumstances will influence behavior. Although social cognition emphasizes the

learning of behavior and neo-associationism emphasize the performance of learned behavior, the two are essentially identical in the hypotheses they would offer in a given circumstance. Both concur that the context of a portrayal makes a critical difference. Likelihood of an effect is enhanced when a portrayal includes various elements that attribute what Comstock and Scharrer (1999) have termed efficacy, normativeness, or pertinence to a way of behaving, or when there is particular susceptibility to influence on the part of a viewer. These terms refer to the presentation of behavior as likely to be rewarded, successful, or helpful in attaining a goal; as accepted or socially approved; as particularly connected to a viewer through the overlap of the portrayal with viewer attributes or circumstances (such as age, gender, race, potential victim, or some aspect of the setting); and (in regard to susceptibility) in the case of aggression and antisocial behavior, anger, frustration, or provocation. Changes in attitudes, norms, and values attributable to the media, proposed by some as a major factor (Eron & Huesmann, 1987), are not a necessary condition. This is made clear by Belson's (1978) documentation in his monumental survey of about 1,600 male London teenagers that a positive correlation between violence viewing and aggression was not mediated by attitudes, norms, or values; this is a strong finding, because attitudes, norms, and values were operationalized in four distinct, highly reliable scales, and in none of these instances did violence viewing predict dispositions favorable to aggression. Efficacy, normativeness, and pertinence, then, well-documented in the experiments derived from social cognition and neo-associationism, may function, in addition to the possibility of changes in dispositions, through enhancing accessibility by giving ways of behaving greater prominence and preference in the behavioral repertoires of young viewers. The data in turn establish the media as important contributors to the behavior of young people.

This role extends beyond aggressive and antisocial behavior to prosocial behavior, as the symmetry in one meta-analysis (Hearold, 1986) makes clear. Individual studies, as well as portions of the meta-analyses, identify four factors that will vary considerably from situation to situation as critical, with three representing attributes of portrayals and one an attribute of the viewer (Comstock & Scharrer, 1999): *efficacy* (the portrayal of successful goal attainment), *normativeness* (the portrayal of behavior as socially approved), *pertinence*

(the portrayal of a link with the viewer, such as age, setting, or adversary), and *susceptibility* (circumstances that render the viewer vulnerable, such as frustration or anger in the case of aggressive behavior).

The meta-analyses now appear regularly in the literature on media and aggression and thereby establish a superior framework in regard to the reliability and validity of evidence, and thus interpretation (Anderson et al., 2003; Comstock, 2004). They have joined the currency of academic exchange. They have also seen more specific applications. Bushman and Anderson (2001) used the Paik and Comstock (1994) meta-analysis to evaluate how the effect size ranked among socially consequential effect sizes (about as large as they come), and used their own meta-analysis, broken into 5-year segments, to show that whereas the findings have become stronger with time, news coverage has become weaker in regard to a media violence-behavior link. The latter may be a consequence of the preoccupation of the news media with the episodic, for in the specific, dramatic instance, news outlets have been quick to indict the media for responsibility, as exemplified by the death of Princess Diana, the Jenny Jones talk show murder, and the shootings at Columbine High School (Scharrer, Weidman, & Bissell, 2003).

There is much also that must be attributed to the varied research on the effects of violent portrayals as a whole, although the research on portrayals and aggressive and antisocial behavior unambiguously has been at the forefront. The gist of all the research, from the viewpoint of the welfare of the child or teenager, has been that violent portrayals, however enjoyable or, in specific instances, true to life and even inspiring, can be problematic for young viewers, with sometimes undesirable consequences. It is difficult to believe that without the context established by this research, an eminence suitably lustrous with disinterested scientific authority, the warning labels that now grace many programs and particularly cable movies would be appearing on our television screens. The industry has every reason to detest and avoid labels, because they narrow the audience, arouse parental concerns, and frighten advertisers with the very noxious (to the industry) result that commercials sell for less on programs with warning labels (Hamilton, 1998). Not surprising, given the economic consequences of labeling, the industry has leaned toward underlabeling (J. C. Allen, 2001; Kunkel et al., 1998), leaving some programs unlabeled or with less restrictive ratings than the content would seem to call for. Nevertheless, the en-

tire enterprise can be regarded as a potential service to parents (Gentile, Humphrey, & Walsh, 2004), and apparently programs labeled with warnings do draw smaller child audiences (Hamilton, 1998).

EMERGING ISSUES

Children and adolescents continue to spend much of their time—outside of school and absent other obligations—watching television, listening to music, logging on to the Internet, and playing video games. Television, for decades discussed by social scientists as a medium that newly captured our attention, is now often relegated, along with radio, newspapers, and magazines, to the status of “traditional media,” in contrast with the newest wave of novel media forms that are computer- and video game console-based. However, despite the semantic shift and the increasing prevalence of new media in the lives of young people, television continues to dominate overall media use and largely commands the way leisure time is spent (Comstock & Scharrer, 1999).

With the growth of new interactive media and the staying power of traditional media have come new concerns about the amount of time young people spend in front of screens as well as about the content to which they are exposed. Neither concern is new in substance. What is new is the cumulative hours spent by young people with media and the recent implementation of ratings and codes to label the media content—in effect, to give warning—delivered through traditional forms (in the case of television) and new forms (in the case of video and computer games). We begin with the codes and ratings, which are now largely (if imperfectly and confusedly) in place. We then turn to the new delivery systems that are becoming increasingly important in the allocation by the young of time and attention to media and popular culture.

Ratings and Codes

Violence is the topic that has garnered the most research and public attention and triggered the most heated and long-standing debates about media. Yet, little to no substantive reform was achieved in past instances in which Congress took up the issue, despite increasing confidence in the causal link between media violence and aggression, desensitization, and fear (C. A. Cooper, 1996). The V-chip and accompanying program labels implemented by the Telecommunications Act of 1996 stand in

stark contrast to the long history of a high degree of attention to the issue of media violence with low levels of responsive changes in the entertainment industry.

In the early to mid-1990s, U.S. Representative Edward Markey began to press for the creation of a policy that would address the issue of media violence, focusing on bringing V-chip technology that had been introduced in Canada to the United States (Price, 1998). This computer chip, contained in television sets, can be programmed to read the rating or codes that are assigned to a television program to flag the presence of potentially objectionable content and allow the user to block the display of the program on the television screen. A parent uses a code or personal identification number to program the V-chip via remote control to block out all programs that carry the label or labels the parent has identified as a concern. The label information of the program is encoded in the television signal using a technology that is similar to that developed for closed captioning (Eastin, 2001; Price, 1998).

Dale Kunkel and Brian Wilcox (2001, p. 592) describe the political process through which the V-chip legislation surfaced:

In a political context shaped by strong scientific consensus about the harms of violent portrayals, and perhaps even stronger public opinion against media violence, United States Representative Edward Markey began to gain support for his V-chip legislative proposal. . . . When President Clinton endorsed the V-chip in his 1996 State of the Union Address, it was only a matter of weeks until Congress adopted Markey’s legislative proposal, adding it as an amendment to the omnibus Telecommunications Act of 1996. Under the law, the television industry was given 1 year to devise its own system of categorizing programs for violence and other sensitive material (including sex and offensive language) and to then submit this system to the FCC for its approval. If the television industry failed to act, or if its system was not deemed “acceptable,” then the FCC would have been required to appoint an advisory committee to design a model V-chip rating system. Oddly enough, the industry would not have been bound to actually employ the system designed by the FCC or, for that matter, any system at all. The only firm requirement in the law was that all television sets sold in the United States must be equipped with a V-chip device that would facilitate program-blocking capabilities.

Thus, the two-pronged system—program ratings/codes and the V-chip that can read them—was implemented in a manner that was technically voluntary on

the part of the industry but in reality was couched in fairly threatening terms. The opposition of members of the television industry on First Amendment grounds was circumnavigated by their freedom to devise the codes themselves and by the fact that parents could choose whether to use the chip (Eastin, 2001; McDowell & Maitland, 1998). Industry leaders also objected on economic grounds, concerned that the labels would decrease audiences and thereby ward off advertisers (Price, 1998).

Research supports the view that child audiences, but not adults or teens, will be smaller when programs carry warning labels. Hamilton (1998) analyzed the impact of “viewer discretion warnings” on the audience composition for movies airing on the broadcast networks from 1987 to 1993. He found that such warnings “resulted in a decrease in children’s ratings of approximately 14%,” translating into approximately “220,000 fewer children in the audience” (pp. 76–77).

Facing the possibility of direct FCC involvement, an industry group comprising members of the National Association of Broadcasters, the National Cable Television Association, and the Motion Picture Association of America (MPAA) joined forces to create codes that would be used to label television programs for potentially sensitive content.

Despite the evidence from a national survey of parents that they would prefer codes that communicated information about the actual content of programs (rather than the ages for which they were deemed appropriate) and the support for such content-based (rather than age-based) codes of many social scientists (Cantor, 1998b; Gruenwald, 1997), the industry group unveiled its newly conceived codes that used the MPAA model of assigning age-based ratings only. The ratings included TV-Y (for youth), TV-Y7 (for youth age 7 and older), TV-G (for general audiences), TV-PG (“parental guidance suggested,” as used by the MPAA), TV-14 (recommended for those 14 and older, “parents strongly cautioned”), and TV-MA (for mature audiences only; Eastin, 2001). News and sports were exempted from labeling, and the decision was made to label each individual episode of a television series, a task given to the program producers or the syndicated programmers (Eastin, 2001).

The lack of content descriptors in the codes initially generated by the industry group sparked a new round of controversy. In addition to reflecting public interest groups’ demands for more informative labels, the ensuing debate was also influenced by the National Televi-

sion Violence Study, a multifaceted, multimillion-dollar research project funded by the cable industry (Kunkel & Wilcox, 2001; S. Smith et al., 1998; Wilson et al., 1997, 1998). One portion of the National Television Violence Study investigated the potential for program labels to actually increase the appeal of a program among young audiences rather than to lead them away (Cantor & Harrison, 1997; Cantor, Harrison, & Nathanson, 1997), a phenomenon that has been referred to as a “boomerang” or “forbidden fruit” effect (Bushman & Stack, 1996; Christenson, 1992). The data from the experiment indicated that age-based labels increased children’s interest in television programs, primarily among boys, whereas content-based labels did not. This evidence, impugning the effectiveness of age-based labels, had a prominent role in the critique of the industry’s original program coding scheme. After press attention to the fresh controversy and another congressional hearing, the industry agreed fairly quickly to add codes that would signify particular categories of content were present (Kunkel & Wilcox, 2001). Furthermore, the composition of the committee designing the labels was expanded to represent such nonindustry organizations as the American Medical Association, the Center for Media Education, and the Parent Teacher Association (Greenberg, 2001).

The result is the presently used system, in place since October 1997, which employs both the age-based labels and content codes: V for violence, S for sex, L for adult language, D for suggestive dialogue, and FV for fantasy violence (usually used for children’s cartoons, and used only in conjunction with the TV-Y7 rating; Eastin, 2001). The combination of the age- and content-based labels introduces the possibility of multiple meanings assigned to the content codes based on the age-related context. A V in a TV-PG program, for instance, signifies “moderate violence,” whereas the same V in association with a TV-14 program means “intense violence” and with a TV-MA program means “graphic violence” (Eastin, 2001).

The labels appear in the opening 15 seconds of television programs in the form of a black-and-white box that appears in the corner of the screen. Parents and caregivers can use the label information itself to make decisions about viewing in the household or, if they have a television set that contains the V-chip, can program the chip to block out programs that feature any combination of labels that the parent chooses. In other words, a parent of a young child can block any program labeled with a V for violence, for instance, or any program with a label

that exceeds TV-Y7. The parent sets the parameters for acceptable programs and can reset them at any time.

Effectiveness

The V-chip and television program labels are positive developments because they give parents and caregivers information about program content and age-appropriateness that may be useful, as well as provide the means to restrict children's access to such content using the chip. The policy is the only tangible and potentially long-lasting reform to come out of more than 30 years of consistent social scientific support for negative effects of media violence (Kunkel & Wilcox, 2001). In practice and at present, however, the effectiveness of the V-chip and program labels is constrained by many obstacles.

Some criticisms of the V-chip and labels have focused on the potential conflict of interest involved when industry professionals themselves rate their programs, the difficulty parents may encounter in actually programming the chip, and the short amount of time that the labels air that makes them easy to miss. In addition to these concerns, research has identified two major areas in which severe limitations to the effectiveness of the V-chip and labels have surfaced: (1) whether and how accurately and consistently television producers label programs using both age- and content-based ratings and (2) a lack of attention, awareness, and understanding of the system among parents.

To investigate whether television producers were labeling their programs with age- and content-based ratings faithfully and accurately, Greenberg, Eastin, and Mastro (2001) examined a 2-month sample of *TV Guide* listings for the four major broadcast networks and four cable channels at three different times of the day. *TV Guide* and other program listing sources were supposed to have made ratings information available to parents to allow them to plan viewing decisions before programs aired. The *TV Guides* examined in the study were from 1998, 5 months after the content-based ratings had been devised. Greenberg and colleagues found that of the 4,001 programs eligible for ratings, only 2,911 actually carried a rating. (NBC programs were exempt from the analysis because the network had decided not to submit content codes, with no discernible consequences as of this writing.) Thus, 27% had no rating (either age- or content-based) available at all. Of those programs that had a rating, only 25% carried a content-based label. Although the data certainly reveal a high degree of noncompliance, the researchers observe that the over-

whelming lack of content-based information is partly attributable to the presence of TV-G and TV-Y programs in the sample that, by definition, are not supposed to contain objectionable content. Greenberg and colleagues note that the ostensible victory that public interest groups and social scientists gained in the fight to add content information to labels "resulted in content information being part of the ratings for only one in four shows" (p. 35). The study found that TV-G (32%) and TV-PG (24%) were the most common age-based, and D (for dialogue, 38%) and V (for violence, 33%) the most common content-based codes in the *TV Guides*. Yet, when the researchers compared the *TV Guide* listed ratings to the ratings that actually aired with the television programs, they determined that "the overall match in ratings between on-air information and *TV Guide* is abysmally low" (p. 50).

Kunkel and colleagues (Kunkel, Farinola, et al., 2001) compared the labels appended to programs with data from content analyses of the treatment of violence and sex. Using a composite week that consisted of 1,147 programs eligible for ratings that aired from early morning to late at night on 10 channels, they chose only those programs that contained violent acts that would cause serious harm. Coders then assigned points for number of acts of violence, sanitization of harm or pain, and graphicness. In the highest-scoring programs in the sample using this procedure (those deemed "high risk" by the researchers), 65% were not labeled with a V for violence and 27% were labeled as appropriate for audience members 14 and older (TV-14). When only children's programs designated as high risk were assessed, only 28% were labeled TV-Y7/FV (indicating fantasy violence, the strictest label available for children's shows). The same pattern was found with sexual content, with a failure to label "high risk sexual portrayals" with an S 80% of the time. The conclusion of the researchers is unambiguous: "Parents cannot rely on the V-chip ratings, as presently applied, to effectively identify and block the most problematic material that poses a risk of harm to their children" (p. 68).

Finally, there is persuasive evidence that young people and parents alike have difficulty ascertaining the meaning of some of the labels used to identify television programs, and children and adolescents pay little attention to the ratings. In 1997, Greenberg, Rampoldi-Hnilo, and Hofschire (2001) surveyed 462 4th, 8th, and 10th graders in Michigan and found that their attention to the television program ratings was low, especially

among the older respondents. Only 52% of respondents were aware that the ratings labeled programs for sexual content, compared to 70% for language and 72% for violence. Fewer than half of the respondents knew that cartoons were labeled (47%). Just over half (52%) could correctly identify the meaning of the label TV-Y, whereas the other age-based labels were understood by at least two-thirds of the respondents. The majority of the young people reported that they used the ratings either “not much” or “not much at all.” Acknowledgment of the use of the ratings to actually seek out a show with sensitive content was more common among the younger respondents and those with more parental mediation of viewing, demonstrating some evidence of the “forbidden fruit” effect.

Greenberg and Rampoldi-Hnilo (2001) conducted a follow-up study a year later to determine knowledge, attitudes, and use of the newer content-based labels among another sample of 510 4th, 8th, and 10th graders. Attention to and use of the labels continued to be modest, and knowledge of the content-based labels was lower for all age groups than knowledge of the age-based labels. Only 25% of the respondents could identify either D as the label used for “adults talking about topics that should not be heard by children” or FV as the label that “means the TV show has cartoons with violence in them” (p. 126). Over half (56%) could match up the letter L with the labeling of language, and nearly three-fourths (73%) could do the same for S and sex, with these results possibly somewhat inflated as measures of comprehension by the match between the first letters.

In a 1998 survey of 1,358 parents of children ages 2 to 17, Foehr, Rideout, and Miller (2001) found that 18% were unaware of the television ratings system and only 55% reported ever having used it. Comprehension among parents of the meaning of the codes was moderate to low. Only 34% could correctly identify the meaning of TV-Y, 41% TV-Y7 or TV-MA, 55% V, 44% S, 40% L, 7% FV, and 2% D. Comprehension was slightly to significantly higher for the aged-based codes that are similar to the recognizable MPAA ratings (TV-G, TV-PG, TV-14). One year later, a follow-up survey (Kaiser Family Foundation, 1999) found little change, and most data pointed toward reduced rather than increased understanding. Yet, these same two surveys make it clear that parents approve of the idea of ratings (by about a 9:1 ratio) even if only about half use them, and they prefer, as earlier survey research had indicated, content-based to age-based ratings. Therefore, even among the

group that would presumably be most interested in the labeling system—parents of children and teens—awareness, comprehension, and use have been low.

New Delivery Systems

Two new media delivery systems whose rising presence in the lives of young people is difficult to ignore are the Internet and interactive games (either computer- or video game console-based). The best data on the use of both by children and adolescents in the United States is the 1999 Kaiser Foundation survey on which Roberts and Foehr (2004) report. They used two different samples, 2- to 7-year-olds and 8- to 18-year-olds, asking the parents of the younger group to respond but allowing the children and teenagers in the older group to report on their own behavior. To maximize validity and lessen the bias of recall and interpretation of “typical” use that often constrains these measures, time use questions were framed around media use the previous day and were measured by specific blocks or “dayparts.” Both samples were nationally representative: The younger group, reached at home, included 1,090 children, and the older group, reached in school, consisted of 2,014 older children and teenagers.

The patterns drawn by the Roberts and Foehr (2004) data assign a staggeringly large role to media in the lives of children and adolescents in the United States (Table 20.2). The new, interactive forms of media—distinguished by technology in which changes in the child’s physical behavior (clicking a mouse, hitting a button) dictate alterations in the content to which they are exposed—are increasingly available and escalating in use. Yet, time spent with television dominates overall media use by far.

Almost 70% of households with children under the age of 18 owned a computer, and 45% had Internet access at home. It is apparent that Internet access has grown since the Roberts and Foehr (2004) data were collected. The 2000 Census reported that 53% of households with school-age children had Internet access (Newburger, 2001). The National Center for Education Statistics found that in 2001, 65% of children ages 5 to 17 could access computers in the home, whereas 81% accessed them in school (DeBell & Chapman, 2003).

Among all of the young people in the Roberts and Foehr (2004) sample, the amount of time spent with computers varied from an average of 6 minutes per day for 2- to 7-year-olds to 31 minutes for 11- to 14-year-

TABLE 20.2 Media Availability in the Homes of Young People

olds and 26 minutes for 15- to 18-year-olds. Among only those with in-home access to computers, the figures were much higher, with 2- to 7-year-olds spending 23 minutes, 8- to 10-year-olds 50 minutes, 11- to 14-year-olds 58 minutes, and 15- to 18-year-olds 47 minutes per day. Generally, boys in these homes spent more time with the computer than girls (an average of 58 compared to 46 minutes), and the gender gap is particularly marked in the older age groups. Among the younger age groups (those 8 to 10 and 11 to 14) who use computers, the largest allocation of time is spent playing computer games, whereas among the 15- to 18-year-olds, playing computer games and visiting Web sites tied for computer time allotment. E-mail and instant messaging, both forms of engaging with others through computer use, also constitute popular practice and enjoyed a substantial proportion of the computer-dedicated time use of young people (Lenhart, Rainie, & Lewis, 2001; Roberts & Foehr, 2004; Roper Starch Worldwide Inc., 1999).

The Roberts and Foehr (2004) data also point to a significant role for video games in the lives of young people. Indeed, the amount of time devoted to console-based games is similar to that devoted to computers. Just over half (53%) of the 2- to 7-year-olds and over three-quarters (82%) of the 8- to 18-year-olds in the sample had a video game console (e.g., Nintendo, Sega Genesis, Xbox) in the home. Children 2 to 7 years old played for an average of 8 minutes per day (2 minutes more than they used the computer), and 8- to 18-year-olds played for an average of 26 minutes (1 minute more than the computer). The data collected by Roberts and Foehr document that the gender differences that were apparent but hardly extreme in computer use appear in more staggering form in video game use. Boys outnumber girls as

video game users in every age group, but never more so than at ages 11 to 14, when 61% of boys and 24% of girls reported playing. Boys also spent significantly more time with video games than girls did and listed action/combat, sports/competition, and simulation/strategic games as preferences more often than girls (Table 20.3).

Access to television has reached a saturation level, where it is about equal across socioeconomic and racial and ethnic differences. Access to computers and the Internet is not at all equal across these groupings. The Roberts and Foehr (2004) data from 1999 showed that among the 2- to 7-year-olds, 71% of White children had computers in the household compared to 45% of Black or African American and 40% of Latino children. Half of White children had Internet access at home, compared to 19% of both Black/African American and Latino children. The differences in access appeared in the older age group as well, although they were somewhat less pronounced. Home computer access in the DeBell and Chapman (2003) data collected 2 years later was highest for White and Asian families (77% and 76%, respectively), followed by American Indian (54%), and Black/African American and Latino families (each at 41%). Having a computer in the home also increased linearly with household income, from a low access figure of 31% in homes with incomes of less than \$20,000 to a high of 89% for incomes of \$75,000 or more (DeBell & Chapman, 2003). Thus, the diffusion of these newer technologies to young people in the United States is not universal and is contingent on a multitude of factors, whereas television access and use is omnipresent.

Data reported by Livingstone (2002) and gathered through the General Household Survey of 1,287 households in the United Kingdom and by Livingstone and

Note: Figures sharing a superscript within a row do not differ at the $p = .05$ level of significance.

Bovill (1999) collected in a multinational survey of Western Europe and Israel indicate that high levels of media access and use are not confined to the United States but are typical of the developed world. In the United Kingdom, 61% of 15- to 17-year-olds and 72% of 12- to 14-year-olds have the ability to use console-based video games in the home, again varying by gender (56% of girls, 78% of boys). The UK data also found that 44% of all boys and 40% of all girls ages 6 to 16 owned a Gameboy, a handheld video game-playing system. Video games are slightly less pervasive in other European locations, lower than UK estimates by about 15 to 20 percentage points for Germany, Spain, France, Switzerland, and Denmark (Livingstone & Bovill, 1999).

Livingstone (2002) also reports on the diffusion of computers and the Internet to British homes, finding in the 1997 data that 53% of homes with young people had a personal computer, yet only 7% had Internet access. These figures are comparable with some other countries in Europe (e.g., Germany and Spain), whereas other locations have higher Internet diffusion rates (e.g., Sweden at 31% and Finland at 26%; Livingstone & Bovill, 1999). However, Livingstone also cites a more recent British poll (Wigley & Clarke, 2000) that estimated 70% of UK homes with children have a personal computer and 36% have Internet access. These latter, more up-to-date diffusion rates for computers and the Inter-

net are very similar to those in the United States and lead us to suspect that as time progresses, computer-related diffusion rates in most Western countries will be much the same.

The bedrooms of children and teens in the United Kingdom, as in the United States, are often replete with personal media. Livingstone (2002) reports that 66% of the young people in the sample had a television, books, and a radio or stereo, 33% a video game console, and 12% a computer in their own room. The distribution of media in bedrooms of children and teens in the United Kingdom is related to their age (older kids have more access) and gender (boys have more access). Other European countries (with the exception of Denmark, which more closely resembles the United States and the United Kingdom on this measure) have significantly fewer young people with access to media in their bedroom (Livingstone & Bovill, 1999). In France, for instance, 28% of children had a television in their bedroom, 25% a video game console, and 3% a computer with a CD-ROM (Livingstone & Bovill, 1999).

Consequences

One of the central concerns about the consequences of high levels of media use is the potential for displacement of time that might otherwise be spent by young people

with something more physically active, educationally rewarding, or socially constructive (Comstock & Scharrer, 1999). The concern about the sedentary nature of time spent with screen media has reached a new intensity in light of recent links between television viewing hours and obesity in adults (Hu, Li, Colditz, Willett, & Manson, 2003; Jakes et al., 2003) and children (R. E. Anderson, Crespo, Bartlett, Cheskin, & Pratt, 1998; Berkey, Rockett, Gillman, & Colditz, 2003; Crespo et al., 2001; W. Dietz & Gortmaker, 1985; Gortmaker et al., 1996; Lowry, Wechsler, Galuska, Fulton, & Kann, 2002; Proctor et al., 2003). The Rideout et al. (2003) data representing very young children found that heavy television viewers (watching 2 or more hours per day) spent less time playing outdoors than lighter viewers. Rideout and colleagues also report that among the 4- to 6-year-olds in their national sample, heavy television viewers spent significantly less time reading than other children. This is consistent with past research pointing to television's role in the reduction of time spent reading among young children (Comstock & Scharrer, 1999; Heyns, 1976; Medrich et al., 1982). As we have pointed out, displacement of time by television viewing that might be spent on more educationally rewarding activities has consequences for scholastic performance. Video games exacerbate this problem because the games most preferred by young people would be unlikely to fulfill an educational function (Roberts & Foehr, 2004). In contrast, considerable proportions of the time that children and teenagers spend with computers and the Internet pertain to schoolwork and/or information acquisition, in addition to the more pervasive entertainment (via games) and communication (via e-mail, chatting, and instant messaging) functions (Roberts & Foehr, 2004).

Other consequences of media use by young people and adolescents stem from exposure to particular types of content. The new, interactive media do little to allay or replace such concerns. The vast, unregulated dominion that is the Internet has been criticized for allowing young computer users to easily access pornographic material, perhaps even unwittingly (Mitchell, Finkelhor, & Wolak, 2003). Studies of video game content have found that portrayals parallel—and sometimes even exceed—the narrow depictions of gender and sexualized female characters (Beasley & Collins Standley, 2002; T. Dietz, 1998; Scharrer, 2004; Ward Gailey, 1993) and the prevalent role for violence (T. Dietz, 1998; Scharrer, 2004; S. L. Smith, Lachlan, & Tamborini, 2003; Thompson & Haninger, 2001) found in television.

The accounts by Montgomery (2001) and Tarpley (2001) specifically focus on these perils. Montgomery points out that the Internet offers new and potentially lucrative means to market to young children and teenagers. In addition to the home shopping model, which is plain enough in its intent and purpose, the Internet makes possible the construction of Web sites built around characters and activities appealing to young people, with the goal not of selling today but of building favorable brand images for purchases in the distant tomorrow: of autos, watches, clothing, cosmetics. Thus, the Internet opens the way to a degree of manipulation far beyond that achieved by directing advertising to children too young to comprehend its vested self-interest. Tarpley, on the other hand, points to the unregulated and extraordinary breadth of user access as posing both threats and opportunities. Chat rooms offer access to information and exchanges involving sex, violence, and racial and political hatred, as well as information—such as building a bomb in the basement—that cannot be said to denote or connote pleasant or constructive outcomes. At the same time, the Internet offers the opportunity to pursue educational offerings, such as specialized tutoring and unusual subjects, and the possibility of socializing and participating in group endeavors that by its comparative anonymity may give respite to the shy or otherwise somewhat disenfranchised while also offering possibilities, ranging into the lurid, for young users to disguise their age, gender, race, and opinions.

The very nature of interactive media has led to new anxieties about their potential to exacerbate media effects. Video and computer games inspire a high degree of involvement in the action, trigger more intense identification with characters, and feature a reward structure in which new levels or components of the game are offered to those who perform well, among other differences that may make them more “hazardous” than television (Gentile & Anderson, 2003). As Calvert (1999, p. 36) explains:

The child is the aggressor in the new technologies, the player of the video or the virtual game. These games certainly amplify personal involvement, because the child identifies more with the character that wins or loses. The child who plays the game directly experiences success or failure when his or her own behaviors lead to those outcomes.

Although no comparative studies pit television violence influence against video game violence influence, recent research has indicated that concern about the

latter may be warranted. An increasing number of studies (C. A. Anderson & Dill, 2000; Calvert & Tan, 1994; Gentile, Lynch, Linder, & Walsh, 2004; Kirsch, 1998; Silvern & Williamson, 1987) as well as two meta-analyses (C. A. Anderson & Bushman, 2001; Sherry, 2001) have documented a link between playing violent games and aggression.

In general, the contemporary child or teenager in the United States and, for the most part, around the world has a veritable cornucopia of media at his or her disposal each day and turns very frequently to screen media—video games, computers, and television—for entertainment, information, and communication. The pervasive role of media in the lives of young people has sparked parental concerns that stem from the sheer amount of time spent as well as from consternation about the content to which they are exposed, with violence consistently among the most frequently voiced worries. Although the V-chip and television program labels represent a historical moment for media and public policy and allow parents the means to exercise some control over the content to which their children are exposed, considerable hurdles currently exist that severely constrain their effective use. Parental negotiation of the media-saturated world of youngsters remains a difficult task.

CONCLUSION

The social and behavioral science research on the roles of media and popular culture in the lives of children and teenagers has provided information that has increased knowledge, helped to build theory, and has had implications—if not always fulfilled—for policymaking and parenting. Previously, media and popular culture had occasionally drawn the attention of those concerned with the welfare of the young, as exemplified by the 13-volume Payne Fund studies of the movies in the 1930s (Charters, 1933) and the campaign by New York psychiatrist Frederic Wertham (1954) in the 1950s against comic books as a school for violence and crime in such books as *Seduction of the Innocent*. But it was the introduction of television that initiated the modern scrutiny by scientific methods of young people's use of media and popular culture. The two landmarks were the large-scale examinations of the effects of the introduction of the medium, involving thousands of young people and hundreds of parents and teachers, in the United States

by Schramm et al. (1961) and in Great Britain by Himmelweit, Oppenheim, and Vince (1958). Soon, papers, journal articles, and eventually books by those in child development, social psychology, sociology, and communication began to appear. Although any given study can become the subject of debate over the legitimacy of its data collection, the appropriateness of the interpretations by the author(s), and the generalizability of the findings to other populations or other circumstances, we believe the proper response is to seek out patterns from the total accumulation of studies as we have done here. In approaching the literature from this perspective, we agree with the recent conclusion of Roberts and Foehr (2004, p. 6) that the past half-century represents a research “tradition that has demonstrated clearly that media messages can influence children's and adolescents' beliefs, attitudes, and behavior across a wide range of topic areas.”

Our major conclusions, which emphasize television and other screen media because of their very large place in the media budgets of most young persons, begin with the recognition that a wide array of media are used regularly by most young people, many younger children and most of those older have access to these media in the privacy of their bedroom, and substantial amounts of media time are spent alone, without the company of peers or the presence of parents. The amount of time allocated to media among those who are their greatest fans is extraordinary, but even among those who use media comparatively sparsely access and use are substantial. Most of what is offered and most of what is consumed is entertainment, so the experience is enjoyable and rewarding, but content of cultural and educational value is dwarfed by entertainment (this is particularly visible in the television schedule).

We conclude, despite the consistently inverse associations between amount of viewing and scholastic achievement, that only the minority who spend many hours per day viewing are at risk for the displacement of skill acquisition by television and interference with the quality of homework, intellectual tasks, and reading that would diminish scholastic performance. However, we are not so conservative regarding the evidence that television facilitates tastes and preferences that favor plots, topics, and themes similar to those found on television and in comic books, and a contemptuous disdain for books as dull and boring. This cultivation of tastes and preferences, while certainly enhanced by greater viewing (because the evidence in its behalf is correlational),

in our judgment would probably affect a much greater proportion because so many view substantial amounts—enough for these effects to occur—in terms of the kind of dispositions with which we are here concerned.

We conclude that children under the age of 8 are deceived by television advertising because at this early stage of cognitive development they cannot usually understand the self-interested motive of the advertiser (“to sell,” a necessary component, is beyond the grasp of most). This, and the evidence on persuasion and nutrition along with the climate of manipulation, was thought by the FTC to be enough for regulatory action, but political opposition foreclosed this option.

We conclude, based on seven meta-analyses and our interpretation of several significant individual studies, that violent entertainment facilitates aggressive and antisocial behavior and that this effect extends beyond incivility to behavior that is seriously harmful. Experiments document that young persons of all ages engage in greater aggressive behavior after exposure to violent portrayals. Surveys attest that young people who view greater amounts of violent entertainment engage more frequently in aggressive and antisocial behavior, and nowhere do the data indicate that this is attributable wholly to any other variable than the influence of television, including any preference of those who are particularly aggressive for violent entertainment. In our interpretation, the generalizability of the experiments is confirmed by the surveys; the two jointly make a case that is much stronger than either taken alone.

We conclude that the codes labeling programs for adult, sexual, and violent content are helpful to concerned parents, although the codes are not widely understood. We observed that the television industry has incentives to avoid such labels because they draw controversy and reduce what can be charged for advertising time, so there should be no surprise that more than the occasional program that merits a label goes unlabeled or that a label sometimes seems insufficient for the content.

Finally, we conclude that despite technological developments of great importance, at the present time the traditional media, especially television, account for the large majority of media use by children and teenagers. It remains the major medium of the young even among those who use the media the least. Nevertheless, the VCR and DVD, increasingly available in the unsupervised bedrooms of the young, increase the viewing of theater movies, and these movies sometimes will be rated for audiences that are older than those who now

will be able to view them. These two devices, along with interactivity, make available content that often is more involving emotionally and cognitively than most television programming. They also make it possible to focus on a narrow range of content. Technological developments promote private consumption, access, involvement, and exclusivity in regard to content. As a result, the recent surgeon general’s report on youth violence (U. S. Department of Health and Human Services, 2001) speculates that technology will enhance media influence on the young (and perhaps beyond effects on aggressive and antisocial behavior). The most recent data available (Roberts & Foehr, 2004) indicate that young people were not yet using computers very much outside of school, but those who did used them more than twice as much as the per capita figure. This pattern identifies a medium that currently is enthusiast-based compared to the universal appeal of television. We expect per capita use to increase with greater access. Technology, as would be expected, is an area for continuing attention to the changes that it may bring to media use. However, it would be our expectation that screen-based media, such as television, VCR, and DVD use, and theater movies in toto will remain paramount because other electronic media will not supplant them in supplying undemanding but enjoyable and occasionally absorbing entertainment, sports, and news.

SUMMARY 888

REFERENCES 890

Children's health and education can be facilitated by systematic supports that span traditional and innovative health care, health promotion, and disease prevention and that apply scientific principles about how young children learn and develop. Conversely, children's development can be impaired by disease and injury, nonoptimal lifestyle, the presence of multiple risk factors, and the failure to receive high-quality experiences to promote cognitive, social-emotional, and physical well-being.

During the past half-century, a new field has emerged—prevention developmental science (e.g., Bryant, Windle, & West, 1997; Coie et al., 1993)—that systematically integrates theories and methods from the broad fields of public health, psychology, medicine, sociology, and education to improve developmental outcomes for

children at risk for a wide variety of poor outcomes in health and education. Exciting integrative advances in developmental neuroscience have conjoined with prevention science to fuel design and implementation of studies about the fundamental interconnectedness of children's health and education (e.g., C. T. Ramey & Ramey, 2004a; Teti, 2004). Indeed, many of the health disparities and inequities in children's educational attainment are likely the result of this complex interplay between health and education (e.g., Livingston, 2004).

David Satcher, 16th surgeon general of the United States and now director of the National Center for Primary Health Care at Morehouse School of Medicine, has used what is termed a health disparities lens to bring into focus the huge toll taken on the well-being of many individuals from historically marginalized and minority

groups, especially children of color and children with disabilities. Satcher (2004, p. xxxi) summarized:

Although major progress has been made in reducing morbidity and mortality, as well as increasing the life expectancy among vulnerable and at-risk populations, such as African Americans, the ethnic divide continues to widen. As a matter of fact, in some cases it has even gotten worse! Because we are essentially dealing with the inherent complexities of human behavior on the micro or individual level, which are inextricably tied to ongoing factors and conditions at the macro or societal level, the reasons for the lack of more substantial improvements over the ensuing years are complex. . . . To suffice, however, it can be reasoned that increased vulnerability to adverse health among [targeted subgroups] is differentially mediated by various environmental factors and conditions. All of these factors and conditions serve to influence individuals' personal choices concerning health lifestyle choices; availability, accessibility, and acceptability of services; and, ultimately, impact negatively on their physiologic functioning, hence the current health disparities dilemma. At the risk of oversimplifying a complex situation, what is desperately needed at the macro level is health-care reform to guide the nation's policies and research agenda.

We concur that such health care reform is imperative, and argue further that the need for educational reform is equally compelling. Satcher's (2004) observations about vulnerability apply soundly to educational inequities as well as to health.

For more than 3 decades, we and many other developmental scientists have constructed broad conceptual frameworks that build on biological systems theory (e.g., Bertalanffy, 1975; Miller, 1978) and social ecology and Gestalt theory (e.g., Binder, 1972; Bronfenbrenner, 1977, 1979; Lewin, 1936, 1951; Stokols, 1992, 1996) and extended it to delineate social transactions (cf. Lewis, 1984; C. T. Ramey & Ramey, 1998a; Sameroff, 1983) that shape the course of individual development. These conceptual frameworks incorporate fundamental assumptions about the interconnectedness of the individual and the environment, biology and behavior, and the dynamic nature of changes over time. Similarly, developmental science has acknowledged that "dividing the child" into separate functional strands of development—such as perceptual, motor, cognitive, social, emotional, and physical growth—is largely arbitrary, based on historical disciplinary fields in which different aspects of human functioning were studied and treated. Today, the evidence compellingly supports the

strong interdependencies among multiple domains (outcomes) of development; that is, a child's development is more aptly depicted as intertwined, overlapping, and codetermined by influences within and outside the child.

The historical disciplinary isolation in both academia and clinical and educational practices that serve children (e.g., education, pediatrics, psychiatry, social work, psychology, rehabilitation, nutrition, physical education) contributes to the lack of a common language and an acknowledged awkwardness in finding words to capture this more integrated transdisciplinary and biosocial perspective. Many developmental and biological scientists have demonstrated the inadequacy of simplistic nature-versus-nurture formulations of development (e.g., Borkowski, Ramey, & Bristol-Powers, 2002; Moser, Ramey, & Leonard, 1990; Shonkoff & Phillips, 2000); comparably, others have highlighted the flaws of trying to measure independent contributions of the environment to the individual, and vice versa (e.g., Landesman-Dwyer & Butterfield, 1983; Lewis, 1984; S. L. Ramey, 2002). We, too, struggle to overcome the dominance of the older ways of thinking. This is reflected in the fact that we still emphasize that health includes mental health, that cognition also refers to social and emotional cognition, and that social competence is more than behavioral interactions but includes mental representations and problem solving in the social realm. Indisputably, brain and behavior are interdependent, perhaps fundamentally inseparable; but current measurement strategies and analytic frameworks constrain how we formulate the role of children's experiences in their biological and psychosocial behavioral development, and how health impinges on education and vice versa.

In this chapter, we describe the broad conceptual framework with which we have been working, known as applied biosocial contextual development (ABCD), that considers health and education as key outcomes influenced by individual, family, and environmental contexts and processes, incorporating biological and behavioral factors. We then present an example of a multidisciplinary, longitudinal, large-scale, randomized trial that embraced this conceptual framework to inform study conceptualization, design, measurement, and analytic strategy. We selectively highlight both health and educational outcomes from these studies. Next, we identify five principles of effective early childhood interventions, supported by results from a wide array of randomized controlled trials (RCTs) of early childhood health and education interventions. We conclude that there is

great potential to apply theoretical, technological, and practical advances in innovative ways to improve children's well-being, to reduce health disparities, and to ensure educational adequacy for all children (S. L. Ramey & Ramey, 2000). We outline key features of community collaborative and participatory research and recommend that universities, scientific organizations, advocacy groups, philanthropy, government agencies, and professional practices seek new alliances that transcend the historical and political boundaries that contributed to unduly complex, inefficient, and often ineffective systems for the delivery of health and education supports and for vigorous scientific inquiry.

THE CONNECTION BETWEEN HEALTH AND EDUCATION

Higher levels of educational attainment have long been associated with better health status among adults, and poor health among children is widely recognized as an impediment to full participation in formal education (cf. Waldfogel & Danziger, 2001). That both educational attainment and health status are closely linked to socioeconomic status, residential conditions, and the presence of major disabilities also is irrefutable. What has not been explored carefully—particularly via prospective, longitudinal scientific inquiry with ethnically and economically diverse populations—are the ways health and education mutually and dynamically influence the course of a child's life, and how educational and health factors in turn influence subsequent generations.

DEFINING BASIC TERMS: HEALTH, EDUCATION, AND DEVELOPMENT

To help promote a common language for the field of young children's health and education, we provide explicit definitions of basic terms. We endorse the World Health Organization's (World Health Organization, 2005) definition of "health" as "*the state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.*" The WHO definition was once considered revolutionary, with its emphasis on health as multifaceted, its endorsement of the centrality of mental and social well-being, and its position that

health was fundamentally synonymous with complete, optimal human functioning.

We regret that the term "education" is frequently used in a quite narrow way to refer only to the formal system of external supports to instruct children academically, often reducing education to a variable measured as "years of education," or "most advanced degree earned." Alternatively, we advocate a broader definition of education intended to reflect an individual's actual attainment and application of knowledge and skills. The Random House Dictionary of the English Language, second edition, Webster's unabridged (1987, p. 621), defines education as "the active process of imparting or acquiring general knowledge, developing the powers of reasoning and judgment, and generally of preparing oneself or others intellectually for mature life." Education, thus defined, encompasses many life experiences outside of formal schooling and didactic instruction. Undeniably, one of the major childhood tasks is to do well in school and to participate in the formal system of education; yet increasingly, social and life skills are recognized by educators and parents as vital to a child's learning. In this chapter, we use the term education to represent *the child's own acquisition of intellectual competencies, including practical, creative, and logical-deductive thinking.* As such, education is a measurable, multifaceted child outcome, just as health is.

We use the term "development" to capture *an ongoing set of biological, psychological, and social processes that result in measurable change(s) at the individual level that reflect increasing differentiation and hierarchical integration of functions.* Development is often described in everyday terms such as increased competencies, greater maturity, and more refined and adaptable skills, which in turn help a child prepare for a large number of diverse and often unexpected encounters and life challenges. Development progresses in ways that alter both internal functioning and external behavior. Internal functioning includes sensory and motor perceptions, feelings, thinking, remembering, and metacognitive strategies that help a child to govern his or her plans, reasoning, and actions; external behavior spans basic actions to complex performance in everyday situations and in formal evaluations or tests of skill, knowledge, and problem solving. Development can include incremental, steady changes as well as major transformations and the emergence of new classes of behaviors at different times and stages of life. Ultimately, devel-

opment is purposive, such that development contributes to the individual's increased adaptability and effectiveness of thoughts and behavior, including social transactions, which in turn promote the individual's ability to understand the world and successfully contribute in an ethically principled and constructive manner to his or her society and its future.

Collectively, these terms characterize important universal goals for children: that children *develop* in ways that promote their *health* and their *education* and that children's *health* and *education* directly contribute to and are part of their *development*.

APPLIED BIOSOCIAL CONTEXTUAL DEVELOPMENT: A CONCEPTUAL FRAMEWORK FOR UNDERSTANDING, DESIGNING, AND TESTING INTERVENTIONS TO IMPROVE CHILDREN'S HEALTH AND EDUCATION

Figure 21.1 presents the conceptual framework with which we work, named applied biosocial contextual development (C. T. Ramey, MacPhee, & Yeates, 1982; C. T. Ramey & Ramey, 1998a; S. L. Ramey & Ramey, 1992). ABCD incorporates both health and education as explicit outcomes, through pathways that represent multiple levels and sources of influence on a child's development. ABCD is well-suited for designing, implementing, and evaluating early interventions and preventive programs to improve children's health and education outcomes, because ABCD addresses the whole child in the child's natural multiple settings and environments.

In the left column of Figure 21.1, the box labeled Child is centered within the Family, because young children are dependent on the care of others (note: As a convention, we capitalize words that denote major components in the figure). The term Family means those caring for the child, regardless of whether they reside together, and recognizing that roles and legal relationships may fluctuate over time. Family identifies those people who assume the ethical, practical, and legal responsibility for a child. Next, the child and family are surrounded by eight boxes indicating major domains of functioning and influence. The status of the child and family in each domain is hypothesized to be interre-

lated. A holistic picture of a child and family is a central feature of ABCD, such that study of one aspect of development, such as a child's health status or a child's reading achievement, is likely to be advanced through more comprehensive study of what is happening in multiple domains of the child's and the family's life. Though this is cumbersome for research and for those who implement interventions to improve child outcomes, the failure to recognize this reality often becomes a serious obstacle to realizing desired comprehensive outcomes. The eight domains are Survival Resources to meet the child's and family's basic needs; Health and Nutrition; Safety and Security; Appraisal of Self; Motivation and Values related to child and family functioning; Social Support; Communication Skills; and Basic Academic, Social, and Work Skills.

Figure 21.1 shows multiple influences on the eight functional domains, deriving from (a) the Community Context, with its specific Community Resources; and (b) Biology and Prior Experiences. The Community Context can be measured from the closely proximal to more distal relationships in the young child's life, and includes Community Resources, such as Social and Child Care Supports, Supports for Learning, Physical Supports, Health Services, and School Systems. For young children, these community resources often directly influence their health and education status, with resources impinging on family supports for the child (e.g., job training and literacy, parenting programs, substance abuse and mental health treatments for family members) and sometimes directly affecting the child (e.g., exposure to toxic substances, risk while in child care, supports from school readiness programs). Of equal theoretical importance are influences subsumed in the lower box labeled Biology and Prior Experiences. These include Intergenerational Influences, Individual Biology, and the cumulative experiences of a child and the child's family members. We admit that trying to display a dynamic, ever-changing systems theory in a two-dimensional, static, black-and-white format that fits onto one page is a nearly insurmountable challenge, and we judge our pictorial representation to be limited in adequately reflecting the complex pathways and feedback loops that are so eloquently identified by David Satcher (2004; see earlier quote). A video representation illustrating how distinctive, time-distributed inputs and processes would be a more suitable format for capturing the ABCD framework. For now, the words and

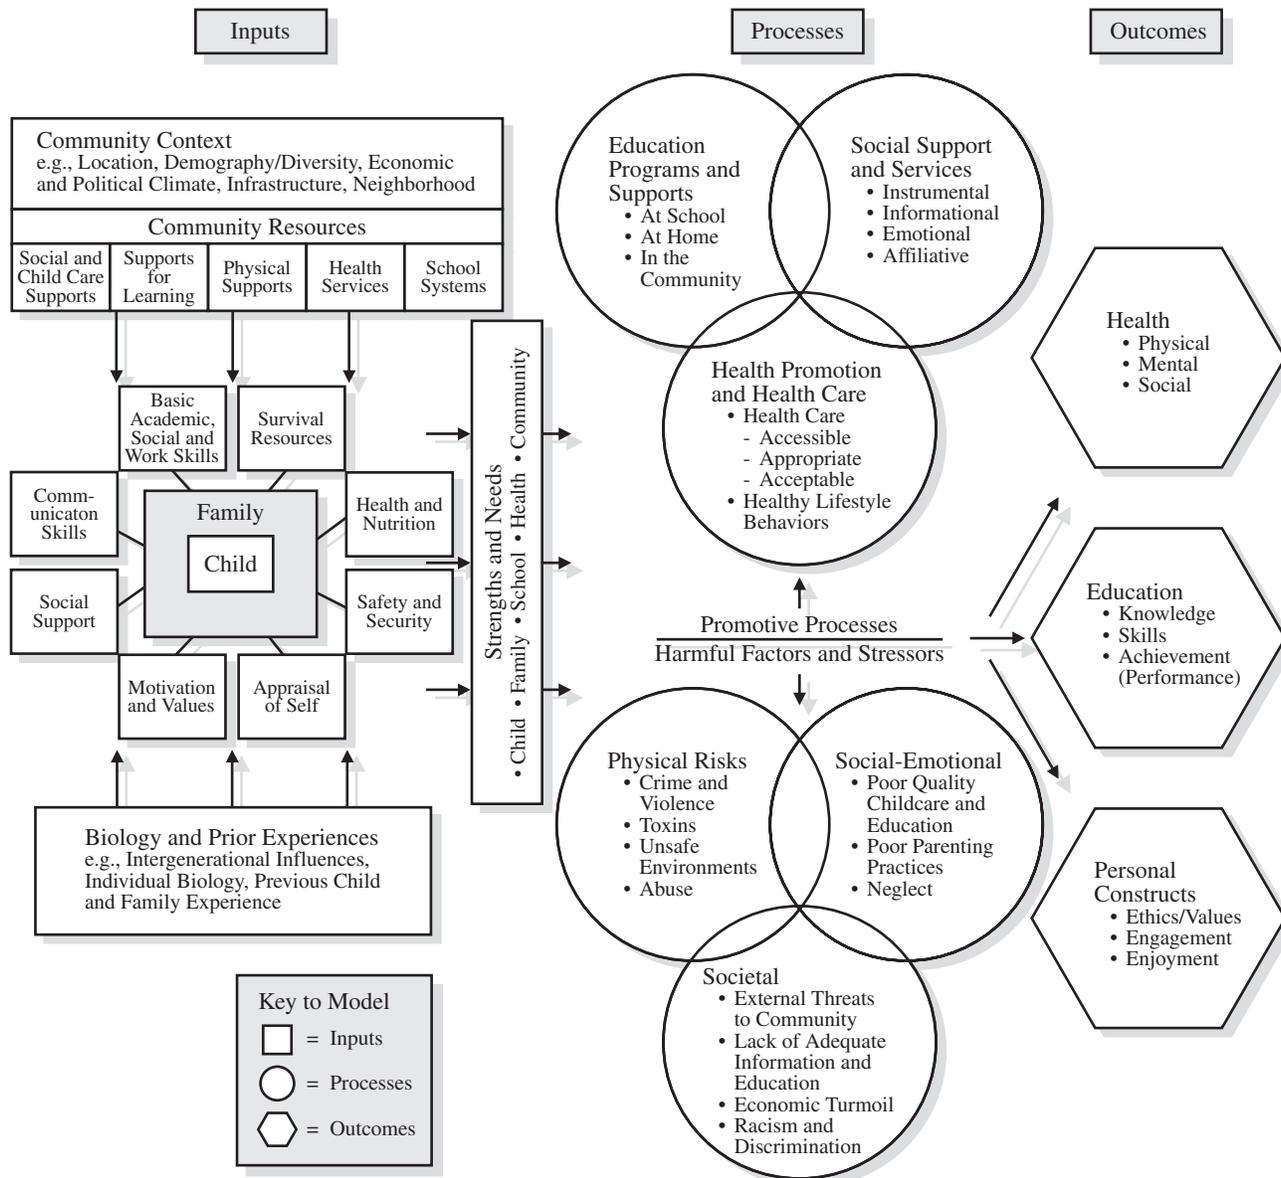

Figure 21.1 Applied biosocial contextual development (ABCD): a conceptual framework for health and education interventions.

the reader's own comprehension of the extensive developmental science findings of the past century will have to suffice.

As a systems theory, a fundamental premise of ABCD is that changes in the child and the family serve to alter both biology and experiences, as well as to possibly alter community context and community resources, particularly when children and families change in ways that affect the availability, the appropriateness, and/or the acceptability of prior community resources.

Together, the child's functioning in all of the major domains serves to undergird what are defined as outcomes, that is, the formal assessment at a specified time or a sequential portrayal of a child's status at multiple time points (i.e., developmental trajectory). We acknowledge that there is considerable ambiguity and circularity in separating an outcome from a child's functioning. In fact, we think these are one and the same, in many cases, because the very processes inextricably linked to a child's development are what become

part of the measurement of an identified outcome. For example, a child's experiences in the realm of language and how a child functions in terms of everyday communication and academic aspects of language and literacy are actually simultaneously developmental processes and developmental outcomes. In the realm of health, for instance, how a child's body handles the metabolism of carbohydrates is part of what defines an outcome related to hyperglycemia (e.g., risk for or presence of diabetes). Typically, the term "outcome" is one of convenience for clinical, administrative, and research purposes, as a check on the child's status at a moment in time. Sometimes, an outcome is represented in terms of a more global and personally meaningful or valued outcome, such as "doing well in school," which is a composite or multifaceted outcome with many indicators rather than a single measure. Rarely are outcomes amenable to measurement in absolute terms, even when the outcome is a biomedical marker. For example, over the past several decades, the clinical definitions used to diagnose diabetes, childhood obesity, and childhood autism have changed considerably (they are relative definitions, not absolutes). Similarly, intellectual and education outcomes rely primarily on nationally normed standardized tests, which means that approximately half of all children will always be classified as "below national average," even if all children realized considerable gains in absolute levels of academic achievement. Accordingly, when selecting outcomes, scientists and practitioners benefit from seeking a consensus about what are positive, valued, and adaptive health and education outcomes for young children. Outcomes can never be value-free, although the measurements can become increasingly well specified, standardized, and scored in ways that allow valid comparisons of changes over time, cohorts, and contexts.

This values and relativistic perspective is part of the reason the name of our conceptual model includes the term "contextual." Applied biosocial contextual development is basically an inductive framework to promote incorporating new findings and greater specificity and directionality to its components, and eventually to inform interventions that are designed to be maximally effective and efficient in yielding desired (valued) child health and education outcomes.

In the realm of outcomes (depicted as octagons on the far right of Figure 21.1), we display the well-recognized areas of Health and Education, as well as a third out-

come to encompass dimensions of a child's life that do not easily fit within health and education. We hearken back to the pioneering work of George Kelly (1955), who advanced the concept of "personal constructs." Kelly's innovative contribution was to bring a phenomenological (personal, experiential) perspective to bear on the major issues in psychology. How an individual understands his or her world, and the personal value assigned to experiences, is an undeniable filter, one that perhaps has been overlooked for too long in the field of developmental science. Similarly, Vygotsky (1978) advanced the theory that consciousness was an end product of socialization, and explicitly identified a cognitive-cultural component that served a central role in creating the child's individual reality. Rarely are these dimensions included in the study of young children's health and education. By explicitly including this personal constructs dimension, ABCD advances the idea that children may respond differently (i.e., in an idiographic way) to the same environments—even environments considered "good" or "bad" for most children—and that the reasons for differential responding transcend variables such as age, gender, ethnicity, skill level, and presence/absence of major health conditions. Also, we provide examples of meaningful dimensions of life such as Ethics/Values, Engagement, Enjoyment, and Perceived Social Support because they capture highly valued aspects of life that are not included in conventional outcome measures of health and education.

The processes hypothesized to influence outcomes (depicted in circles in the center of Figure 21.1) are represented in terms of two major types: Promotive Processes and Harmful Factors and Stressors. Depending on the focus of a study and an intervention, greater or lesser specificity about the particular types of processes is needed. Children's outcomes, in general, are hypothesized to be supported by Educational Programs and Supports at School, Home, and in the Community; by Social Support and Services that provide Instrumental, Informational, Emotional, and Affiliative support (e.g., Reid, Ramey, & Burchinal, 1990); and by Health Promotion and Health Care, including Healthy Lifestyle Behaviors. Even when children receive promotive supports, their development can be threatened by Harmful Factors and Stressors. These represent actual risks the child experiences directly, not merely the community or family context that may increase or decrease the probability that risks will occur. Harm can occur in

many domains, including the child's physical, social and emotional, and personal constructs development. In general, harmful factors and stressors have exerted a strong effect on children's outcomes, although there has been high interest in children who appear resilient, invulnerable, or successful in overcoming these risk factors (e.g., Garmezy, 1983; Grotberg, 2003; Rutter, 2000; Werner, Bierman, & French, 1971).

OVERVIEW OF APPLICATION OF THE MODEL TO EARLY INTERVENTION RESEARCH

The ABCD conceptual framework has been used for several multidisciplinary RCTs of prevention and intervention programs in early childhood. These include the Abecedarian Project and Project CARE (e.g., Campbell, Pungello, Burchinal, & Ramey, 2001; Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002; C. T. Ramey, Bryant, Campbell, Sparling, & Wasik, 1988; C. T. Ramey & Ramey, 1998b; Wasik, Ramey, Bryant, & Sparling, 1990), which sought to prevent intellectual disabilities and to improve school achievement among extremely low resource families; the eight-site RCT called the Infant Health and Development Program (IHDP), which adapted the Abecedarian Project and CARE early intervention program for use in the first 3 years of life with premature, low-birthweight infants (e.g., IHDP, 1990; C. T. Ramey et al., 1992); and the National Head Start-Public School Transition Demonstration Project conducted in 31 sites to test the effectiveness of 4 continuous years of comprehensive health and education supports (cf. S. L. Ramey, Ramey, & Phillips, 1997; S. L. Ramey et al., 2001; the latter study is described in detail later in the chapter). All of these studies were grounded in theory and prior research findings and adopted an explicit and broad integrative, multidisciplinary conceptual framework, derived from ABCD, (a) to inform the design of the intervention or prevention strategy; (b) to select the measurement approach to document inputs, processes, and outcomes; (c) to guide the data analyses that considered multiple and intersecting influences on the major health and education outcomes; and (d) to refine and further specify the nature and magnitude of influences on child developmental trajectories in specified developmental domains.

In writing this chapter, we would like to acknowledge that it has not been "standard science" to endeavor to conduct a rigorous study of both health and education for young children within a single longitudinal study. Although almost all longitudinal research in developmental psychology includes some marker-level variables in health and education, research historically has been more focused, studying, for example, children's mental illnesses (usually a particular form of mental illness), children's cognitive and academic development, children's social skills and behavioral problems, or children's medical illnesses or injuries. These studies have led to a rich scientific literature in these discrete but remarkably unlinked fields. The scientific journals have multiplied and become, in most cases, narrower and more topic-specific, with only a few integrative and transdisciplinary in their focus. This reflects, in large part, the traditional organization of universities into departments and schools, as well as the scientific review process that favors proposals that are more narrowly focused. For an argument in favor of major university reform to support multidisciplinary and transdisciplinary scientific inquiry and practice related to children's health and education, see S. L. Ramey and Ramey (1997b) and C. T. Ramey and Ramey (1997b).

There is strong evidence that the National Institutes of Health (NIH) has embraced the need for new, innovative, and integrative approaches—with corresponding implications for university organization and operations—in the evolving NIH road map (described on the NIH Web site), as well as the reorganized National Science Foundation, the National Academy of Sciences in the U.S. Department of Education (e.g., see the outstanding summary of early childhood research by Shonkoff & Phillips, 2000), and the Institute of Education Sciences, newly created by the U.S. Congress.

We judge the greatest challenges that derive from ABCD to be the discovery of ways to support the preparation of scientists, practitioners, and policy shapers to work collaboratively and to understand this integrative worldview of how children develop. An urgent priority is to align intervention, prevention, and promotion activities in productive and open ways with research, practice, evaluation, and policies to achieve maximal benefit for children, their families, their communities, and society at large (S. L. Ramey & Ramey, 2000). An exceptionally promising line of scientific inquiry directly addresses the dynamic relationship of a child's

education to his or her health and the ways healthier children may be more likely to benefit from opportunities to advance their education. In turn, intergenerational effects of increased health and increased education may convey particular benefits to the next generation, mediated through interdependent biological and social mechanisms.

THE NATIONAL HEAD START-PUBLIC SCHOOL EARLY CHILDHOOD TRANSITION DEMONSTRATION PROJECT: A 31-SITE RANDOMIZED TRIAL TO PROVIDE COMPREHENSIVE HEAD START-LIKE SUPPORTS TO CHILDREN AND FAMILIES FROM KINDERGARTEN THROUGH THIRD GRADE

In this section, we provide an overview of a longitudinal and experimental study that adopted a prevention science approach to the design and measurement of systematic, multipronged health and education interventions to decrease risk and to increase both the educational competence and the health and well-being of young vulnerable children. We selected this study because it represents a well-supported, multiyear effort to transform the field of early childhood inquiry by engaging individuals from multiple disciplines; working closely with practitioners, scientists, and policymakers from the start and throughout the project; establishing internal and external oversight mechanisms to promote scientific rigor and integrity; and creating public use data sets that are amenable to productive secondary data analyses to advance the field. Within the confines and intent of this chapter, we do not strive to provide a compendium of all the findings from this research project. Rather, we selectively describe the project's purposes, delineate the key components of the intervention program and its corresponding data collection strategies, and report some of the findings to date that have implications for practice, policy, and future large-scale studies of health and education.

Study Purpose and History

In 1991, the U.S. Congress passed legislation titled the Head Start Transition Project Act, authorizing funding to test the value of extending comprehensive and contin-

uous Head Start-like service and supports to children for the first 4 years of elementary school. Local sites competed for funding to do the following: (a) develop promising strategies in which Head Start programs, parents, local education agencies (LEA), and other community agencies joined together to plan and implement a coordinated, continuous program of comprehensive services for low-income children and their families beginning in Head Start and continuing through third grade; (b) to develop ways to support the active involvement of parents in their education of their children; and (c) to conduct rigorous research at the local and national levels, using a randomized design to assign children and schools to the transition demonstration condition or the comparison group. The 31 funded sites were dispersed across 30 states and one Indian nation. More than 8,700 former Head Start children were enrolled and nearly 3,000 additional classmates. A distinctive feature of this intervention was that it was provided for the entire classroom, rather than just singling out former Head Start children.

Application of the Conceptual Framework to the Design and Evaluation of the Intervention

Figure 21.2 shows how ABCD was used to help frame the conceptualization of the interventions and to represent, in a general way, how the health and education components of the intervention were hypothesized to improve child health and education outcomes. As shown on the lower left side of the figure, the Planning Stage (a 1-year period) for the Transition Demonstration Program involved local adaptation of a national Program Model that mandated certain components to achieve the "comprehensive Head Start-like" feature of the program. The model established a Governing Board (with at least 51% of membership from parents of children to be served); local decision making regarding Program Implementation (the logistics of who would be hired, how local partnerships would be formed and operate, and specific plans to change Community Resources designed to improve outcomes); and Program Costs (an essential area for ensuring that intervention programs can be adequately implemented and replicated across sites).

The Planning Stage also involved creating and nurturing a National Consortium of the 31 sites, with each site having a three-way partnership of Head Start, the public schools, and an evaluation team typically at a university or research firm. At the national level, the consortium

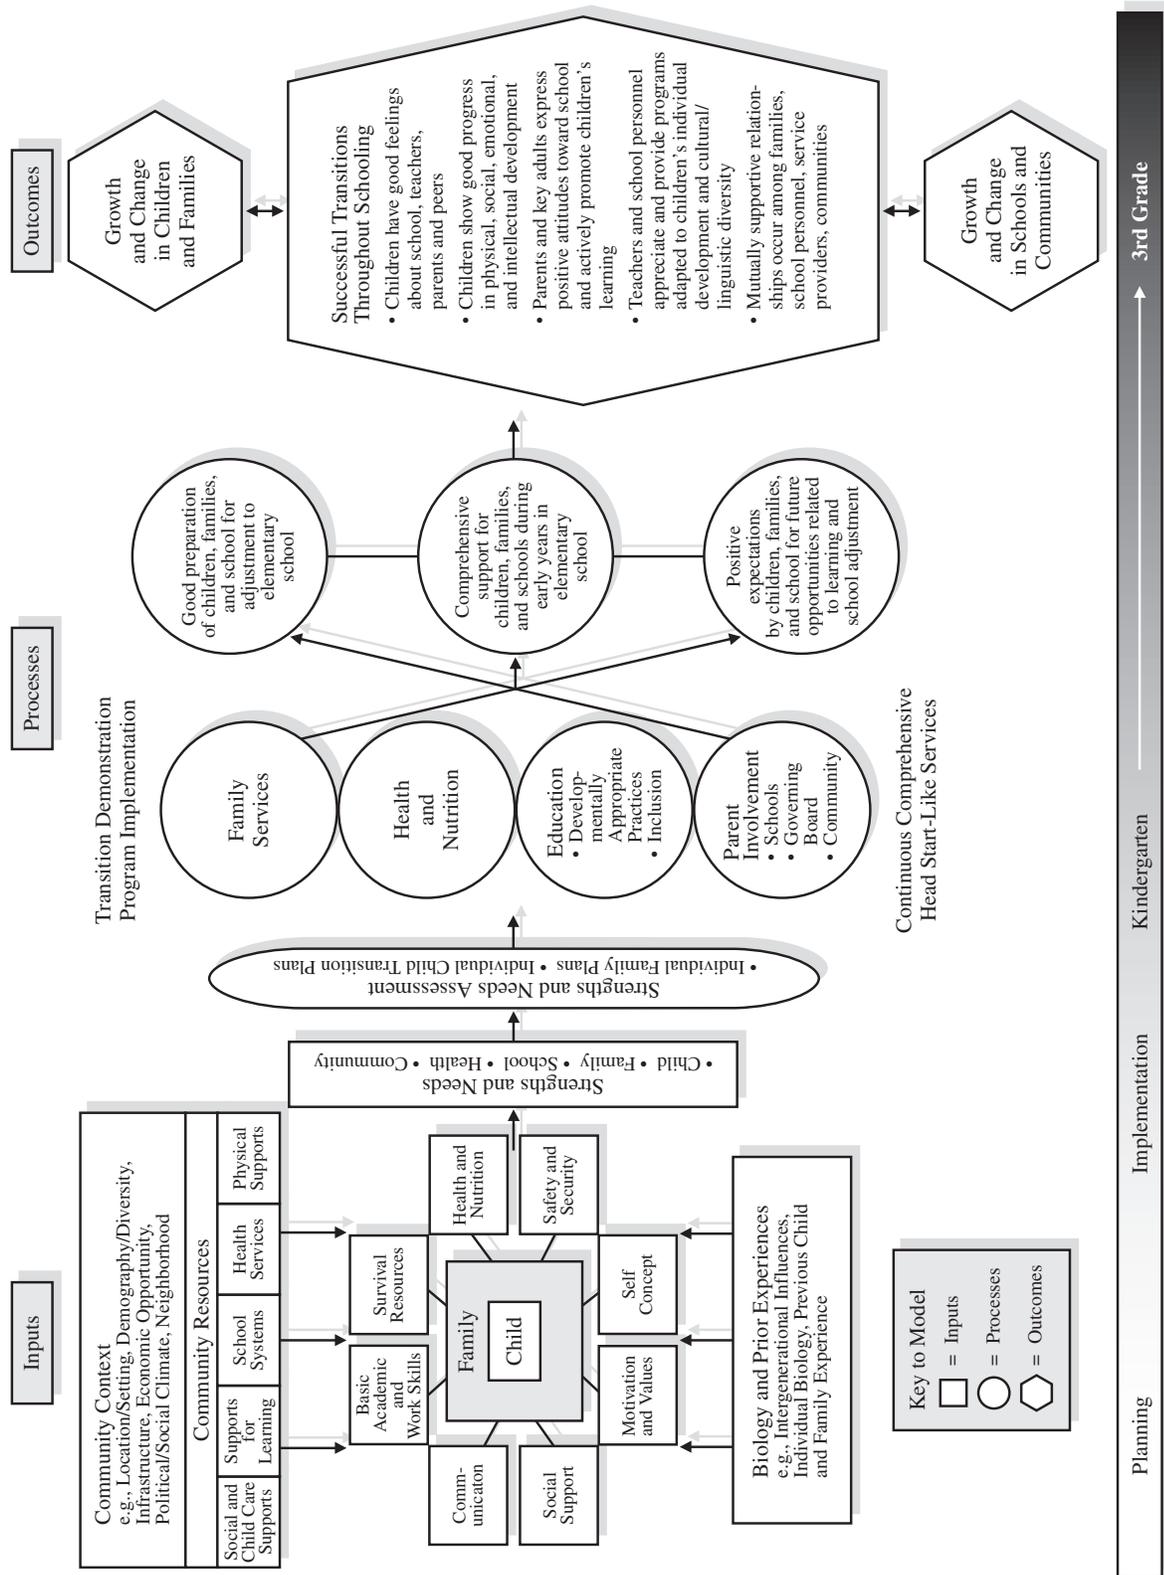

Figure 21.2 The conceptual framework used for the National Transition Demonstration Program. *Source:* From “Evaluating Educational Programs: Strategies to Understand and Enhance Educational Effectiveness” (pp. 274–292), by S. L. Ramey and C. T. Ramey, in *Continuing Issues in Early Childhood Education*, 2nd ed., C. Seefeldt and A. Galper (Eds.), 1997b, Englewood Cliffs, NJ: Prentice-Hall. Reprinted with permission.

addressed the eight functional domains (represented by eight boxes surrounding the child and family), endorsing their importance for the intervention and the research, and further specifying how these domains would be assessed at the beginning of the study (baseline) and throughout the course of the study (4 years).

As Figure 21.2 displays in the Implementation Phase (identified along the x-axis at the bottom of the figure), each site was to conduct an individualized Strengths and Needs Assessment for all participating children and families. This assessment was referred to as an Individualized Transition Plan that addressed the strengths and needs of the child and the family. This assessment was designed to maximize early identification of any special supports and services for a successful transition to school. As shown to the right of the oval on assessment, the major components of the Transition Demonstration Program are identified in four major areas: Family Services, Health and Nutrition, Education, and Parent Involvement. Collectively, these four areas constitute the comprehensive Head Start-like services. The time period for implementation was from the planning for kindergarten entry (ideally, in the year children were served by traditional Head Start) through each of the next 4 years in public school, with systematic efforts to ensure continuity of planning and supports from grade to grade.

For evaluation, the ABCD conceptualization was used to identify what would be measured, starting with descriptions of each local site in terms of the Community Context and Community Supports; comprehensive assessment of the child and family's health and education, including multiple measures designed to tap the constructs in each of the eight functional domains; and ongoing and annual documentation of program implementation, combining program participation data from the local site with external multidisciplinary site visits during which additional data were collected and the local site program documentation was verified. In Figure 21.2, the Transition Demonstration Program services are shown to contribute to three general areas (processes). That is, the intervention program was hypothesized to change children's health and education outcomes through three primary pathways. The first was creating "good preparation of children, families, and schools for the child's adjustment to elementary school." The Individualized Transition Plan and the process of creating local partnerships around the topic of positive school transitions were central features altering the

community- and family-specific context for school readiness. The second pathway was "comprehensive support for children, families, and schools during the early years in elementary school." This was hypothesized to result from the many in-school supports and community-based activities for children and parents, increased professional development activities for educators, and multiple parent involvement programs to facilitate children's academic progress. Third, "positive expectations by children, families, and schools for future opportunities related to learning and school adjustment" was included as a specific pathway. Measures of this were obtained by in-depth open-ended and structured interviews with families, teachers, principals, and children themselves.

This project recognized that in many communities, the poor performance of children in the past set the stage for low expectations and concomitant dismal predictions of outcomes for children from low-income families. An explicit component of the intervention was to change these expectations for academic and life success, that is, to create an expectation that the historical health disparities and educational inequities could be significantly reduced or eliminated. Collectively, the processes of increasing preparation for school success, providing supports for health and education during the early elementary school years, and increasing expectations for positive outcomes among a large stakeholder group surrounding the child are the general pathways—each of which was measured by multiple indicators throughout the study—conceptualized as producing positive outcomes.

Finally, Figure 21.2 indicates the outcomes (the octagons in the far right column) specified for the Transition Demonstration Project. These agreed-upon outcomes, building on an earlier shared vision and local community partnerships and input to the national evaluation, transcend the typical academic indicators of test scores only, and reflect the fact that outcomes for a large, intensive intervention or community reform effort should correspond to ways that the stakeholders actually think about children and their well-being. Specifically, we note that some subjective measures are identified as legitimate outcomes, such as "Children have good feelings about school, teachers, parents, and peers" (what most people call "liking school" and "positive school attitudes"), as well as their parents and teachers having positive attitudes and being actively engaged in their children's learning. Although outcomes such as

having “mutually supportive relationships among families, school personnel, service providers, and communities” can be challenging for researchers to measure, these are important valid outcomes to target. Of course, children’s health and educational status are also measured, but these did not constitute the sole indicators of effectiveness for this National Transition Demonstration Program.

By using the ABCD conceptual framework, the progress of the project and the extent to which goals were realized could be studied in a prospective way, assessing year-by-year changes at the level of the child, the family, the school, the health and social service delivery system, and the community as a whole. More important, the steps from Planning through Implementation could be tracked, so that if intended outcomes did not occur, the supportive processes could be carefully reviewed to consider likely explanations for differential benefits across and within the 31 sites.

Measurement of Inputs, Processes, and Outcomes

The ABCD framework facilitated the identification of constructs to be measured. Table 21.1 presents an overview of the measures selected and links these to the ABCD model. (For further details and references about methodology, see S. L. Ramey et al., 2001.) Note: this data set is now in the public domain, with supportive data dictionaries and summary variables available.

Selected Findings from the National Transition Demonstration Study about Children’s Health and Education

In this chapter, we chose findings about three topics often overlooked in conventional studies of children’s health and education: children’s perceptions about their school experiences, the developmental trajectory of academically gifted former Head Start children, and the ways families protect children from injuries.

Children’s Feelings about School

Children’s feelings about school, as revealed during a Vygotskian-style dialogue, permitted children as young as 5 years of age to tell the child assessors how they felt about things happening in school. The areas rated by children included how well they got along with their teacher and peers; how important they and their parents (separate queries) thought it was to do well in

school; how much they liked school; how well they thought they were doing in academic areas; and how good their teacher was at teaching them new things. The dialogue “What I Think of School” (Reid et al., 1990) has good psychometric properties and is sensitive to individual differences. For example, S. L. Ramey, Lanzi, Phillips, and Ramey (1998) reported that by the spring of kindergarten, about 7% of former Head Start children were having multiple negative perceptions of school. Especially impressive was the finding that children’s negative early perceptions were highly predictive of subsequent academic progress in reading and math, as measured by standardized assessments and teacher ratings, and that children’s feelings about school contributed significant information above and beyond the measures of their kindergarten-level language, reading, math, and social skills. Children’s impressions of school fit within the outcome labeled Personal Constructs in the ABCD conceptual model (Figure 21.1). We interpreted this finding to support the recommendation that children’s experiences warrant inclusion in almost all investigations of children’s school adjustment and their mental and physical well-being. Also, this finding exemplifies a practically useful result well suited for sharing with educators and program staff. That is, in a collaborative style of program research and evaluation, information such as this can help inform subsequent changes in the intervention—perhaps to encourage the programs, teachers, and parents to consider children’s feelings as important early warning signs that are likely to precede awareness by the adults that things are not going well.

High-Achieving Low-Income Children

Another interesting set of findings from this multisite, multidisciplinary longitudinal study concerns identifying a subgroup of children with exceptionally positive development. Analysis sought to understand the supportive and protective factors in their lives (Robinson, Lanzi, Weinberg, Ramey, & Ramey, 2002; Robinson, Weinberg, Redden, Ramey, & Ramey, 1998). All too often, studies grounded in a commitment to eliminate the health and educational disparities concentrate disproportionately on the negative outcomes, or the reduction in negative outcomes. In the process, the presence of highly accomplished children and families is overlooked, and negative stereotypes are reinforced. Analyses such as these are important for both practical and theoretical reasons. In the Transition Demonstration Project, for example, the children who scored in the upper 3% of this former Head

Start sample on individually administered standardized tests of vocabulary, reading, and math came from all ethnic groups and many sites; these children also were highly accomplished by national norms, not just project norms. In addition to their academic achievements, these children were thriving socially and emotionally as well, according to both teacher and parent ratings (although, interestingly, parents did not rate their children as more cooperative). The social ecological factors contributing to the positive outcomes for these children included some predictable, and some unexpected, factors. For instance, parents reported significantly fewer stressors in their lives, but they did not report significantly more family strengths. Residential stability, somewhat higher father involvement, fewer single-parent households, and higher rates of parent high school graduation were predictably associated with higher-achieving children. Unexpectedly, however, rates of maternal depression did not differ for the highest-achieving versus remaining children (25% versus 23%), and parental Nurturance and Consistency (factor scores from the Parenting Dimensions Inventory; Slater & Power, 1987) were comparable for these groups. What was important were the dimensions of parent Responsiveness and Nonrestrictiveness, such that children whose parents endorsed less restrictive parenting practices and were more responsive to individual child needs had children with higher academic achievement. Further, teachers rated parents of the highest-achieving former Head Start students as more strongly encouraging of their children to succeed in school, despite the fact that the

parents did not so describe themselves. Parents of the highest-achieving children did not report discussing school with their children, being in touch with the teacher, or participating in planned parent activities at school more than other parents, but they did report volunteering more often at their child's school.

Findings such as these bring into focus the importance of differentiating subgroups or clusters of children and families within a larger at-risk population. Indeed, in this study, we identified and verified six major family types, based on the strengths and needs assessments, living in poverty (e.g., C. T. Ramey, Ramey, & Lanzi, 1998). This type of differentiation permits study of the likelihood of differential courses of development and the importance of different processes to support children having more or less positive outcomes.

Unintentional Child Injuries

Schwebel, Brezausk, Ramey, and Ramey (2004) explored children's unintentional injury risk, the leading cause of deaths among children 1 to 18 years (National Safety Council, 2001). At the time we conducted these analyses, available data supported the view that children's impulsive, hyperactive behavior patterns served to increase risk of injury and that poor parenting might also independently increase injury risk in the same samples. Remarkably, no analyses had considered whether active, positive parenting (supportive processes) could reduce injury among children at risk because of difficult behavior patterns. Using a logistic regression approach

that considered child, parenting, and contextual factors and their possible interactions, this data set affirmed that children's hyperactivity was a strong predictor of injuries (odds ratio = 28.4). The ABCD conceptualization, however, contributed to the important additional finding that parents' report of the adequacy of their temporal resources—that is, time available to parents for desired activities, including time to be with their children—was a significant protective factor for this increased-risk group of children. Thus, the family environment and parental behavior emerged as key promotive processes. (For further findings about the National Transition Demonstration Project, see S. L. Ramey, Ramey, & Lanzi, 2004.)

Collectively, these findings provide a window on ways to study developmental pathways to alternative health and education outcomes and to consider how aspects of the child's context, initial status of the child and family, and supportive as well as harmful processes can alter the course of development and children's outcomes.

PRINCIPLES OF EFFECTIVE INTERVENTION SUPPORTED BY LONGITUDINAL RESEARCH ON CHILDREN'S HEALTH AND EDUCATION

For many decades, the single most pressing question in early childhood education was simply "Do early education and health interventions work?" There was robust skepticism that early educational interventions could alter the cumulative negative toll that poverty and other risk circumstances take on the development of young children. But by the mid-1980s, a professional consensus was reached (cf. Guralnick & Bennett, 1987) that early educational interventions can—under certain conditions—produce meaningful benefits, as reflected in the academic achievement and social progress of young children. Just as important, when early interventions fail to produce intended benefits, the likely reasons are important to understand for practice and theory. Given the cross-study consistencies in findings, we summarize findings about early educational interventions in terms of five major scientific principles (C. T. Ramey & Ramey, 1998a; S. L. Ramey & Ramey, 1992). We postulate that these principles are likely to hold true for health interventions, although there is scant scientific support from randomized controlled trials designed to improve the physical health of at-risk children or to pre-

vent prevalent childhood disorders such as asthma, obesity, depression, and chronic dental disease. We have endeavored to incorporate health examples, however, as much as possible, including several dramatic public health interventions that have altered the Community Context and Community Supports directly. These five major principles are (1) the dosage principle, (2) the timing principle, (3) the direct receipt of services principle, (4) the differential benefits principle, and (5) the continuity of supports principle.

The Principle of Dosage

Programs that provide higher amounts of intervention (i.e., full dosage) produce greater benefits in health and education outcomes. This principle of dosage or intervention intensity has considerable scientific support, derived from cross-study comparisons of magnitude of benefits from multipronged and educational interventions that varied in their dosage, as well as some experimental studies that directly tested different dosage levels within the same study, and from post hoc analyses that analyzed rates of participation using sophisticated analytical techniques. Dosage is indexed in different ways, for different types of interventions; we caution that for medical interventions, the intensity principle refers to administering the full dosage, recognizing that overdosage could be dangerous.

For educational interventions in the first 8 years of life, dosage can be indexed by variables such as number of hours per day, days per week, and weeks per year that children receive the educational intervention. An ideal measure—which has never been calculated, to our knowledge, in educational interventions—would be the actual amount of instructional and learning time children have when they attend, multiplied by the child's attendance. Theoretically, the reason that more intensive programs produce significantly larger positive effects than do less intensive programs is straightforward: Children are engaged in more learning, which in turn supports their continued growth and development in the domains in which the learning occurs. For health, the greater the amount of time spent in health promotion activities and the greater the compliance with recommended health care treatments (representing a complex interplay of availability, accessibility, and acceptability of appropriate services), the healthier the child should be.

Many early interventions do not significantly improve children's intellectual or academic performance

(see S. L. Ramey & Ramey, 2000, for discussion of some reasons why these likely fail). A key characteristic of many of these unsuccessful interventions is that they were not very intensive. For instance, none of the 16 randomized trials of early interventions for young children with disabilities or delays evaluated by the Utah State Early Intervention Research Institute (White, 1991) provided full-day 5-day/week programs, and none of these programs produced any measurable benefits for children in terms of their competencies. Similarly, Scarr and McCartney (1988) provided intervention only once per week to economically impoverished families in Bermuda in an effort to replicate the findings of Levenstein's (1970) Verbal Interaction Project. They also failed to detect any positive cognitive effects.

In marked contrast, two RCTs conducted in North Carolina using the same educational curriculum, the Abecedarian Project and Project CARE, produced multiple significant benefits to participants in this high-dosage educational intervention. The Abecedarian Project and Project CARE both provided educational supports to children within a full-day, 5 days a week, 50 weeks per year program for 5 consecutive years, using a structured and individualized curriculum delivered in a high-quality, university-based child development center that was continuously monitored and supported for quality of curriculum implementation (C. T. Ramey & Ramey, 2004a, 2004b, 2004c). To our knowledge, these two programs are among the most intensive (high dosage) that have been subjected to rigorous experimental study, and the principle of dosage may account for a large portion of the increased magnitude of benefit detected at ages 8, 12, 15, and 21 years. We particularly note the benefits for language and literacy, as demonstrated in significant gains at every age on every language measure and all reading assessments (C. T. Ramey et al., 2000; C. T. Ramey & Ramey, 2004c). Other educationally important outcomes include markedly lower rates of placement in special education, reduced from 48% in the comparison group to 12% in the educational intervention group (close to the national average of 11%), and reduced rates of grade repetition, from 56% in the control group to 30% in the educational group.

The Milwaukee Project was an RCT that produced large, immediate benefits in intelligence and language (Garber, 1988) and provided a high-dosage, daily early educational intervention from birth through the transition to school, with a university child development program offered daily (see review by S. L. Ramey & Ramey,

2000). However, long-term benefits were not sustained to the same degree as in the North Carolina projects, perhaps because of the influence of the principle of continuity of supports and the differences in the enrollment criteria across these projects (i.e., the North Carolina projects enrolled on a combination of family risk variables; the Milwaukee Project enrolled only children born to mothers with mental retardation).

Two studies provide experimental evidence that program intensity matters: An early intervention home visit program (Grantham-McGregor, Powell, & Fletcher, 1989) that systematically tested different levels of intensity discovered significant cognitive benefits at a dosage level of three visits per week, whereas fewer visits per week did not produce any significant gains, and the Brookline Early Education Project (Hauser-Cram, Pierson, Walker, & Tivnan, 1991) reported that only the most intensive services were sufficient to benefit children from less well-educated families, whereas the lowest and intermediate intensities had no measurable consequences.

The eight-site Infant Health and Development Program RCT systematically investigated program intensity effects at the level of the individual child's participation. Originally, C. T. Ramey et al. (1992) reported that the intensity of educational intervention each child and family received related significantly to cognitive outcomes at age 3. Dosage was a sum of three program components: total days the child attended the child development center between 12 and 36 months; number of home visits from birth to age 3; and number of monthly educational meetings the parents attended. This "participation index" demonstrated a strong, linear relationship to the child's intellectual and behavioral development at 36 months, even after controlling for variables that might have influenced individual rates of participation (such as maternal education, maternal verbal competence, family income, child health status, and ethnicity). When considering the efficacy of this 3-year, multipronged educational intervention to prevent mental retardation (IQ less than 70 points) at age 3, the results showed that children in the highest participation group had nearly a nine-fold reduction in the percentage of low-birthweight children who were mentally retarded (under 2%), compared with control children who received only high-quality pediatric follow-up services (about 18%). Later, Blair, Ramey, and Hardin (1995) demonstrated that year-by-year participation rates produced significant and independent effects on the course

of the child's measured cognitive competence at 12, 24, and 36 months of age.

Hill, Brooks-Gunn, and Waldfogel (2003) extended these intensity analyses to answer the question "Do longer-term effects, at ages 5 and 8, relate to participation rates?" When the children were 3, 5, and 8 years of age, multiple assessments of language and cognition were completed, with the 8-year battery including the full Wechsler Intelligence Scale for Children (WISC; Verbal, Performance, and Full-Scale IQ scores), the Woodcock-Johnson Reading and Math assessments, and the Peabody Picture Vocabulary Test-Revised (PPVT-R). On 12 major outcome measures across 3 age periods, all measures showed higher performance for children in two higher-participation groups (attending more than 350 days and attending more than 400 days in the child development center) relative to the randomly assigned follow-up group, which received pediatric and social services, but not the educational component of this multipronged early intervention. The first set of analyses confirmed that children who participated at higher rates differed significantly from the comparison group, with site-specific differences in which variables (e.g., maternal ethnicity, maternal education, maternal use of drugs, and prenatal care) correlated with amounts of participation. Accordingly, this team applied a sophisticated set of data-analytic techniques that are well-known in medical RCTs, involving an adaptation of a propensity score matching procedure coupled with logistic regression to reduce the influence of the natural selection bias when evaluating treatment effects. The results yielded compelling support for the dosage principle, demonstrating differences between matched high-dosage and control children, and between higher- and lower-dosage children within the treatment group. The magnitude of these differences is impressive at all 3 ages analyzed, and extends to the reading and math scores at age 8, with sustained benefits of the early educational intervention corresponding to gains of 6.1 to 11.1 points higher (depending on the definition used for high dosage) on the Woodcock-Johnson, as well as sustained (although slightly reduced) benefits at ages 5 and 8 for PPVT (4.1 to 6.6 points at age 8) and WISC IQ scores (6.5 to 8.4 points at age 8).

The Principle of Timing

Generally, when interventions begin earlier and continue longer, they produce larger and longer-lasting benefits to the participants than do those that begin

much later and do not last as long. The age when children enter early educational interventions ranges from birth through 8 years of age. Typically, children from economically disadvantaged families become eligible for early educational interventions (e.g., Head Start, public school pre-K for at-risk children) in their home communities beginning at 4 years of age, and sometimes at 3 years of age. Many of the well-cited early educational interventions, however, began when children were young infants, such as the Abecedarian Project (C. T. Ramey, Bryant, Campbell, Sparling, & Wasik, 1988; C. T. Ramey, Yeates, & Short, 1984), the Brookline Early Education Project (Hauser-Kram et al., 1991), the Milwaukee Project (Garber, 1988), Project CARE (Wasik et al., 1990), and the Infant Health and Development Program (1990). Two noteworthy exceptions, however, are the Perry Preschool Project, conducted in Ypsilanti, Michigan (Schweinhart & Weikart, 1983), and the Early Training Project (Gray, Ramsey, & Klaus, 1982), which began when children were 3 years of age. An important difference in these two interventions that began later in life and did produce significant benefits is that the children were documented to be significantly delayed in their cognitive development at age 3, whereas the other studies that enrolled children earlier sought to prevent intellectual decline linked to early and continued impoverished language and learning environments.

The principle of timing has always been one of high interest and is associated with vigorous debate. Concerning neurobiology and education outcomes, the stunning technology advances to document brain growth and development, coupled with research on early brain development (primarily experimental animal research) and how experiences shape brain activities lend support, in a general way, to the principle that earlier and more sustained educational interventions are especially promising to maximize benefits to children. Even the carefully controlled animal experiments on early experience, which support the general principle of timing, do not refute the possibility that educational interventions begun at later ages can produce measurable gains (S. L. Ramey & Sackett, 2000). One of the most consistently cited areas that lend support to the principle of timing comes from the observational research of Kuhl, Tsao, and Liuh (2003) concerning acquisition of speech and language perception, demonstrating that an infant's exposure (naturally) to his or her first language results in the loss of a generalized discrimination ability that existed at earlier ages. This reflects development (see

earlier definition) in which there is increasing selective differentiation and hierarchical integration, that is hypothesized to facilitate (and to reflect) more efficient, higher-order functioning. When young infants are not exposed to certain sensory-perceptual experiences very early in life, they seem to lose their initial capacity (such as the universal ability of young babies to recognize phonemes in all languages, later narrowing to recognize primarily phonemes in their native language).

Just as we cautioned earlier regarding possible negative effects of overdosage, we recognize that certain types of interventions may be infeasible, ineffective, or even iatrogenic (producing unintended negative consequences) if provided too early. There are some historical examples of this, often given in textbooks, such as a study that trained babies to walk earlier than usual by practicing the walking reflex daily, and efforts to teach complex motor skills to nursery school children. Both studies found short-term changes, but these seeming benefits were washed out when the age-typical display of these motor skills occurred for the control (untreated) children.

The Abecedarian Project involved a two-phase educational intervention, with 50% of the children who received 5 consecutive years of early educational intervention and 50% in the control group (receiving nutritional, pediatric, and social services only) who were randomly selected to participate in an elementary school Home-School Resource Program for 3 consecutive years. This partially tested the issue of timing, offering extra educational supports during the school year (provided by individualized assistance to children and their families with schoolwork and school-family communication) and a summer educational camp that sought to increase children's learning opportunities from kindergarten through entry into third grade. The results demonstrate two clear sets of findings. First, the elementary school support program (i.e., the later onset of intervention) did yield measurable benefits to participants, as indexed by higher scores on standardized assessments of reading and math achievement at age 8. However, there were not comparable gains on general tests of intelligence or language, compared to children who received the preschool early education intervention. Second, the magnitude of benefits, even for the reading and math achievement scores, was smaller than for children who received the earlier-onset education intervention (see C. T. Ramey et al., 2000). This study is not germane, however, in helping to resolve the vital

question about differential timing benefits during the preschool years. Further, this study tested a reasonably well-designed and replicable public school enhancement program, but did not seek to directly control the overall classroom curriculum and instruction and thus is not a simple and pure test of timing effects alone.

In summary, the principle of timing has modest support from human studies, but further research is needed for conclusive evidence about its importance for different aspects of language, literacy, and other academic competencies. For health interventions, examples among deaf children such as timing of cochlear implants and age of teaching infants sign language confirm the greater malleability or recoverability of the brain when such corrective procedures are implemented. In general, early detection and treatment are so widely accepted as positive in health care that they rarely are studied systematically. There are no compelling data, at this time, to support the notion of an absolute critical period, such that educational intervention or health supports provided after a certain age cannot be beneficial at all; rather, this is a principle of *relative* timing effects.

The Principle of Direct Receipt of Services

This principle affirms that early educational and health interventions that directly alter children's daily health and education produce larger positive and longer-lasting results than do those interventions that rely primarily on indirect or pass-through routes to change competencies.

Early education and health interventions have been presented in many different forms, including those that are based in child development centers with trained teaching and health staff, those that are home-based and seek to change parents' health behavior and provide environmental enrichments (books, learning games, educational videos), and those that combine center- and home-based components. These different types of early educational and health interventions may be divided into two major categories: those that rely primarily on direct provision of academic and health instruction to children and those that seek indirect means of enhancing child learning, such as seeking to change the parents' behavior and, through that mechanism, to alter the child's health and education.

The empirical findings regarding the differential effects of these two quite different strategies are clear: The indirect interventions that seek to change intermediary factors are not as powerful in changing children's

language, reading, intellectual, or health performance (Lewis, 1984; Madden, Levenstein, & Levenstein, 1976; C. T. Ramey, Ramey, Gaines, & Blair, 1995; Scarr & McCartney, 1988; Wasik et al., 1990). This generalization holds true for economically disadvantaged children, seriously biologically disadvantaged children, and high-risk children with both environmental and individual risk conditions.

C. T. Ramey, Bryant, Sparling, and Wasik (1985) conducted the first systematic and experimental study with direct provision of instruction versus intermediary forms of early educational intervention. In an RCT, high-risk children were randomly assigned just after birth to receive one of three interventions: (1) the daily, highly intense child development center program, identical to that provided to children in the Abecedarian Project, coupled with the home visiting program; (2) a home visiting (intermediary) program that lasted for 5 years, used the same educational curriculum as the center-based intervention, and sought to have parents deliver the intervention; and (3) a comparison group that received enhanced nutritional, pediatric, and social services only (both intervention groups also received these health and social support services). An important achievement in this study, the longest-lasting home visiting program we know of, is that participants in all three groups remained highly engaged in the program and the assessments. The home visiting was planned to be weekly during the first 2 years of life and then every other week for the next 3 years. Further, the home visitors received ongoing supervision and continuing support throughout the 5 years and used a structured but adaptable curriculum, and both the home visitors and the families reported that they perceived the home visiting program to very positive. Despite the enthusiasm for the effort to change parents, who in turn could transmit increased learning opportunities to their children, the outcome data demonstrated no measurable gains for the children in the home visiting program compared to the control children, and both of these groups fared significantly worse than the group that received the daily, year-round center-based educational curriculum plus home visiting. Post hoc analyses indicated that magnitude of benefits associated with the children who received direct language and academic instruction (in the center) plus the 5 years of home visiting was almost identical to that reported for the Abecedarian Project participants, who did not receive the same intensive home visiting educational component. On a promising

note, from another home visiting program, Powell and Grantham-McGregor (1989) indicated that three home visits per week—but not less—produced significant child improvement through the intermediary or indirect intervention approach.

Just recently, Olds et al. (2004) reported positive but modest education and health benefits from a nurse home visiting program detected 2 years after the program ended but not during the program. These results were particularly noteworthy in the areas of receptive language and intelligence. These high-risk children were also more likely to have been enrolled in formal out-of-home care, so it is not clear whether a direct or indirect route of influences or a combination best accounts for the results.

There clearly is popular appeal to the idea that increasing the skills and knowledge of young children's first teachers—their parents—will be beneficial, because parents are children's natural support system and, typically, care deeply about their children's well-being. Also, most programs hope that changing parents and improving the home environment will have spillover effects to the next children born into these families and will help to increase the local community's competence in providing the right types of education and health experiences, at the right times, for many other young children. Increasingly, many of these parent-focused educational and health interventions consider that some parents themselves lacked good educational and health opportunities when they were growing up, and some parents lacked positive parenting models in their own lives. Accordingly, the curricula used for the parenting and home visiting programs often address the parent's own developmental needs and crucial aspects of culture and local community, along with "how to parent" issues.

What are the likely reasons that center-based programs with more traditional types of language enrichment, health care, and teacher-provided instruction relating to academic skills yield positive results in terms of academic achievement and cognition, whereas the indirect or intermediary programs do not? We hypothesize that at least four factors may be contributing to this pattern of results. One is that most home visiting programs are not equal in intensity or dosage to the center-based programs. Another is that the natural language and academic skills of some parents in at-risk families may not be equal to those of teachers or caregivers in the center-based programs, even when parents are encouraged to provide more language and academic learning

experiences to their preschool children. Thus, the children in the two groups would not receive similar levels of exposure to a rich language environment on an everyday basis (cf. Hart & Risley, 1995; Huttenlocher, 1990). A third reason is that parents who respond positively to the home visiting still may not spend enough time with their children for the children to have the full benefit of their parents' increased skills. For many parents, their children may be in the care of others for extended periods during the day or night, and these other caregivers may not be meeting the needs of these at-risk children (National Institute of Child Health and Human Development [NICHD] Consortium for the Study of Early Child Care, 2005). Fourth and finally, the rate at which participating parents acquire and then implement their enhanced parenting and instructional skills may not be rapid enough to achieve the intended benefits for their children. This harkens back to the principles of both dosage and timing. We note that home visiting programs may serve other valuable purposes, such as preventing child neglect and abuse and increasing children's health and safety, as demonstrated in research projects such as those by Olds and colleagues (2004).

For reasons we do not fully understand, the early childhood community has become polarized around issues that concern direct or explicit teaching of certain skills to young children. It appears common knowledge that babies are born without knowing any specific words or ideas, and that skills related to reading, writing, and math require direct exposure; that is, their advancement cannot occur without some introduction, scaffolding, modeling or demonstration, and practice and feedback. We believe that some practitioners in early childhood programs mistakenly tried to enact kindergarten- or first-grade-level instruction for much younger children, and adopted ineffective methods of repetitive drill, restricted young children's spontaneous play and exploration, and tried to force very young children to attend and behave in ways that were counterproductive. Accordingly, the anti-instruction movement could be viewed as a backlash to such inappropriate applications of early educational interventions. An alternative explanation is that some of the competent caregivers for young children, particularly low-income and minority children, in the United States have low levels of formal education and lack formal teaching credentials. There may be a fear that all of these individuals will be excluded from the future of child care and early education and judged to be incompetent simply because they can-

not articulate precisely how they instruct children and help to prepare them for school. Although there are many published studies documenting a general relationship between an adult's level of education, language skills, and intelligence and the adult's skills in promoting children's cognitive and language development (cf. NICHD Consortium for the Study of Early Child Care, 2005), there are many notable exceptions to the generalization. From our own professional experience, we have observed highly competent teachers of young children who come from all types of educational backgrounds and all types of linguistic and cultural backgrounds. Advanced degrees in early childhood education are not a guarantee of high-quality instruction occurring on a responsive and regular basis; neither does the lack of a college degree prohibit an adult from providing high-quality language and academic learning opportunities.

Currently, the Institute of Educational Sciences is coordinating an effort to evaluate RCTs that test the benefits of different published preschool curricula, mostly for 4-year-olds. This effort is designed to yield much needed information about "what works" in pre-K settings. There are, however, already recognized limits that have surfaced in this new research endeavor, such as differences across sites regarding the dosage of the intervention (hours per day, weeks per year), the degree of risk in the children participating, the quality of and control over curriculum implementation, and the levels of participation from the children and families. What is admirable about this research initiative is that both educational science and curriculum development are being advanced, and the practical importance of this type of scientific inquiry has become paramount by creating a national network of projects concerned with children's language and literacy outcomes. Content analysis of existing early educational interventions that have already produced large and lasting benefits through RCTs would be a worthwhile endeavor, as well as efforts to measure the actual classroom instruction at levels that correspond to the particular types of learning and language experiences hypothesized to be the most essential for young children's learning (e.g., C. T. Ramey & Ramey, 1999; S. L. Ramey & Ramey, 1998).

The Principle of Differential Benefits

This principle asserts that some children show greater benefits from participation in early educational and health interventions than do other children. These indi-

vidual differences appear to relate to aspects of the children's initial risk condition and the degree to which the program meets the child's needs or services to prevent the harmful consequences of those risk conditions over time (e.g., by providing sufficient amounts of direct positive learning experiences that otherwise would not have been present).

A fundamental assumption in the fields of education and social ecology is that of person \times environment (read as "person by environment") or person \times treatment effects. This assumption is that different individuals respond differently to the same program, and correspondingly, different programs may be needed to produce the same outcome for different participants. These ideas have long prevailed in the clinical and educational literature, but only recently have they been explored systematically in the early intervention field.

In providing broad-based early intervention for premature, low-birthweight infants, the Infant Health and Development Program (1990) reported that children at greater presumed biological risk, as indexed by their lower birthweight (less than 2,000 gm), at age 3 years did not initially benefit as much from the program as did children at lesser presumed risk (with birthweight between 2,000 and 2,499 gm), even though both groups showed significant gains. In a longer-term follow-up of these children at 5 and 8 years of age, Hill et al. (2003) reported large and significant risk \times intervention effects, such that the heavier low-birthweight children showed IQ point benefits of about 14 points, and lighter babies had effects of about 8 points, compared to their appropriate-birthweight matched controls who did not receive the educational component of the intervention.

Another study focused on early educational intervention for children with disabilities and considered two influences simultaneously: the degree of the child's impairment and the form of educational intervention provided. Cole, Dale, Mills, and Jenkins (1991) found an aptitude \times treatment effect in a randomized design comparing Feuerstein's "mediated learning" techniques and more traditional direct instruction. Contrary to conventional wisdom, students who performed relatively better (as measured on the pretest battery of cognitive, language, and motor tests) gained more from direct instruction, whereas students who performed worse showed greater benefits from the mediated learning treatment.

From the Abecedarian Project, Martin, Ramey, and Ramey (1990) discovered that the children who showed the greatest relative gains (i.e., compared to controls)

were those whose mothers were the most intellectually limited (i.e., maternal IQ scores below 70; in fact, all experimental children whose mother was mentally retarded performed at least 20 points higher and averaged 32 points higher than did their own mother; Landesman & Ramey, 1989). These dramatic findings are comparable to the large benefits reported in the Milwaukee Project, which enrolled only economically disadvantaged mothers with IQs below 75 (Garber, 1988).

Some of the programs that have failed to detect any significant overall benefits may have enrolled a highly heterogeneous group of children, some of whom were at very low or no risk for poor educational outcomes. This could serve to lessen the power to detect real intervention effects if, in fact, only the high-risk children showed benefits. As an example, analyses conducted on children participating in the Infant Health and Development Program showed significantly different levels of benefit based on the educational level of the children's mother. As Figure 21.3 shows, the degree of benefits, as indexed by children's IQ scores on the Stanford-Binet at age 3, displayed a highly orderly relationship to mother's education. The gains were the greatest (comparing treated and control children) for those children whose mother had less than a high school education, followed by those whose mother earned a high school

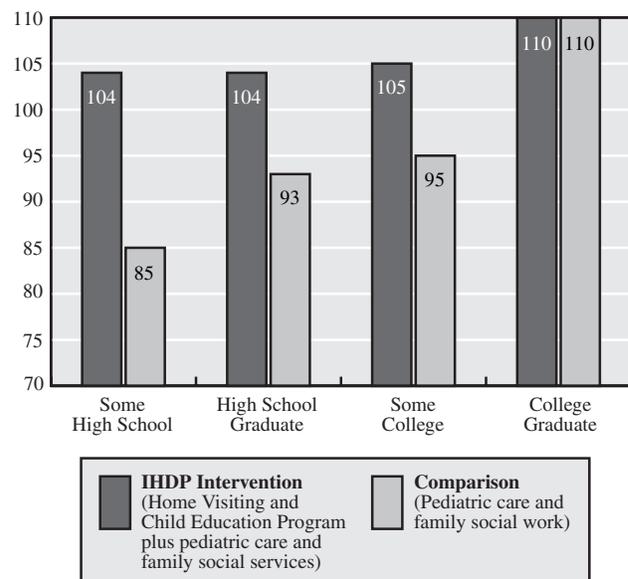

Figure 21.3 Differential effects of the Infant Health and Development Program on age 3 IQ outcomes (Stanford-Binet) as a function of maternal educational status.

degree or GED, and then those whose mother had some college education. Interestingly, there were neither any benefits nor any harm related to participating in this educational intervention for children whose mother had earned a 4-year college degree or higher (see S. L. Ramey & Ramey, 2000). These findings of differential benefits are consistent with an interpretation that these educational interventions supplement children's experiences at home in ways that are essential for the development of average (or above-average) intelligence; accordingly, for children whose cognitive and linguistic development is strongly supported by their family and other natural environments, additional educational interventions are not needed to prevent subaverage performance. We also note that in this study, the control children, like those in all of the RCTs we have reviewed, were never prevented from participating in other programs, and many of the college-educated parents in the Infant Health and Development Program sought, on their own, additional help and information to support the early development of their premature and low-birthweight infants.

The Principle of Continuity of Supports

This principle states that over time, the initial positive effects of early interventions will diminish if there are inadequate later supports to maintain children's positive outcomes. This has been demonstrated mostly in the educational realm, but logically is just as important for children's health. The reason postintervention programs continue to matter is that children continue to learn at high rates, with educational and health progress that depends not only on a child's entry-level skills or health status but his or her continued acquisition of the cognitive, language, and academic skills—complemented by appropriate physical, social, and emotional skills—to have a positive transition to school (S. L. Ramey, Ramey, & Lanzi, 2004).

For many early intervention programs for at-risk children, long-lasting and substantial effects on school achievement, grade retention, and special education placement have been repeated. In some, but not all, studies (e.g., Garber, 1988), the long-term effects of early educational intervention on IQ scores lessen over time. Two important issues are relevant. First, it is not sufficient for disadvantaged children merely to maintain the advantages from effective early educational interventions. Rather, children must continue to develop at normative rates in multiple domains if they are to succeed

in school settings. Second, no currently influential developmental theory is premised on the assumption that positive early learning experiences are sufficient *by themselves* to ensure that children will perform well throughout their lives. A poor school environment, suboptimal health, a seriously disrupted home environment, and many other conditions influence the behavior of children at all ages. Thus, longitudinal inquiry about the long-term effects of early intervention must take into consideration children's subsequent environments and experiences (i.e., after early intervention ceases).

As described earlier, only one RCT early intervention study, the Abecedarian Project, has extended early intervention into the elementary school years to evaluate the importance of additional systematic supports during the transition to school. As Figure 21.4 shows, at 8 years of age, children who had received continuous educational intervention for the first 8 years performed the best of any group in reading and mathematics, followed next by those who received early intervention for 5 years, followed by those who received the elementary school treatment only (Horacek, Ramey, Campbell, Hoffman, & Fletcher, 1987). Longitudinal analysis of IQ scores revealed effects only for the early intervention groups; that is, the supplemental program from kindergarten through age 8 did not result in higher IQ scores (C. T. Ramey & Campbell, 1994). Later, at age 12, children who had received the early intervention continued to show benefits in terms of both academic achievement and IQ scores and a reduction of nearly 50% in the rate of repetition of at least one grade in the elementary school years. Overall, however, the group of children who performed best across all measures were those who had *both* the preschool and school-age educational interventions.

Currie and Thomas (1995) have conducted important analyses of the long-term educational progress of former Head Start children and demonstrated that those who go to average or above-average schools continue to keep up with their age or grade peers, whereas those in the very lowest performing schools show a decline (relative to their school entry level). Tragically, 50 years after *Brown v. Board of Education*, it remains true that African American low-income children disproportionately attend very poor quality schools, at rates far higher than for other ethnic groups even when family income is below the poverty line.

Recently, Barnett (2004) has written an excellent and integrative review that confronts the "myth of fade-out." Although it is true that IQ scores per se show dimin-

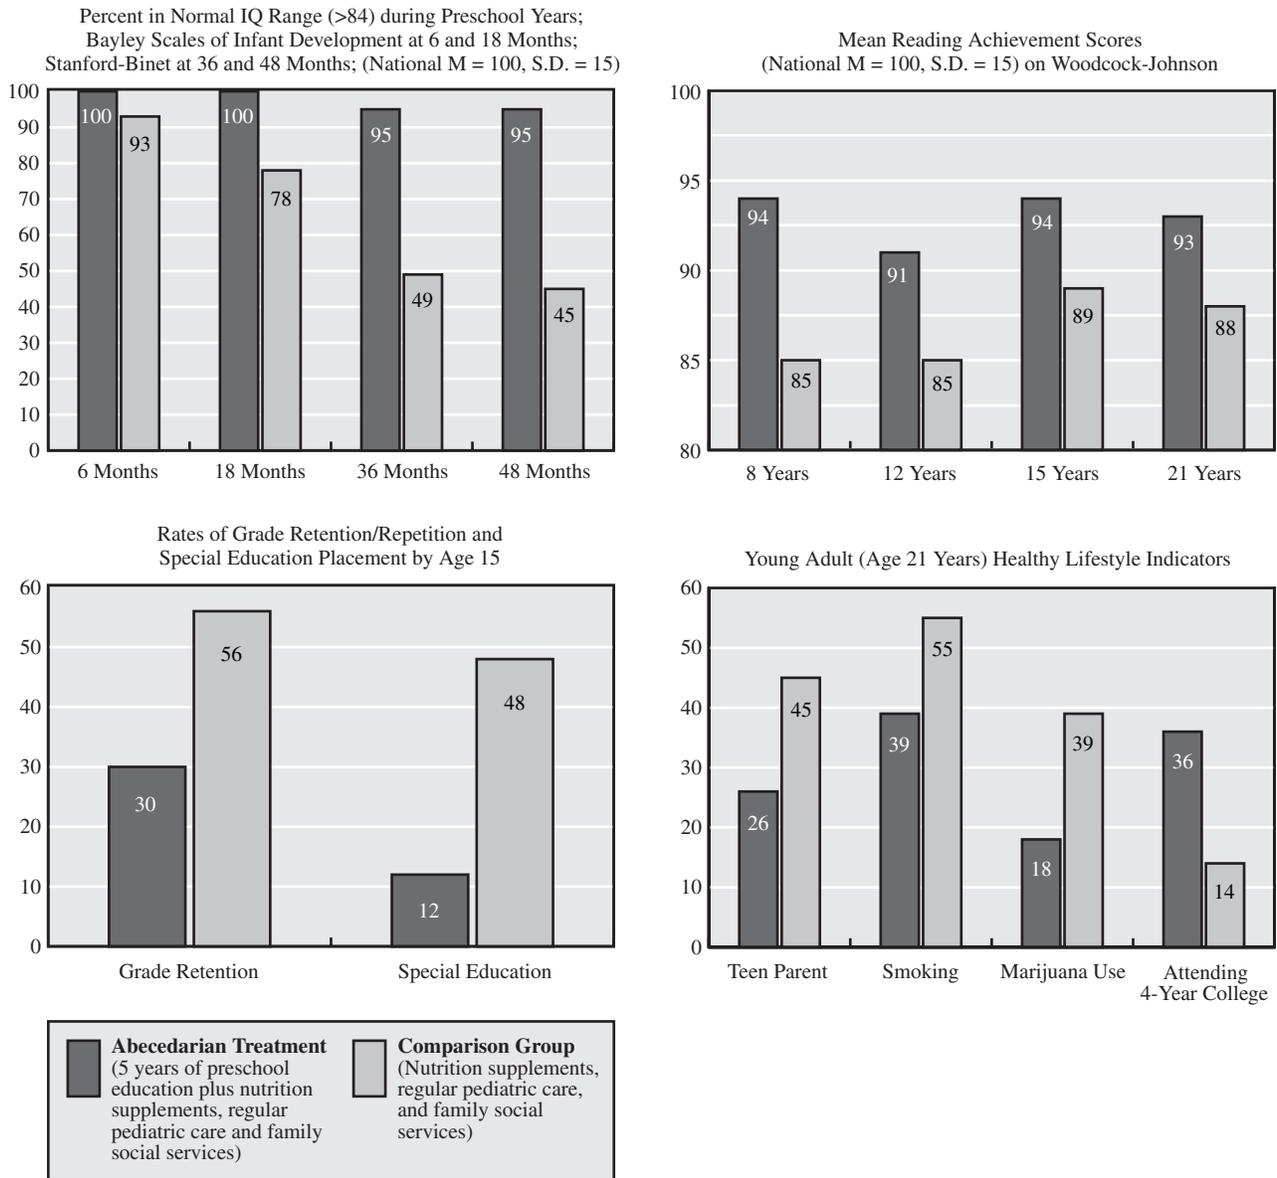

Figure 21.4 The Abecedarian Project: selected health and education outcomes from infancy through young adulthood.

ished group difference over time, achievements in reading, language, math, and overall school adjustment as indexed by grade retention and special education placement show long-lasting benefits. When these sustained effects do not appear, one of the contributing factors—in addition to the principles already detailed in this chapter—may well be the quality and intensity of the educational programs that follow the early educational intervention. The opportunity to conduct more rigorous post hoc analyses about the schools that children attended across the well-conducted RCTs that have longitudinal data would be valuable, as well as more de-

scription about the natural variation in the alignment and educational supports for children transitioning from early educational interventions into public school programs (Kagan, 1994).

KEY FEATURES OF COLLABORATIVE AND COMMUNITY PARTICIPATORY RESEARCH

Traditionally, scientific inquiry about child development has been guided primarily by scientists with interests in advancing scientific theory and practical understanding

of what influences the course of human development. Some research has been fueled by advocacy concerns, such as increased research into Autism, mental retardation, AIDS, and learning and reading disabilities. Rarely, however, is research conducted in a way that adequately includes the perspectives of those whose lives are the primary topic of the research. Further, clinicians, educators, and community members often have extensive in-depth knowledge of topics germane to longitudinal research on children and families, yet these individuals seldom participate as full partners in the design and conduct of longitudinal research. Increasingly, scientists recognize the tremendous potential value of conducting research in a way that actively engages and respects a much broader range of expertise, from multiple disciplines, practices, and community experiences. The challenge is how to efficiently and effectively create new types of partnerships in which multiple groups of "experts" can be combined to yield a more complete understanding of important influences on children's health and education.

We have established and used guidelines for conducting collaborative research to evaluate the effects of interventions in education and health settings (S. L. Ramey & Ramey, 1997b). Figure 21.5 summarizes critical activities in planning and conducting responsive, useful research on education and health interventions. Briefly, these include early engagement of key individuals and groups as participants to create a shared vision and framework to guide decision making and the identification of key questions and plans for gathering and analyzing data. Vital to the success of collaborative and community participatory research is the generation of timely interim reports that provide practical information about the progress of program implementation and early evidence about program impact and children's development. Active maintenance of these partnerships is equally important to ensure continuity in the conduct of longitudinal intervention research and to understand other changes occurring over time in the community and families' lives that may affect measured health and education outcomes. These research partnerships facilitate accurate identification of changes in the community and family context that may independently and interactively affect child health and education. These partnerships not only serve to foster scientific integrity in terms of the appropriate measurement of relevant multiple influences, but also set the stage for informed interpretation, dissemination, and application of the results of such re-

search. In addition, the partnerships themselves can serve as an ongoing means of timely exchange of relevant information, including opportunities for scientists to provide practitioners and families with valuable findings from previous research that could be practically applied in the community (see Figure 21.5).

We would be remiss if we did not state there are serious challenges associated with conducting such complex, ambitious, and action-oriented research. These include the importance of identifying the appropriate individuals who will be engaged in the partnership, recognizing that the members in the partnership will change over time (for many reasons), finding ways the partnership can offer tangible benefits and appropriate recognition to all participants throughout the partnership, anticipating and proposing how to resolve likely problems and disagreements, and creating stronger supports within most universities for this type of research. Ideally, clearly written agreements (e.g., memoranda of understanding) signed by key participants and community and university leaders, widespread public media about the partnership, and ongoing documented meetings to exchange information in ways that are open and honest serve as important mechanisms for maintaining project integrity, acceptability, and productivity.

As an example, when we created a long-term research partnership between a geographic community and a major research university, we developed and endorsed a set of guiding operating principles (for more details, see C. T. Ramey & Ramey, 1997a, 1997b). These were (a) a pledge that there will be joint university and community development of all programs; (b) a commitment to research that benefits both the community and the university; (c) a commitment to programs that make a difference in people's everyday lives; (d) a pledge from partners to maintain the partnership for an extended period (e.g., a decade); (e) a belief that over time both the community and the university will become better places as a direct result of the quality of partnership; and (f) a commitment to conducting the partnership in a way that could serve as a model for others (e.g., to expand the benefits and to facilitate productive university-community partnerships).

Universities and Public Policy

Universities have been the largest incubator for model research programs to enhance young children's education and to test health interventions. Unfortunately,

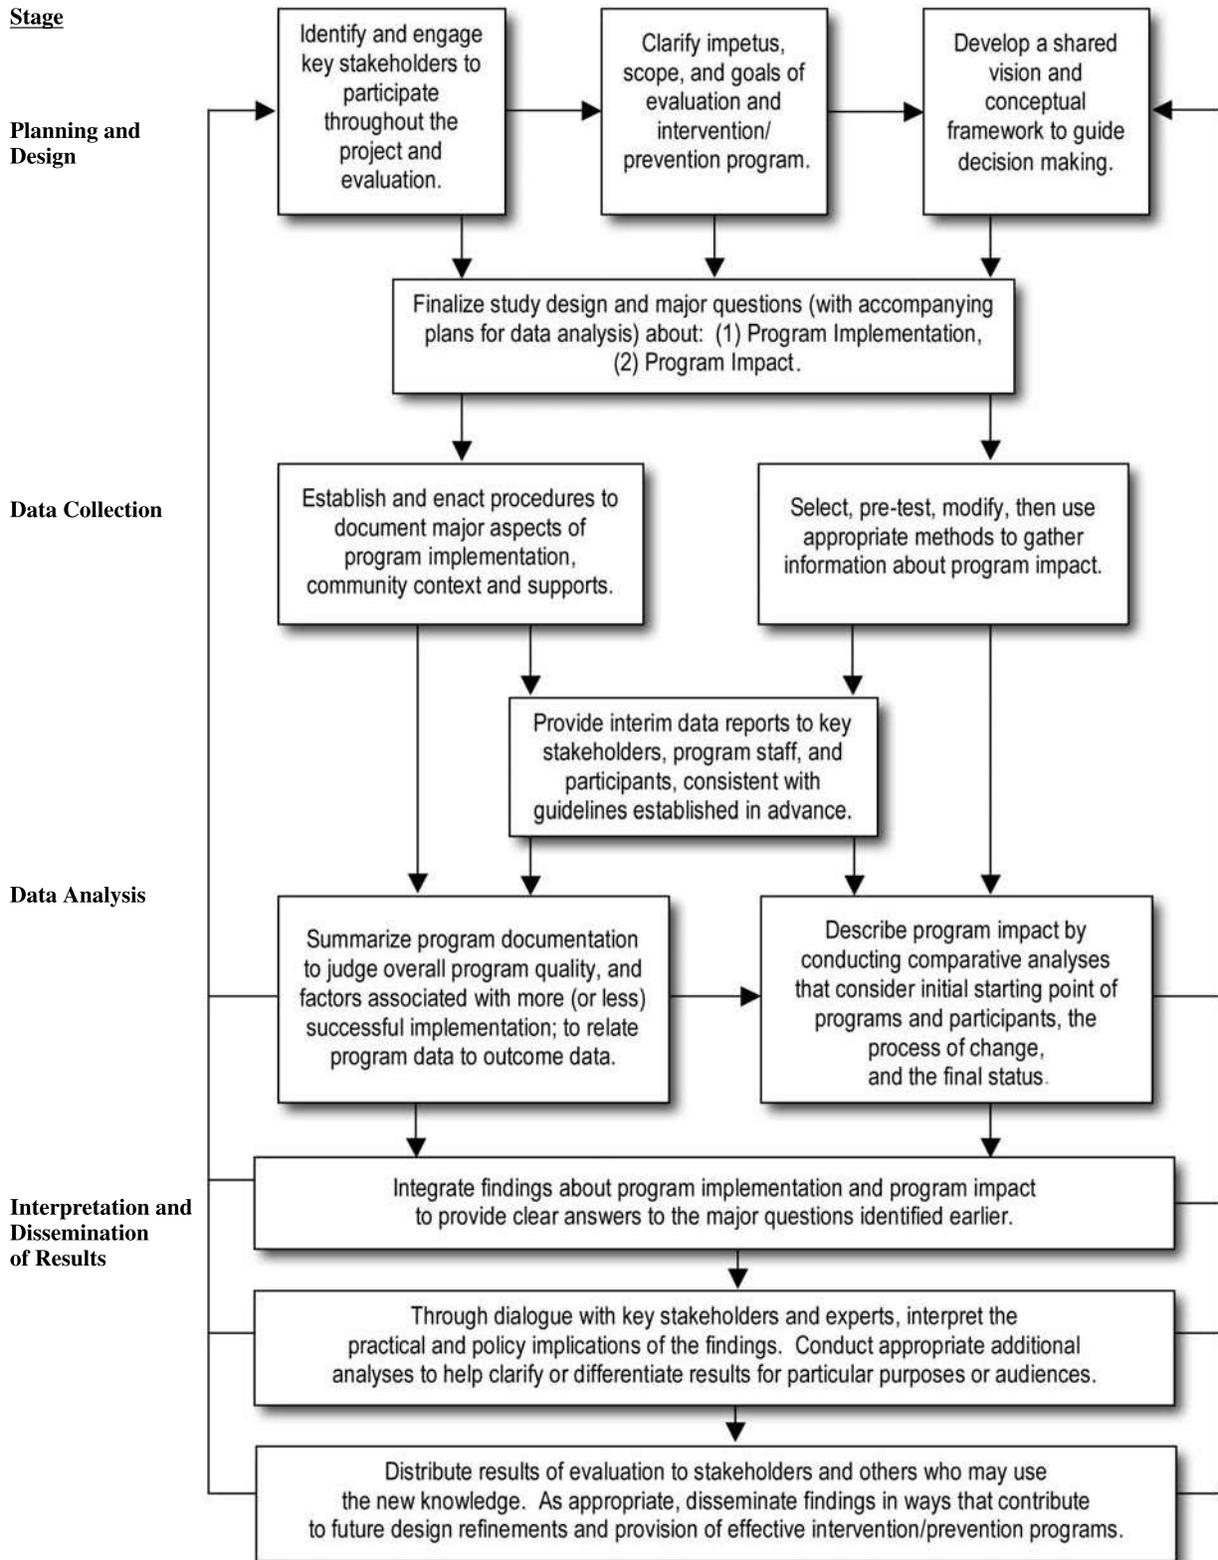

Figure 21.5 Critical activities in planning and conducting responsive, useful health and education evaluations. Adapted from “The Role of Universities in Child Development” (pp. 13–44), by S. L. Ramey and C. T. Ramey, in *Children and Youth: Interdisciplinary Perspectives*, H. J. Walberg, O. Reyes, and R. P. Weissberg (Eds.), 1997b, Thousand Oaks, CA: Sage. Reprinted with permission.

many of the model programs shown to yield positive benefits have not been adopted and implemented in community settings to realize comparable benefits on a large scale. We think this indicates an inherent limitation in the old-style research that has been primarily conducted within one or two major disciplines, led by university scientists, funded by federal agencies without requiring early and sustained engagement of key community stakeholders, and not designed to take into account public policies and practical issues that will determine whether new programs can readily be implemented in the community.

To a remarkable degree, the historical structure of universities also has guided the structure of the research funding and the ways communities are organized to provide supports for children and families (C. T. Ramey & Ramey, 1997b). Specifically, the historical disciplinary training that grants degrees in areas such as social work, psychology, pediatrics, pediatric dentistry, pediatric rehabilitation, early childhood education, special education, educational psychology, child and family nursing, child psychiatry, public health, and urban planning (and many others) contributed to the creation of parallel types of service organizations and community-based practices that have hindered the provision of well-coordinated, efficient, and comprehensive supports for children and families. This dispersion has created a remarkable fragmentation and duplication of services in a time of limited resources and high need. Similarly, within universities, a highly compartmentalized knowledge base about children and families has evolved, with no obvious way to create a unified understanding of child development and effective means of enhancing the development of the most at-risk children.

Potential benefits of reorganization within universities and communities, consistent with the scientific evidence about how children learn and how their health is promoted, are great. Just as the university-led research and demonstration projects are inherently limited, so, too, are many well-intentioned community-based programs that have not realized their intended benefits, even when they have sought to be comprehensive and coordinated. The community initiatives often do not include rigorous research from the beginning, just as many university-led efforts have not adequately included community input and partners. We think this further supports the need for major policy and organizational changes in both universities and communities—changes that will not be easy or welcomed by all. Genuine reor-

ganization would likely mean the end of some disciplines and practices as we know them today and the creation of new combined or coordinated fields and practices designed to better meet the needs of children and families in ways that are more holistic, informed by scientific findings, and responsive to communities and consumers.

This type of research also places universities in a new position, one in which they are actively supporting relationships to improve well-being in the community, while at the same time generating new knowledge. Accordingly, universities may need to consider how to strategically invest in infrastructure support for this type of research (i.e., on a par with planning for new technology and laboratory supports), how to recognize and reward faculty and staff for productively sustaining these research-service partnerships, and how to operate in more flexible and accommodating ways to promote these partnerships (e.g., creating easy-to-handle subcontracts, joint hiring or supervising of staff, reducing indirect cost rates for certain activities, flexibility in paying for community consultation, offering access to university courses and services to community partners). Finally, universities need to anticipate that the emerging results from longitudinal research may sometimes be controversial and politically charged. Ideally, the partnership agreements will have anticipated a full range of results, and active partnerships will accept responsibility for agreed-upon ways to share and act on the findings. Scientific and academic freedom cannot be compromised; neither should the needs of the community and research participants be ignored in how the findings are interpreted and disseminated. These complicated and thorny issues need to be openly discussed and considered in an ongoing fashion, consistent with the overall goal of promoting children's health and education.

SUMMARY

Both early childhood education programs and community-based prevention and health promotion interventions need to incorporate a transdisciplinary approach that builds on recent scientific findings and reflects advances in integrating the historically separate fields of health and education. This relatively new and innovative approach can be characterized as a systematic endeavor to individualize and integrate the supports provided to treat and educate "the whole child." Health is defined consistent with the

WHO definition as including an individual's psychosocial well-being, not merely the absence of disease or disability. Similarly, education is defined as more than just intellectual ability and performance on standardized measures of academic achievement; that is, a child's progress in the educational arena includes social-emotional skills, the ability to adapt to change, and a wide array of cognitive and problem-solving skills that support lifelong learning and competence.

There are many well-intentioned federal, state, and local multicomponent initiatives under way, including the well-known Head Start, Early Head Start, early intervention programs for children with developmental disabilities and risk conditions, subsidized child care quality enhancement efforts, and school readiness and transition-to-school programs. This chapter presented as an example the Head Start-Public School Early Childhood Transition Demonstration Project, a multisite, congressionally mandated intervention to help promote the educational attainment and health of former Head Start children and their classmates, based on an ideology of two-generation, community-based family support.

Children's health and education are widely recognized as vital for their success as contributing members of society, yet relatively few studies have endeavored to understand how health and education mutually influence each other and combine to determine the course of a child's development. Applied biosocial contextual development is a general conceptual framework that is strongly supported by research findings and has proven useful in designing and studying interventions to improve children's health and education. ABCD identifies multiple and co-occurring types of influences on development from a systems theory perspective. Children's development is dimensionalized in terms of biological and social processes that can be more or less supported or hindered by environmental conditions, and thus contribute to three major classes of interrelated outcomes: children's health status and health promotion behaviors (health); children's behavioral, intellectual, and social development, and their educational progress (education); and children's own internal representations of themselves, their environments, and their experiences (personal constructs).

Many carefully planned interventions have yielded scientific findings about what constitutes effective childhood interventions. We reviewed and summarized these findings by delineating five major principles of ef-

fective early intervention. The scientific principles supported by research are the following:

1. The principle of dosage, in which more intensive or higher-dose interventions yield larger and longer-lasting effects, whereas less intensive interventions often yield limited or no demonstrable benefits.
2. The principle of timing, supporting the conclusion that interventions that are well-timed to take advantage of children's neuroplasticity in multiple domains, by beginning fairly early in life and continuing through periods of rapid growth and learning, produce more positive outcomes.
3. The principle of direct receipt of supports, indicating that, to date, programs that seek to change children only by changing their parents and community providers have not produced evidence of significant benefits to children themselves, whereas programs that provide services directly to children (often accompanied by family and community supports) can alter the developmental trajectories of individual children.
4. The principle of differential benefits, which predicts that planned interventions are likely to have greater or lesser impact on children, depending on a combination of factors, such as the initial type and magnitude of a child's risks and needs and the extent to which these are specifically addressed in the intervention. For example, children whose mother has limited resources to meet her young children's cognitive and language learning needs have benefited significantly more from early educational interventions than have children whose mother initially had much greater amounts of educational, economic, and health resources.
5. The principle of continuity of supports, which affirms the importance of children receiving the right types and amounts of environmental supports for health and education throughout their development. That is, there is no evidence that early intervention programs alone can produce large and sustainable benefits in the absence of children receiving reasonably good supports from schools, families, and communities after the planned intervention.

Much remains to be learned about the ways these five major principles interact across different ages and stages of development and within and across diverse cultural and regional settings. The future of scientific inquiry

about children's health and education research will depend largely on the degree to which studies are more carefully designed, implemented, documented, and summarized in ways that can be compared and combined within a practically useful knowledge framework.

To conduct such complex research, especially involving large-scale and sustainable prevention and intervention programs, a new style of collaborative research that engages the community and broader expertise from professionals, scientists, and citizens is vitally needed. Engaging individuals and groups in the early stages of planning and implementation has great promise for producing results that are more valid, more sensitive, and more acceptable and useful to families, practitioners, and communities. Conducting such research necessitates an in-depth understanding of the complex and changing ways that policy, economics, politics, and practice operate in the fields of education and health. The goal of such research is undeniably both basic and applied, and potentially may yield insights to move into an era where the large disparities and inequities in health and education for low-income, historically marginalized groups of children are drastically reduced and eventually eliminated.

States Parties agree that the education of the child shall be directed to:

- (a) The development of the child's personality, talents and mental and physical abilities to their fullest potential. . . .
- (c) The development of respect for the child's parents.

Article 29

CONVENTION ON THE RIGHTS OF THE CHILD
(UNITED NATIONS CHILDREN'S FUND, 1990)

Each day approximately three-quarters of a million adults around the world experience the joys and rewards as well as the challenges and heartaches of becoming a new parent (Population Reference Bureau, 2000). As individuals, each of us has had the experience of being parented, and many of us relive the experience when we parent our own children. Yet, parenting remains a somewhat mystifying subject about which few

people agree, but about which almost everyone has opinions. That said, a surprising amount of solid science is recently accumulating about parenting. Figure 22.1 shows the increasing popularity of parenting studies today. As a testament to the demands for information

This chapter summarizes selected aspects of my research, and portions of the text have appeared in previous scientific publications cited in the references. Preparation of this report was supported by the Intramural Research Program of the NIH, NICHD. I thank H. Bornstein, K. Crnic, M. Heslington, S. Latif, J. Sawyer, C. S. Tamis-LeMonda, and C. Varron for comments and assistance; L. Davidson, M. A. Fenley, L. Gulish, E. L. Pollard, M. F. Rogers, M. Rosenberg, D. C. Smith, and S. Toal of the Center for Child Well-being, and R. Bradley, K. Crnic, E. Galinsky, M. Juzang, W. Juzang, J. Kagan, S. Lee, R. M. Lerner, V. Murry, L. Steinberg, and R. Wooden of the Parenting Network.

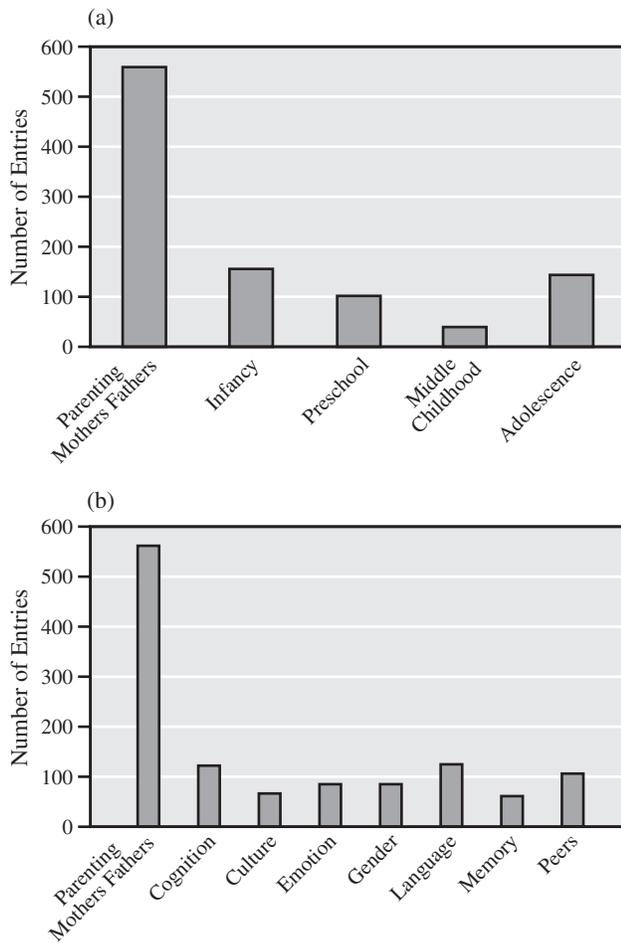

Figure 22.1 (a) Number of entries at the 2005 meeting of the Society for Research in Child Development for parenting, mothers, and fathers versus four phases of childhood. (b) Number of entries for parenting, mothers, and fathers versus the seven next most popular subject areas.

about parenting and to bring order to existing information, this is the first formal chapter on *parenting* per se to appear in the *Handbook of Child Psychology*.

Parenting is a job whose primary object of attention and action is the child—human children do not and cannot grow up as solitary individuals—but parenting is also a status in the life course with consequences for parents themselves. Parents are concerned about the everyday well-being of their children as well as their children's long-term development, and parents are concerned about themselves as parents and want to know how best to cope with the unrelenting demands of parenting. Parenting is a 24/7 job.

Parents are fundamentally invested in their children: their survival, their socialization, and their education.

Evolutionary psychology distinguishes between bringing a new individual into the world and caring for an existing individual, childbearing versus child caring (Bjorklund, Younger, & Pellegrini, 2002). Whereas species lower in the phylogenetic hierarchy are principally childbearers, mammals such as human beings tend to be devoted child carers perhaps because young human children are totally dependent on parents. Childhood is also the time when we forge our first social bonds, first learn how to express and read basic human emotions, and first make sense of the physical world. In childhood, individual personalities and social styles also first develop. It is parents who lead children through all these dramatic firsts.

Thinking about parent-child relationships highlights parents as agents of child socialization; to a considerable degree, however, parenting is a two-way street. Almost nothing stirs the emotions or rivets the attention of adults more than the birth of a child. Furthermore, by their very coming into existence, children alter the sleeping, eating, and working habits of their parents; they change who parents are and how parents define themselves. In point of fact, parent and child activities are characterized by intricate patterns of synchronous interactions and sensitive mutual understandings (Bornstein, 1989a, 2002b; Kaye, 1982; Stern, 1985; Trevarthen & Aitken, 2001). Infants cry to be fed and changed, and when they wake, they tell parents they are ready to play and to learn. Sometimes, parents' initiatives are proactive; often, however, they are reactive. Parents and their children interact with one another over time to co-construct parenthood as well as childhood.

Historically, theorists of many stripes looked to parents as those thought to influence children the most, although in modern societies, childhood socialization is acknowledged to involve a variety of individuals and to take place in a variety of contexts: families, peer groups, day care centers, school classrooms. Bronfenbrenner (Bronfenbrenner & Morris, 1998) described an apt ecological perspective on parent-child relationships and children's development that has stimulated developmental scientists to think about parents, children, and families from a systemic point of view. This chapter on parenting adheres to that developmental contextual perspective.

Parents are charged with the larger and continuing task to enculturate children, that is, to prepare them for the physical, economic, and psychosocial situations that are characteristic of the environment in which

they must survive and, it is hoped, thrive (Benedict, 1938; Bornstein, 1991; LeVine, 2003). Parents have the moment-to-moment job of disambiguating novel, complex, and rapidly changing, uncertain information that arises from children. Yet, despite this flux they are expected to parent consistently, appropriately, and effectively. Parents everywhere appear highly motivated to carry out these assignments. Adults already know (or think they know) something about parenting by the time they first become parents (Zero-to-Three, 1997). Indeed, human beings appear to possess an amount of intuitive knowledge about parenting (Papoušek & Papoušek, 2002), and some characteristics of parenting may be wired into our biological makeup (Fleming & Liu, 2002). For example, parents almost everywhere speak to their infants even though they know that babies cannot understand language *per se*, and parents even speak to babies in a special speech register. However, human beings also acquire knowledge of what it means to parent by living in a culture: Generational, social, and media images of parenting, children, and family life—handed down or ready made—play significant roles in helping people formulate their parenting cognitions and guide their parenting practices (Holden & Buck, 2002; Sigel & McGillicuddy-De Lisi, 2002). For these reasons, parents from different cultures differ in their opinions about the significance of specific competencies for their children's successful adjustment, they differ in the ages they expect children to reach different milestones or acquire various competencies, and so forth (Goodnow, 2002; Harkness & Super, 1996). Direct experiences with children and self-constructed aspects of parenting are other important factors in developing parenting attitudes and actions.

For their part, children seem primed to profit from parental care. Early childhood in particular has long been thought to be a period in the life cycle when humans are especially plastic, a time when they are open to influences they will carry with them long after they have left their family of origin. The characteristics thought to be especially vulnerable to influence in the first years of children's lives range from the language they speak and the foods they prefer to the politics they follow and religious beliefs they profess.

Parenting is not an activity we normally think of as being especially scientific. Most people just seem to parent, without giving it much thought. Like most things, however, better parenting requires knowledge. Happily, there *is* a science of parenting with much systematic research behind it. The contemporary parenting literature

contains thousands of empirical studies. This chapter is based on the emerging science of parenting. One important consequence of the increasingly sophisticated view of the origins and conduct of parenting is the conclusion that parenting can be influenced and modified through education and culture, and thus what we learn about parenting can have far-reaching practical implications.

Scientific analysis of parenting has also helped to shed light on how and why parental practices influence child outcomes. Studies of parenting often rely on correlational designs, but also use experimental manipulations and other techniques that make it possible to examine parenting variables as potential causal mechanisms for specified child outcomes. What forces affect when and how children change? What conditions determine differences among children in their rates of development or their ultimate achievements? These questions constitute the heart of much of parenting science. Of course, children's genetic makeup affects their characteristics and also influences the way they are treated by their parents. However, children's inherited dispositions and their parents' child-rearing choices are closely interwoven and function jointly. There is unassailable evidence that parents can and do influence children.

Parents have many roles to play in child development: to nurture and protect children, to guide children in understanding and expressing proper feelings and emotions, to educate children in behaviors that are acceptable for the stage of childhood they occupy as well as to prepare children for adaptation to a wider range of life roles and contexts they will encounter as they grow (Bornstein, 1989a, 2002a; Badley & Caldwell, 1995). All cultures prescribe certain beliefs and behaviors in their members and proscribe others, and children in the culture must learn both (Maccoby, 2000). For parents, some prescriptions and proscriptions are essentially universal, such as the requirement that parents nurture and protect their offspring. Others, such as what kinds of emotions can be expressed in public, vary from culture to culture. All cultures socialize children in such a way that each new generation acquires relevant prescribed beliefs and behaviors. In the tripartite organization of culture/parent/child, parents bridge cultural practices and ideals to children's everyday life and learning. It is sometimes said that only two kinds of information are transmitted across generations: genes and culture. Parents are "final common pathway" of both. Undergirding all these considerations is the fundamental fact that parenting is requisite to the survival and success of the human race.

PARENTING FOR PARENTS

Parenting is most certainly a functional activity, but parenting is pleasures, privileges, and profits as well as frustrations, fears, and failures. Sociobiological theories of human evolution assert that all individuals are compelled to see their childbearing and child rearing succeed on the argument that it is in that way that they ensure the continuation of their genes (Dawkins, 1976). However, there is much more to parenting than biological continuity. Parenting has its intrinsic rewards. According to a nationwide survey conducted by the National Center for Children, Toddlers, and Families, more than 90% of parents say that when they had their first child, they not only felt “in love” with their baby, but were personally happier than ever before in their lives (Zero-to-Three, 1997). Parents can find interest and derive considerable and continuing pleasure in their relationships and activities with their children.

Parenthood can also enhance one’s psychological development, self-confidence, and sense of well-being. Parenting translates into a constellation of new trusts and opens a vista on the “larger picture” of life. Of course, parenthood also gives adults ample opportunity to confront new challenges and to test and display their competencies (Crittenden, 2004). Markus, Cross, and Wurf (1990) reported that feelings of competence as a parent constituted a highly common aspect of the self desired by adults. Furthermore, from infancy, children recognize and show that they prefer the sights, sounds, and smells of their caregivers, and over the course of just the 1st year of life children develop deep and life-long attachments to sensitive and responsive parents. In essence, then, parents receive a great deal in kind for their hard work and commitment: They are often recipients of unconditional love, and they even pretend to immortality.

Adults are motivated by strong self-interest to parent. Becoming or being a parent means assuming new and vital responsibilities for oneself as well as for others. To parent well, however, parents’ own needs must be met. When women are inadequately nourished, for example, their health and social development may be compromised, and their ability to bear and rear healthy children is threatened. Malnourished women fall ill more often, and they have smaller babies. Where birth rates are high and child mortality is also high, women’s bodies are stressed and their children are trapped in a cycle of poor health and nutrition.

Mostly, however, parenting is defined by its functional role in the human life cycle. A functionalist approach to parenting asserts that it is desirable to promote traits in children that will lead to their becoming adults who function well within the requirements of the social groups among which they live. The conception of parenting as a set of functions expands the focus of discussion beyond biological parents; other related and nonrelated caregivers may also be centrally engaged in parenting (Leon, 2002). In this functional sense, too, parenting cannot be separated from child development. This chapter focuses on parenting and parents to the degree possible, but does not eschew significant others in the lives of children or children’s development.

Becoming a parent is a transforming experience (C. P. Cowan & Cowan, 1992; Heinicke, 2002). New parents experience change in aspects of their personality (i.e., self-efficacy expectations, personal control, anxiety, and depression). Generally during the transition to parenthood, gender roles become more traditional, with women becoming the primary caregiver, and marital satisfaction also normatively declines.

Freud reputedly counted bringing up children as one of the three “impossible professions,” the other two being governing nations and psychoanalysis. Some parents are more fully committed than others to the parenting role (Greenberger & Goldberg, 1989; Pulkkinen, 1982). In the end, degree of commitment may rival in importance and for effect the style with which commitment to parent is expressed.

HISTORY AND THEORY OF PARENTING IN BRIEF OVERVIEW

How did parenting studies begin, and how did they arrive at the state we find them in today? A glance backward and a short excursion into parenting theory also helps to show the way we are headed.

A Glance Backward at How Parenting Study Got to be the Way It Is

Child-rearing responsibilities have been viewed as fundamental to societal well-being throughout time, and so every society has paid considerable attention to parenting (French, 2002). Written speculation and sermoniz-

ing on parenting date back at least to ancient Egypt, the Code of Hammurabi, and the pre-Socratic philosophers. In the *Laws*, Plato (*ca.* 355 B.C.) theorized about the significance of parenting. Over the centuries since, the writings of clergy and philosophers—as well as popular wisdom—have been replete with theories, convictions, and aphorisms concerning what kinds of child training best ensure social order. Historians, anthropologists, and sociologists of family life have documented evolving patterns of primary child care (Colón with Colón, 1999). However, the formal study of parenting had its beginnings in attempts by philosopher, educator, and scientist parents to do systematically what parents around the world do naturally everyday: observe their children. Such reflections on child rearing first took form as diary descriptions of children in their natural settings written by their own parents, referred to as “baby biographies” (Darwin, 1877; Hall, 1891; Preyer, 1882; Rousseau, 1762; Taine, 1877; Tiedemann, 1787; see Jaeger, 1985; Prochner & Doyon, 1997; Wallace, Franklin, & Keegan, 1994), and they still regularly appear (Brazelton, 1969; Church, 1966; Greene, 1984; Mendelson, 1993; Stern, 1990). These systematic observations of parenting had many salutary effects, heightening awareness in parents and provoking formal studies of how to guide child development. It was only in the twentieth century, however, that parenting became the focus of scientific study.

On account of high rates of child mortality, parents in early times may have cared for but resisted emotional investment in the very young (Dye & Smith, 1986), an orientation that appears to persist where especially dire circumstances reign (Scheper-Hughes, 1989). One historian theorized that parents have generally improved in their orientation to and treatment of children because parents have, through successive generations, improved in their ability to identify and empathize with the special qualities of early childhood (deMause, 1975). Today, advice on parenting children can be found in professional compendia that provide comprehensive medical treatises of prenatal and perinatal development, such as *Effective Care in Pregnancy and Childbirth* (Chalmers, Enkin, & Keirse, 1989); in classic how-to books, such as *Dr. Spock's Baby and Child Care* (Spock & Needlman, 2004) and *Your Baby and Child* (Leach, 1997); in research-grounded academic compilations, such as the *Handbook of Parenting* (Bornstein, 2002a) and *The 10 Basic Principles of Good Parenting* (Steinberg, 2004); as well as in numerous popular periodicals

that overflow magazine racks in supermarkets, airports, and pharmacies.

Parenting Theory in Perspective

Historically, many theories in philosophy and psychology focused on parenting. This recapitulation closely follows Maccoby (1992) who observed that at first two overarching theories presumed to encompass most of what was significant about the socialization of children, psychoanalysis and behavior theory, but these all-encompassing perspectives on parenting yielded over time to narrower views specific to domains or ages. Early research also consisted largely of a search for direct connections between parental practices and child outcomes, whereas current work focuses on processes that may mediate the ways parental practices affect a child. Parents were once seen primarily as trainers or transmitters of culture and children as empty vessels who were gradually filled up with the necessary social repertoires; today complex models of socialization involve bidirectional and transactional processes.

Sigmund Freud (1949), founder of *psychoanalytic theory*, asserted the principal role of parenting in child development. Freud hypothesized that the parent's personality determined the nature of parenting, the parent-child relationship, and the child's development as children “internalize” models of their parents and “introject” their values. Another consistent theme among psychoanalytic theorists was that, if parents' emotional needs had not been met during the course of their own development, then their own neuroses would be reflected in their parenting (Holden & Buck, 2002). Anna Freud (1955/1970) described mothers who rejected their children, sometimes due to psychosis but more often because of their own neurotic conflicts. Likewise, Winnicott (1948/1975) and Spitz (1965/1970) saw the roots of aggressive, impulsive, immature, self-centered, and self-critical parenting of abusive parents in the parents' own upbringing. Psychoanalytic theorizing was applied to studies of the role of personality in family life, but the psychoanalytic movement failed to foster much systematic empirical research (Cohler & Paul, 2002). Recent advances redress this imbalance.

Early empirical studies of parenting from a *behavior theory* perspective consisted of straightforward demonstrations that specific behaviors in babies (smiles or vocalizations) could be instrumentally conditioned or extinguished (Rheingold, Gewirtz, & Ross,

1959). From Watson (1924/1970) to Skinner (1976), attempts were made to relate learning theories to socialization. Children's aggression, dependency, sex typing, and identification with parents were often foci of behavioral study. N. E. Miller and Dollard (1941) reformulated hypotheses derived from psychoanalytic theory into simple testable propositions stated in behavior-theoretical terms. Their efforts to predict more complex outcomes such as children's personality attributes from parental socialization methods proved unsuccessful. Sears, Maccoby, and Levin (1957), for example, found few connections between parental child-rearing practices (as reported by parents in interviews) and independent assessments of children's personality characteristics.

Many theories of child psychology place strong emphasis on parents. According to *scaffolding theory*, for example, cognitive and social development occur mainly in interactive contexts with trusted, more competent partners (Rogoff, 1990) who do not reward, punish, or correct children so much as provide a structure for learning that increases the likelihood of children's succeeding in their own attempts to learn. Parents who move their children forward in development arrange circumstances so that the demands of a situation fall beyond the child's "zone of actual development" to within the child's "zone of proximal development." According to Vygotsky (1978), the parent, being more advanced than the child, raises the child's level of competence through reciprocal interactions. This view implies that enduring parental influences stem mainly from the nature of the relationships parents co-construct and continually reconstruct with their children.

Other prominent theories emphasize the active role of the child in parent-child interaction. In one view, children acquire new behaviors without ever performing them overtly and without ever being rewarded, but merely by observing them being performed by nurturant and powerful parents (Bandura, 1962, 1965). A central tenet of this *social learning theory* posits that the primary method by which children learn about the world is through observing the actions of their caregivers. In this way, children gradually internalize the behaviors and values of key figures in their lives (Maccoby, 1959). What children imitate in others, what they remember, and how they process what is remembered all depend on their level of development. Piaget's (1952) *interactionist theorizing*, for example, strongly suggested that children

use parental input rather than parental input into learning determining what children learn.

Bowlby (1969) infused ethological theory into socialization. He contended that parent and child develop reciprocal behaviors particularly through attachment (Ainsworth & Bell, 1969). *Attachment theory* postulates the formation of an internal working model or representation of the attachment relationship, a schema that affects the nature of new relationships formed later in life (Main, Kaplan, & Cassidy, 1985). What is internalized from a child's attachment experience is the quality of the relationship with a parent rather than the personality characteristics of the parent (Sroufe & Fleeson, 1986). A sensitive and responsive parenting style provides a secure base from which children develop cooperation, self-regulation, and social initiative (Putallaz & Heflin, 1990; van IJzendoorn, 1995), internalize social values (Grusec & Goodnow, 1994), and explore the world and engage socially with others (Ainsworth, Blehar, Waters, & Wall, 1978; Sroufe, 1988).

Finally, in the view of *family systems theory*, what transpires between a parent and a child is governed not only by the characteristics of each individual but also by patterns of transaction between them and others (Bornstein & Sawyer, 2005; Broderick, 1993; Cox & Paley, 2003). Parent and child develop in a family system that functions as an organized whole, composed of interdependent elements or subsystems that include individuals as well as relationships among individuals. Each element or subsystem within the family both affects and is affected by other elements; a change in any one aspect of the system can lead to changes in others. How responsive a mother or father may be at any given moment is determined not only by that parent's characteristic warmth and the child's characteristic responsiveness, but also by the patterns they have created jointly and therefore come to expect in their relationship. Moreover, a full family systems approach examines parenting in the context of all relationships within the family and between the family and its many larger social contexts (such as culture). For example, Deal, Hagan, Bass, Hetherington, and Clingempeel (1999) observed that parents behaved one way when the whole family was together and another when each interacted one-on-one with their young child. Like other living systems, families continually strive to attain a dynamic balance amid the experiences of growth and maturation on the one hand, and the need for consistency on the other. In the family systems view,

emphasis falls on relationships and interactions as well as contexts that reach beyond the parent and child to encompass the full diversity of the dyad's social embeddedness. "Models that limit examination of the effects of interaction patterns to only the father-child and the mother-child dyads and the direct effects of one individual on another are inadequate for understanding the impact of social interaction patterns in families" (Parke, 2002, p. 41). In family systems theory, interconnected subsystems are also organized in a hierarchical structure; the asymmetrical nature of the parent-child relationship is necessary for child development.

This multidomain family systems model is built on a set of central assumptions. One is that the whole is greater than the sum of its parts. This means that the structure or organization of relationships in the family affects the quality of the relationship between any two family members. For example, each parent's relationships with his or her parents affect their joint ability to work together to parent their child. A major life transition for one family member is likely to affect other family members. Influences within the family system and between the family and other social systems in the culture are transactional. Furthermore, family members are always in the process of development, so that the family system is always in the process of change.

Key questions that must be addressed in parenting theory concern the specification of mechanisms by which parent cognitions and practices produce change in children (Patterson & Fisher, 2002). By the same token, theorists must explain how the child impacts the parent. Successful parenting theories will also have two common characteristics: They will be based on constructs that are readily operationalized, and they will specify effective means of assessment.

Many theoretical accounts for how socialization takes place have been proposed. For most theories, it is primarily through parental control and teaching that the adult culture is passed down to each new generation of children. Parents are the primary agents who set the agenda for what children learn and who administer the rewards and punishments that strengthen desired characteristics and weaken undesired ones in children. More recent theoretical formulations recognize the role of the child in interaction with the parent. Central assumptions of all socialization theories are that, even though socialization and resocialization can occur at any point in the life cycle, childhood is a particularly plastic period

when enduring social skills, personality attributes, and values are inculcated, and that parent-child interactions robustly influence children in other circumstances and at later times.

Looking Ahead to Where Parenting Theory and Research are Going

We know some, but not nearly enough, about parenting. The challenge for the future of the discipline is to acknowledge that up to now we have focused too narrowly on households of predominantly Anglo-Saxon background (Tomlinson & Swartz, 2003), even though such families are in the minority worldwide. Contemporary study fails to adequately represent the cultural diversity and complexity of contemporary parenting. A pervading critique of developmental science is that research in the field has tended to describe the constructs, structures, functions, and processes of child rearing and child development that accord with ideals mostly or exclusively appropriate to middle-class, industrialized and developed, Western societies (Bornstein, 2002c). This unhappy situation cries for change. In the meanwhile, what follows must be seen and understood in light of the extant literature.

PARENTS

The majority of children throughout the world grow up in family systems where there is more than one significant parenting figure guiding more than one child's socialization at a time (McHale et al., 2002). Biological and adoptive mothers and fathers are children's acknowledged principal caregivers. However, parents are not the only agents who contribute to the upbringing and socialization of children. Brothers and sisters (Zukow-Goldring, 2002) and members of the extended family (P. K. Smith & Drew, 2002) all have roles to play. Outside the family, peers (J. R. Harris, 1995, 1998; Hartup, 1992), for example, also have an undeniable impact. Moreover, in different cultures (now and historically) children have been tended by nonparental, nonfamilial care providers—day care workers and metaplot, nurses and slaves—whether in family day care at home, day care facilities, or fields (Clarke-Stewart & Allhusen, 2002). In short, many individuals, other than mother and father, "socially" parent children (Leon, 2002). This chapter is circumscribed to parents, although the

choices parents make to share caregiving with nonparents are briefly mentioned.

Mothers

Almost all mammalian species are matrilocal (Wilson, 1975). Trivers (1972, 1974) acknowledged the reality that in land-dwelling mammals after copulation, the female is left in physical possession of the embryo. Even if she lays the fertilized egg almost immediately, the male still has time to abscond, leaving the female with the decision of whether to leave the young to certain death or stay and rear it. On this account, maternal care is more common than paternal care among mammals who are devoted “caregivers” (Bjorklund et al., 2002). Even among species where males show considerable parental altruism, they commonly do less work than females and vanish more quickly (Wilson, 1975). Among human beings, fathers may withdraw from their children when they are unhappily married; mothers typically never do (Kerig, Cowan, & Cowan, 1993). Mothers and fathers do not necessarily share the same parental “investment strategies.”

Human cultures distribute the tasks of child care in different ways. Even if fathers’ social and legal claims on and responsibilities for children were preeminent historically (French, 2002), most people agree that mothers normally play a more central role in children’s development (Barnard & Solchany, 2002; Zero-to-Three, 1997). Cross-cultural surveys and meta-analyses alike attest to the primacy of (biological or adoptive) mothers in child rearing (Holden & Miller, 1999; Leiderman, Tulkin, & Rosenfeld, 1977). The maternal role is better articulated and defined than is the paternal role, and mothers generally have more opportunities to acquire and practice skills that are central to child rearing than do fathers. Normally, mothering helps to interpret and condition fathering, and mothers often serve as gatekeepers to children’s fathers and other caregivers (Allen & Hawkins, 1999). DeLuccie (1994) reported that fathers are more involved with their children when mothers assess them to be more competent at caring for children and when mothers are more satisfied with their care of children. Parke (2002) observed that many paternal influences on child development tend to be indirectly mediated through the father’s impact on the mother.

For these reasons, theorists, researchers, and clinicians have historically concerned themselves preponderantly with mothering, rather than parenting. Mothers

and mothering are investigated much more often and comprehensively than fathers and fathering. There is thus a more extensive body of information about mothers and children than about fathers, siblings, other relatives, or nonfamilial caregivers and children. Western industrialized nations have witnessed increases in the amount of time fathers spend with children; in reality, however, fathers still typically assume little responsibility for child care and rearing, and fathers are primarily helpers to mothers (Cabrera, Tamis-LeMonda, Bradley, Hofferth, & Lamb, 2000). On average, mothers spend between 65% and 80% more time than fathers do in direct one-to-one interaction with their young children (Parke, 2002), and such ratios hold in many different lands (Belsky, Gilstrap, & Rovine, 1984; Collins & Russell, 1991; Greenbaum & Landau, 1982; Jackson, 1987; Kotelchuck, 1976; Montemayor, 1982; Pedersen & Robson, 1969; A. Russell, 1983; G. Russell & Russell, 1987; Szalai, 1972). In both traditional American families (Belsky, Garduque, & Hrcneir, 1984) and traditional versus father primary-caregiver Swedish families (Lamb, Frodi, Frodi, & Hwang, 1982), parental gender exerts a greater influence on the quality of parent-child interaction than parental role in the family or employment status.

Fathers

If motherhood goes along with apple pie, the status of fathers is curiously more debatable. Some contemporary observers point to the continuing and widespread abrogation of responsibility by fathers (Blankenhorn, 1995; Popenoe, 1996), whereas others praise fathers’ increasing involvement with their children (Lamb, 2000; Parke, 2002; Yeung, Sandberg, Davis-Kern, & Hofferth, 2001). One finds many fewer nonresident moms than dads (King, 1994; Seltzer, 1991). But fathers are neither inept nor uninterested in their children, of course. Fathers engage children in all of the parenting practices that mothers do and hold the same diversity of cognitions. When feeding children, for example, fathers, like mothers, respond to children’s cues, either with social bids or by adjusting the pace of the feeding (Parke, 2002). Both father and mother touch and look more closely at a child after the child has vocalized, and both equally increase their rates of speech following a child’s vocalizing. Although fathers are capable of performing sensitively, they still yield principal responsibility for child tending to their wives

(Coltrane, 1996). A. Russell (1983) found that most Australian fathers believed in a “maternal instinct” in regard to child care and that fathers who endorsed that belief participated less in child care. But some have argued that fathers are occupied with many more internal family concerns, such as planning, monitoring, and worrying about finances (Palkovitz, 2002). Fathers also contribute uniquely to their children’s development; Isley, O’Neil, and Parke (1996) reported that, when maternal affect was accounted for, fathers’ affect and control predicted children’s social adaptation. Indeed, father presence is critical: Having a resident versus a nonresident father during their first 3 years of life means fewer behavior problems and a better developmental course at ages 4 to 6 in both European American and Latin American children (Crockett, Eggebeen, & Hawkins, 1993).

Coparenting and the Division of Parenting Labor

In point of fact, mothers and fathers appear to interact with and care for children in complementary ways; that is, they tend to divide the labor of caregiving and engage children by emphasizing different types of interactions. When mother-child and father-child play were contrasted developmentally (Power, 1985), both mothers and fathers were found to follow interactional rules of sharing attentional focus on a toy; however, mothers tended to follow the child’s focus of interest, whereas fathers tended to establish the attentional focus themselves. Mothers’ language but not fathers’, and fathers’ physical play but not mothers’, predict the popularity of boys (MacDonald & Parke, 1984; Parke et al., 1989). Mothers’ and fathers’ perceptions of their parental efficacy vary in complementary ways as well. Perozynski and Kramer (1999) reported that mothers of young children were more confident than fathers in their ability to use strategies that involve reasoning or talking to the child. In contrast, fathers were more confident than mothers in their use of directives or the threat of force.

Marital relationships affect the quality of mother-child and father-child relationships and child outcomes (Gable, Crnic, & Belsky, 1994; Tamis-LeMonda & Cabrera, 2002), just as how parents work together as a coparenting team can have far-reaching consequences for children (Fincham, 1998). Coparenting *broadly* refers to ways that parents (or parental figures) relate to each other in the role of parent (McHale et al., 2002). Coparenting comprises multiple interrelated

components: agreement or disagreement on child-rearing issues; support or undermining of the parental role; and the joint management of family interactions (Feinberg, 2003). This literature closely articulates with the family systems perspective that marital and parent-child relationships are interdependent (Grych, 2002), as each is to the child’s development (Cox, Paley, & Harter, 2001; Cummings & Davies, 1994). Mutual emotional support and validation, modeling and sharing parenting skills, buffering marital conflict or dissatisfaction from spilling over into relationships with children constitute some of the ways coparenting functions to nurture child development. The direct-effects model of coparenting postulates that exposure to interparental conflict, for example, influences children’s behavior. Erel and Burman (1995) documented changes in children’s physiology, cognitions, and emotions in response to marital conflict. Marital discord not only affects children’s psychological health and functioning (Cummings, Iannotti, & Zahn-Waxler, 1985; Grych & Fincham, 1990), such as child internalizing and externalizing behaviors and disorders (P. A. Cowan, Cowan, Schultz, & Heming, 1994; Fincham, Grych, & Osborne, 1994), but also their peer relationships (Kerig, 1995; Ladd & Pettit, 2002). The indirect-effects model posits that the impact of marital relationships on children is mediated by the nature and structure of the parent-parent relationship *per se* (Cummings & Watson-O’Reilly, 1997; Grych & Fincham, 2001), for example, how each parent regulates the other’s interactions with the child (gatekeeping). Marital status makes it easy or difficult for a parent to provide social support and opens or limits adults’ physical and emotional availability to children.

More specific hypotheses have also been advanced to the effect that emotional security (Davies & Cummings, 1994) and emotion (dys)regulation patterns (Crockenberg & Langrock, 2001) explain the links between parents’ interactions as a couple and children’s relationships with peers. For example, Cummings (Cummings & Davies, 1995; Cummings & Wilson, 1999) found that destructive marital conflict threatens the child’s sense of safety and emotional security in the family.

Other Caregivers

In many underdeveloped societies, siblings or other family members regularly care for children (Zukow-Goldring, 2002), and large numbers of young children

today in developed societies normatively participate in nonparental care, enter that care early, stay for longer periods of time, and change types of care often (Clarke-Stewart & Allhusen, 2002; Lamb, 1998). Based on data from the National Longitudinal Study of Youth, Fuller-Thompson, Minkler, and Driver (1997) reported that 11% of grandparents were the primary caregivers of their grandchildren (Chase-Lansdale, Brooks-Gunn, & Zamsky, 1994). Using data from the National Study of Families and Households, Baydar and Brooks-Gunn (1998) reported that approximately 12% of grandmothers resided with a grandchild, and approximately 43% provided child care on a regular basis. An estimated 12.9 million American children under age 6 are enrolled in some kind of nonparental child care on a regular basis (U.S. Bureau of the Census, 1997). Moreover, the National Institute of Child Health and Human Development Early Child Care Research Network (1997) found that the vast majority of children (81%) in a U.S. national study experienced regular nonmaternal child care during their first 12 months of life, with most starting prior to 4 months of age and enrolled for nearly 30 hours per week. Fewer than 20% of children spent their entire 1st year at home with no supplemental care. As a consequence of contemporary social and cultural changes, most notably dual parent employment, the demand for high-quality community-based child care services has burgeoned, and nonparental caregivers have assumed increasing responsibility for meeting children's developmental needs and essentially for preparing children for a future in society (A. E. Gottfried, Gottfried, & Bathurst, 2002). As more families have two parental wage earners earlier in the family life cycle, and more children are cared for by nonparental caregivers earlier in their lives, a looming issue for parents (as well as child care educators, researchers, and policymakers) is the long-term cumulative impact of nonparental child care on parents and children alike.

Summary

Mothers and fathers share central parenting responsibilities for child rearing, although siblings, grandparents, and various nonparental figures also fill salient roles in child care. Often, child caregivers behave in a complementary fashion to one another, dividing the full labor of child rearing by emphasizing mutually reinforcing responsibilities and activities. Still unclear, however, are the long-term cumulative implications of diverse patterns of parenting.

DETERMINANTS OF PARENTING

A critical step on the path to fully understanding parenting is to evaluate forces that shape it. The origins of individual variation in maternal and paternal caregiving, whether of cognitions or practices, are extremely complex. Evolution and history; biology and ethology; family configuration; formal and informal support networks; social, educational, legal, medical, and governmental institutions; socioeconomic class, designed and natural ecology, and culture—as well as children themselves—each contributes to constructing the parent. Nonetheless, certain groups of factors seem to be of paramount importance: (a) intrapersonal and intrapsychic characteristics of parents, (b) actual or perceived characteristics of children, and (c) contextual characteristics. This text follows an ecological orientation from proximal to distal to describe and evaluate the multiple antecedents of parenting (Belsky, 1984; Bronfenbrenner & Morris, 1998). Each of these domains is thought to influence parenting directly and, indirectly through parenting, child development.

Characteristics of Parents Affect Parenting

Forces within the parent shape parenting. Even if most parents face the formidable challenges of parenthood with a degree of psychological naiveté, parents do not meet the test totally unprepared. Both biology and culture equip parents to interpret and respond to the tasks of parenting as well as to childhood and its vicissitudes.

Biological Forces That Shape Parenting

Because securing the survival of offspring is an important element underlying evolutionary selection, it is likely that specific brain mechanisms developed to subservise these operations. Animal studies show that the mammalian forebrain plays an important part in the expression of reproductive behavior, one that is different in female and male animals and is reflected in functional and morphologic sex differences in neural forebrain circuitry (Simerly, 2002). The pivotal role of the forebrain in parenting in mammals is further supported by its involvement in the regulation of specific behaviors during nursing and maternal care of offspring (Champagne, Diorio, Sharma, & Meaney, 2001; Corter & Fleming, 2002; Sheehan & Numan, 2002). Imaging studies reveal that mothers show neural activation in limbic forebrain structures in response to infant crying compared with

neutral sounds (Lorberbaum et al., 1999) and bilateral activation of the orbitofrontal cortex while viewing pictures of their own versus unfamiliar infants (Nitschke et al., 2004). Such experience-dependent neuroplastic effects in the human brain are likely to subserve the biological requirements of child care. This can be a critical element in bonding and in securing offspring survival and well-being, thus fostering the reproductive fitness of subsequent generations.

The expression of parental behaviors also depends on hormonal factors that are at least homologous in females and males (Cortez & Fleming, 2002; Reburn & Wynne-Edwards, 1999). For example, increases in prolactin levels have been implicated in the expression of parenting behaviors in female as well as male mammals (Dixson & George, 1982), and, whereas estradiol plays a role in regulating maternal behaviors in female animals, the conversion of testosterone into estradiol is believed to be involved in regulating paternal behavior in male animals (Trainor & Marler, 2001, 2002). Human fathers show different peripheral steroid hormone levels compared with childless men (Storey, Walsh, Quinton, & Wynne-Edwards, 2000).

H. Papoušek and Papoušek (2002) developed the notion that some parenting practices are biologically wired in human beings. Intuitive parenting involves responses that are developmentally suited to the age and abilities of the child and that often have the goal of enhancing child adaptation and development. Parents regularly enact intuitive parenting programs in an unconscious fashion; such programs do not require the time and effort typical of conscious decision making, and, being more rapid and efficient, they utilize less attentional reserve. An example of such intuitive parenting is the use of child-directed speech (M. Papoušek, Papoušek, & Bornstein, 1985). Special characteristics of child-directed speech include prosodic features (higher pitch, greater range of frequencies, more varied and exaggerated intonation); simplicity features (shorter utterances, slower tempo, longer pauses between phrases, fewer embedded clauses, fewer auxiliaries); redundancy features (more repetition over shorter amounts of time, more immediate repetition); lexical features (special forms like “mama”); and content features (restriction of topics to the child’s world). Cross-cultural study attests that child-directed speech is (essentially) universal (Jacobson, Boersma, Fields, & Olson, 1983; Snow, 1977; but see Ratner & Pye, 1984). Indeed, parents find it difficult to resist or modify such intuitive behaviors, even when asked to do so (Trevarthen, 1979). Additional sup-

port for the premise that some interactions with children are intuitive comes from observations that nonparents (males *and* females) who have little prior experience with children modify their speech as parents do when a young child is present and even when asked to imagine speaking to one (Jacobson et al., 1983). When communicating with their children, even deaf mothers modify their sign language the way hearing mothers use child-directed speech (Erting, Prezioso, & Hynes, 1994). Many parenting cognitions and practices are likewise unconscious, habitual, and possibly thoughtless (see Goodnow, 1997; Kuczynski, 1984).

Personality and Parenting

The idea that personality has a significant part to play in parenting is commonsensical: “One cannot take the ‘person’ out of the parent” (Vondra, Sysko, & Belsky, 2005, p. 2). This idea has been acknowledged formally at least since Sigmund Freud (1949; see Cohler & Paul, 2002), and a more contemporary view derived from personality psychology is that some features of parenting might reflect general and stable personality characteristics (Kochanska, Clark, & Goldman, 1997). Bronfenbrenner and Morris (1998) contended that personality factors constitute person “force characteristics” most likely to influence children’s development because personality not only affects parenting directly but also shapes other social contextual factors and forces that influence parenting, including spouse selection, marital relationships, occupational experiences, and friendships and social supports (Belsky, 1984).

Empirical investigators have long connected various forms of psychopathology with impaired parenting (Downey & Coyne, 1990; Rutter & Quinton, 1984). Belsky, Crinic, and Woodworth (1995), for example, reported that neuroticism is a robust predictor of negativity/rejection toward children, and Kochanska et al. (1997) found that mothers high in the personality characteristics of negative emotionality and disagreeableness were rated by observers as being more rejecting of their children (see also L. A. Clark, Kochanska, & Ready, 2000). Whether fleeting, as in response to economic circumstances or even the birth of the baby (Zahn-Waxler, Duggal, & Gruber, 2002), or enduring, depression affects parenting adversely. Depressed mothers fail to experience—and convey to their children—much happiness with life. Such feelings diminish responsiveness or discoordinate interactions (Tronick & Gianino, 1986), and so depressed parenting is thought to have short- as well as long-term consequences for children (Lyons-Ruth, Zoll, Connell, &

Grunebaum, 1986). Field, Healy, Goldstein, and Guthertz (1990) observed that in face-to-face interactions, children of depressed mothers show less positive and more negative facial affect, vocalize less, protest more, and seem to make less effort to change or improve their lot than do children of nondepressed mothers.

Relative to the amount of attention that has been devoted to studying associations between psychological disorders and parenting, the study of “normal” personality and parenting has been neglected (Belsky & Barends, 2002; Vondra et al., 2005). Parenting reflects transient feelings as well as enduring personality traits (Belsky & Barends, 2002). Features of personality favorable to good parenting might include empathic awareness, predictability, nonintrusiveness, and emotional availability (Martin, 1989). Perceived self-efficacy is also likely to affect parenting positively because parents who feel competent are reinforced and thus motivated to engage in further interactions with their children, which in turn provides them with additional opportunities to read their children’s signals fully, interpret them correctly, and respond appropriately. The more rewarding the interaction, the more motivated are parents to seek quality interaction again (Teti & Candelaria, 2002).

Within the normal range, personality characteristics such as self-centeredness and adaptability might be especially pertinent to parenting. For example, adult adaptability would be vital in the first few months, when children’s activities appear unpredictable and their cues undifferentiated, and children themselves generally less readable. Self-centered parents may be less likely to put children’s needs before their own (Dix, 1991). Women who are more preoccupied with themselves, as measured by physical and sexual concerns, show less effective parenting patterns in the postpartum year (Grossman, Eichler, & Winikoff, 1980). Self-absorbed, these mothers may not show sensitivity to their children’s needs (C. P. Cowan & Cowan, 1992), a situation that also seems prevalent among teen mothers (Osofsky, Hann, & Peebles, 1993).

Family of Origin and Parenting

Through intergenerational transmission, via interlocked genetic and experiential pathways, purposefully or unintentionally, one generation influences the parenting beliefs and behaviors of the next (van IJzendoorn, 1992). Fraiberg and her colleagues (Fraiberg, Adelson, & Shapiro, 2003) referred to these influences as “ghosts in

the nursery.” So a parent’s experiences with his or her own parents may have continuing effects on his or her own parenting (Caspi & Elder, 1988; P. K. Smith & Drew, 2002). Mothers who report having had secure and realistic perceptions of their attachments to their own mother, for example, are themselves more likely to have securely attached children (Cummings & Cummings, 2002; Main & Goldwyn, 1984). Ruoppila (1991) found significant correlations between grandparental and parental child rearing in a Finnish sample. Vermulst, de Brock, and van Zutphen (1991) examined parental functioning across generations in a Dutch sample of grandmother-mother dyads. Approximately one-third of the variation in mothers’ parental functioning could be explained in terms of earlier parental functioning of the grandmother. The use of physically aggressive and punitive techniques in the grandparent-parent generation predicts similar behavior in the parent-grandchild generation and antisocial behavior in grandchildren (Farrington, 1993; Murphy-Cowan & Stringer, 1999). Marital violence in the family of origin tends to repeat in the successive generation (Stith et al., 2000). When parents abuse their children, the children are at risk of repeating the pattern as adults with their own children (Cicchetti, Toth, & Maughan, 2000; Newcomb & Locke, 2001; Pears & Capaldi, 2001). Sociological studies and meta-analyses find that adult children whose parents divorced are more likely to end their own marriages in divorce (Amato, 1996; Chase-Lansdale, Cherlin, & Kiernan, 1995). Maritally dissatisfied couples are more likely to have had unhappily married parents (Amato & Booth, 2001; Schneewind & Ruppert, 1998).

The Adult Attachment Interview (AAI; George, Kaplan, & Main, 1985) assesses an adult’s model of his or her own relationship with his or her parents. A strong predictive link has emerged between the child’s attachment with the mother and the mother’s own AAI classification (P. K. Smith & Drew, 2002). Van IJzendoorn (1995) reviewed AAI studies that included 854 parent-child dyads and found 75% concordance between the parent’s autonomous/nonautonomous classification on the AAI and a child’s secure/insecure classification in the Strange Situation. The different components of the person are not equally telling, however. Barends and Belsky (2000) compared the predictive power of three personality traits (Neuroticism, Extraversion, Agreeableness) with that of mothers’ working models of attachment, as measured by the AAI: Personality traits predicted mothering observed under naturalistic condi-

tions in the home better than whether a mother's internal working model of attachment was autonomous, dismissive, or preoccupied.

Age and Stage of Life in Parenting

The contemporary demographics of parturition indicate that the rate of teenage motherhood, though epidemic (421,626 babies in the United States in 2003; Hamilton, Martin, & Sutton, 2004), has been decreasing slightly, as has the birth rate for women in their early 20s. At the same time, increasing numbers of older adult women are delaying conception, extending the age range for pregnancy and birth (Hamilton et al., 2004). These demographic changes might be ascribable to several factors. Among teens, the fear of AIDS and the impact of AIDS-prevention education, the introduction and increased use of new forms of birth control, welfare reform, compulsory education, the rise of a more religious and conservative generation, an economic climate with more opportunities for women, and an array of youth sex education programs that stress both abstinence and contraception may have contributed to the decline (McKay & Carrns, 2004). Similarly, multiple factors operate at the other end of the age continuum. The aging of the baby boom generation translates into greater absolute numbers of women in their late 30s and 40s than in previous decades (Ventura, Martin, Curtin, & Mathews, 1997). Moreover, delayed marriage, the pursuit of advanced education, careerism, and high rates of divorce all can contribute to the decision to postpone childbearing. In addition, advances in birth control have made it possible to delay becoming pregnant, and advances in assisted reproductive technologies (*in vitro* fertilization) have made it possible for older women to become pregnant (Golombok, 2002).

These demographic trends, in turn, raise questions about effects that may obtain between age or stage of life and parenting. The psychosocial impacts of early childbirth are fairly well established. Adolescent mothers experience more pregnancy and delivery problems and have less healthy babies than do adult mothers (Coley & Chase-Lansdale, 1998). Very young mothers are also known to express less desirable child-rearing attitudes and to hold less realistic expectations about child development than older mothers (J. Hardy, Astone, Brooks-Gunn, Shapiro, & Miller, 1998; Moore & Brooks-Gunn, 2002). In general, parenthood at very young ages is associated with less favorable maternal actions toward children (Barratt & Roach, 1995; Coley &

Chase-Lansdale, 1998; Moore & Brooks-Gunn, 2002; Pomerleau, Scuccimarri, & Malcuit, 2003).

The effects of aging on parenting are not so clear-cut. A 35-year-old woman has a 1 in 400 chance of conceiving a child with Down syndrome, and this likelihood increases to 1 in 110 by age 40, and to approximately 1 in 35 by the age of 45 (National Down Syndrome Society, 2000). However, older mothers are more likely to adhere to good diets and gain weight appropriately during pregnancy and to begin prenatal care in the first trimester of pregnancy, and are less likely to smoke during pregnancy. Age is often conceived of as a marker for maturity, perspective, and patience; older adult mothers tend to possess more experience and information and may feel more psychologically ready to assume responsibilities of child rearing. When Garrett, Ferron, Ng'andu, Bryant, and Harbin (1994) created a structural model of the determinants of children's motor and social development, for example, mothers' readiness to be a parent was found to be determined by competency and maturity as measured by her age at childbirth.

Whether and how age relates to parenting cognitions or practices appears to depend on specifics of the assessment. On the one hand, mothers of all ages possess implicit beliefs (Holden & Buck, 2002) and engage in child-directed speech (H. Papoušek & Bornstein, 1992). On the other hand, the more mature, experienced, and well-to-do mothers are, the more appropriate and optimal their parenting cognitions and practices are likely to be. However, on the third hand, it was once standard to believe that optimal childbearing takes place between about 20 and about 30 years of age (Rindfuss & Bumpass, 1978). Rossi (1980) proposed a "timing-of-events" model that suggests that socially off-time childbearing results in decreased social reinforcement and leads to the expectation of curvilinear relations between age and parenting. Thus, having a child when very young or very old might represent "off-time" versus "on-time" variations in the progression through this key phase in the life cycle (Helson, Mitchell, & Moane, 1984; Lowenthal, Thurner, & Chiriboga, 1976; Neugarten, 1968).

Of course, age is a "social address" (Wohlwill, 1973), and more proximal intrapersonal factors may play a more central role in parenting. At present, however, there is no comprehensive theory of women's adult development (Roberts & Newton, 1987). For this reason, age usually stands as a reasonable proxy. We can nonetheless point to some critical developmental phenomena that would help to mark adult caregiving.

Executive functions, for example, coordinate cognitive and metacognitive processes through monitoring and controlling the use of knowledge and strategies (Butterfield, Albertson, & Johnston, 1995). Normally, executive functions include self-regulation, sequencing, flexibility, response and inhibition, planning, and organization of behavior (Denckla & Reiss, 1997; Eslinger, 1996). The orderly approach to problems, maintenance of problem solving sets for future goals, control processes for organizing behavior over time, flexibility and effectiveness of verbal self-regulation, skillful use of strategy, and behaviors that alter the likelihood of later events and behaviors are all executive functions and describe well the requirements of parenting.

Grattan and Eslinger (1992) suggested that cognitive flexibility and perspective-taking ability are cognitive prerequisites to empathic understanding; impulse control, temporal integration, and synthesis of multiple pieces of information are cognitive prerequisites to identity formation; symbolic thinking, weighing alternative possibilities, and considering consequences among alternatives are cognitive prerequisites to moral maturity. Thus, executive functions exert powerful influences on social behavior, and immaturity or impairment of executive function can lead to demanding and self-centered behavior, lack of social tact and restraint, impulsive speech and actions, disinhibition, apathy and indifference, and lack of empathy, all of which are hallmarks of dysregulated parenting.

Pennington, Bennetto, McAleer, and Roberts (1996) further detailed the neuropsychological underpinnings of executive function. The prefrontal cortex and its extended networks are thought to mediate executive functions, and they show the most prolonged course of postnatal development of any region of the human brain, with changes in synaptic density detectable even into the teenage years (Huttenlocher, 1990). Giedd et al. (1999) also showed that increases in white matter continue through adolescence into early adulthood, particularly in frontal brain regions. Notably, individuals with localized injury to the prefrontal lobe display poor parenting (Eslinger, Grattan, Damasio, & Damasio, 1992). Consider patient DT, who

proved unable to anticipate and meet her child's needs, such as planning meals, changing clothing, and providing nurturance and comfort. . . . Her performance has . . . been erratic, impulsive, and marked by poor follow through on required tasks, failure to learn from mistakes,

and very negative reactions to criticism. . . . [She has] very limited capacity for empathic understanding, inadequate identity development, difficulties in vocational adjustment, and a concrete level of moral reasoning. (Grattan & Eslinger, 1992, p. 185)

DT shows how a profound and devastating lack of executive functions undermines parenting in an individual who otherwise possesses normal motor and sensory functions and a broadly normal range of intellectual performance, perceptual abilities, language, and memory.

Characteristics of Children Affect Parenting

Subtle as well as not so subtle characteristics of children also influence parenting (Hodapp & Ly, 2005; Karraker & Coleman, 2005). Some "child effects" are universal and common to all children; others are unique to a particular child or situation. Children actively select, modify, and create their own environments, including their parenting (Bell, 1968, 1970; Scarr & Kidd, 1983). An experimental study by Anderson, Lytton, and Romney (1986) paired conduct-disordered boys with mothers of conduct-disordered boys and with mothers of normal boys. Conduct-disordered boys elicited negative parenting practices from both sets of mothers. Clearly, in this experimental setting (which controls for genetic effects), characteristics of the child contributed to the type of parenting displayed. A reciprocal effect or transactional model, which asserts that parenting not only affects child behavior but that child behavior also affects parenting, contemporaneously prevails in parenting theory and research.

Some physical features of children likely affect parents everywhere, perhaps in similar ways. By the conclusion of the first trimester, fetuses are felt to move in utero ("quickening"), and soon after (with support) fetuses may survive outside the womb ("viability"). These are significant markers in the life of the child *and* in the lives and psyches of the child's parents. Similarly, after birth, common child characteristics likely influence parenting. The newborn has a large head dominated by a disproportionately large forehead, widely spaced sizable eyes, a small snub nose, an exaggeratedly round face, and a small chin. The ethologist Lorenz (1935/1970) argued that these physiognomic features of "babyishness" provoke adults to express nurturant reactions—even across different species (Alley, 1981, 1983). And from the moment of birth, babies exercise many effective sig-

nals that influence parenting: Crying motivates adults to approach and soothe, for example, and smiling encourages adults to stay near (Ainsworth et al., 1978).

Other structural characteristics of children affect parenting and the quality of parent-child interaction; child health status, gender, and developmental age are three significant factors. Preterm children, for example, often have difficulty regulating engagements with parents, as evidenced in increased gaze aversion, decreased play, and lower levels of joint attention, and, reciprocally, their mothers are more active and directive (Goldberg & DiVitto, 2002). Although there is evidence that parenting girls and boys is surprisingly similar in many ways (Leaper, 2002; Lytton & Romney, 1991), child gender organizes parents' descriptions, impressions, and expectations of children from the start of life (Condry & Condry, 1976; J. Z. Rubin, Provenzano, & Luria, 1974): Newborn nurseries provide color-coded blankets, accessories, and so forth; baby showers are carefully adorned with regard to sex; and children are fastidiously dressed in sex-typed clothing (Shakin, Shakin, & Sternglanz, 1985). Mondschein, Adolph, and Tamis-LeMonda (2000) found that mothers of 11-month-old males overestimated how well their babies would crawl down a sloped pathway, whereas mothers of 11-month-old females underestimated how well their babies would do, but subsequent tests of crawling ability on the sloped path revealed no sex differences in infant crawling. Finally, stage of child development per se exerts pervasive control over parental behavior. Cross-cultural study shows that mothers of younger children use more affect-laden speech, but that, as children achieve more sophisticated levels of motor exploration and cognitive comprehension, mothers increasingly orient, comment, and prepare children for the world outside the dyad by increasing amounts of information in their speech (Bornstein et al., 1992). Similarly, children's achieving the ability to stand upright and walk alters the nature and quality of parenting (Biringen, Emde, Campos, & Appelbaum, 1995). With each child advance, parenting changes in some corresponding ways.

Idiosyncratic characteristics of individual children are no less stimulating to parents. Goldberg (1977) taxonomized three salient child characteristics that affect parents: responsiveness, readability, and predictability. Responsiveness refers to the extent and quality of child reactivity to stimulation. Readability refers to the definitiveness of child behavioral signals. Predictability refers to the degree to which child behaviors can be anticipated reliably. Each child possesses his or her unique profile of

these characteristics that will influence parents. For example, an "easily read" child produces unambiguous cues that allow parents to recognize the child's state of arousal quickly, interpret signals promptly, and thus respond contingently. Having a temperamentally easy child or perceiving a child as temperamentally easy (relatively happy, predictable, soothable, and sociable) enhances a mother's feelings of competence (Deutch, Ruble, Fleming, Brooks-Gunn, & Stangor, 1988).

Childhood is also change, and every child changes at his or her own rate. Understanding, anticipating, and responding to dynamic change in the context of individual variation challenge parents. Parents need to know about and be vigilant to all the complications and subtleties of child development. Child development involves parallel and rapid growth in biological, psychological, and social spheres, and normal development may be nonlinear in nature, stalling sometimes, or even regressing temporarily (Bever, 1982; C. C. Harris, 1983; Strauss & Stavey, 1982).

Every child is an original. Parenting a child is thus akin to trying to judge a moving target, the ever changing child developing in fits and starts at his or her own pace. Interest in the origins and expression of child-to-child variability occupies a central position in parental thinking about child development. The ages at which individual children might achieve a given developmental milestone typically vary enormously (some children say their first word at 9 months, others at 29 months), just as children of a given age vary dramatically among themselves on nearly every index of development (at 1 year, some toddlers comprehend 10 words, others 75). Of course, when and how their children talk or achieve puberty exercises strong psychological and behavioral impacts on parents.

A major problem faced by parents is that, at base, they are constantly trying to divine what is inside their child's head: what children want, what they know, how they feel, what they will do next vis-à-vis the things and people around them. Thus, parents seem constantly in search of patterns, often inferring them on the basis of single transient events.

Contextual Characteristics Affect Parenting

In addition to biology, personality, and children, social and societal factors condition and channel beliefs and behaviors of parents. Family structure, social support

networks, socioeconomic class, and culture, for example, encourage or discourage diverse patterns of parenting principles and practices. It is also important to recognize that child-rearing cognitions and practices evolve and change (Bronfenbrenner, 1958; French, 2002), and the attitudes and actions of parents at any one time may differ from those characteristic of parents of different generations.

Family Structure and Parenting

Parenting is influenced by family configuration, among other social situational factors. One of the more dramatic changes in family dynamics is the one that takes place when a second baby is born (Mendelson, 1993; Stewart, 1991); consequently, the social and physical ecologies of first- and later-borns differ (Dunn & Plomin, 1990). Parents treat their second-born children in many ways differently than they treat their first-born children (Sulloway, 1996). Mothers engage, respond, stimulate, talk, and express positive affection more to their firstborns than to later-borns, even when first- and later-borns show no differences in their behavior, indicating that these maternal behaviors do not reflect child effects (Belsky, Gilstrap, & Rovine, 1984). However, mothers are also prone to rate their firstborns as more difficult (J. E. Bates, 1987), which may derive from the fact that firstborns actually are more difficult children, or alternatively, because first-time mothers are less at ease with their children and thus tend to perceive them as more demanding. Reciprocally, multiparas report higher self-efficacy than primiparas (Fish & Stifter, 1993).

The same parents may treat their children in different ways for a multitude of reasons. Dunn (1995), Plomin (1994), and their colleagues (Hetherington, Reiss, & Plomin, 1994) have drawn attention to the importance of understanding variation in parent-child relationship quality within families. Parents may treat children in the same family differently because children differ in age, cognitive level, personality characteristics, sex, or other personal experiences. Combined with variation in genetic makeup, within-family variation in parental treatment is a potent factor in accounting for why children in the same family differ from one another (Dunn & Plomin, 1990; Hetherington et al., 1994).

Social Network and Parenting

Having a baby is a major transition in a person's life, marked by dramatic changes in information seeking,

self-definition, and role responsibility (Belsky, 1984; C. P. Cowan & Cowan, 1992). Integration or isolation from potential support networks mitigates or exacerbates parenting (Cochran & Niego, 2002). Social support refers to the psychological and tangible resources available to individuals through their relationships with family, friends, neighbors, work associates, and others (Cutrona & Suhr, 1990; Cutrona & Troutman, 1986; Jennings, Stagg, & Connors, 1991). Crockenberg (1988) taxonomized social support as emotional, instrumental, or informational. Both informal support systems (the extended family) and formal ones (schools, child care, parent education programs, and professionals) influence parenting (Cochran & Niego, 2002; Cotterell, 1986; Crockenberg, 1988; Jennings et al., 1991). Lee and Colletta (1983) studied support-parenting relations in adolescent parents with young children. Mothers who were satisfied with their support reported that they were more affectionate with their children, whereas mothers who were dissatisfied with their support reported more hostility, indifference, and rejection of their children. More child care support is associated with higher-quality face-to-face interactions between mothers and babies (Levine, Garcia Coll, & Oh, 1985). Levitt, Weber, and Clark (1986) confirmed the importance of support from the spouse for mothers' well-being in intact families and extended the impact of that support to differences in the infant-mother relationship. Emotional and child care support from the spouse, but not from other family members, are associated with greater life satisfaction and more positive maternal affect. In fact, intimate support from husbands appears to have the most general positive consequences for maternal competence (Crnic, Greenberg, Ragozin, Robinson, & Basham, 1983). Mothers' social support moderates the effects of daily hassles of parenting (Crnic & Greenberg, 1990): Socially supported mothers are less harried and less overwhelmed, have fewer competing demands on their time, and as a consequence are more available to their children.

A generalized benefit of social support could occur because large social networks provide mothers with regular positive experiences and a set of stable, socially rewarded roles in the community. This kind of support could be related to overall well-being because it provides for positive affect, a sense of predictability and stability in one's life situation, and recognition of self-worth. Members of support networks teach and encourage parents to use more developmentally appropriate caregiving (Bronfenbrenner & Crouter, 1983;

Tolson & Wilson, 1990). A critical question in this literature is whether it is the objective amount of support available to a parent that is important, or parents' perceptions of that support. Hashima and Amato (1994) found in a nationally representative sample that mothers' perceived social support was negatively associated with punitive and other negative parenting behaviors. Another question in this literature relates to the nature and source of support. To establish social support networks for information about child rearing, middle-class American parents typically consult professionals, books, and magazines, as well as relatives and friends (Clarke-Stewart, 1998; Young, 1991). Mothers in other social classes and cultures vary from this mode of data collection, however.

Socioeconomic Status and Parenting

Socioeconomic status (SES) is influential in parenting (Bornstein & Bradley, 2003). Mothers in different SES groups behave similarly in certain ways; however, SES also orders the home environment and other practices of parents toward children (Bornstein, Hahn, Suwalsky, & Haynes, 2003; Hoff, Laursen, & Tardif, 2002). SES-related variation in parenting has diverse effects, as in the likelihood that parents serve their children spinach and read books on child care (Hoff et al., 2002). Large numbers of new mothers in the United States have not finished high school, are not married, or are only teenagers themselves when their babies are born.

Parental education is a key factor in SES (Bornstein et al., 2003). Lower-SES mothers refer to books or other written materials less readily as sources of information about child rearing and child development, whereas middle-SES mothers report that reading material is their primary source of information (Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989; Hofferth, 1987; Young, 1991), and they seek out and absorb expert advice about child development (Lightfoot & Valsiner, 1992). Parents with more education possess more formal knowledge about child development norms and theories and about child-rearing practices (Conrad, Gross, Fogg, & Ruchala, 1992; MacPhee, 1981; Palacios & Moreno, 1996; Parks & Smeriglio, 1986). Not surprisingly, parent education links to many child health and psychosocial outcomes (E. Chen, Matthews, & Boyce, 2002; J. R. Smith, Brooks-Gunn, & Klebanov, 1997). When Duncan and Brooks-Gunn (1997) statistically controlled for household income and other demographic characteristics, they still found that higher levels of ma-

ternal education were associated with better cognitive and educational outcomes in children.

Conversely, low SES and poor education are risk factors in parenting and children's development on many accounts. Low SES adversely affects mothers' psychological functioning and is associated with harsh or inconsistent disciplinary practices (McLoyd, 1998; Simons, Whitbeck, Conger, & Wu, 1991). Low- compared to middle-SES parents typically provide children fewer opportunities for variety in daily stimulation, less appropriate play materials, and less total stimulation (A. W. Gottfried, 1984). Significantly, middle-class mothers converse with their children more, and in systematically more sophisticated ways, than do working-class mothers (Hart & Risley, 1995; Hoff, 2003). These social class differences in maternal speech to children are pervasive: In Israel, for example, upper-class mothers talk, label, and ask "what" questions more often than do lower-middle-class mothers (Ninio, 1980). Higher-SES mothers' encouragement in language undoubtedly facilitates self-expression in children; higher-SES children produce more sounds and later more words than do lower-SES children (Hart & Risley, 1995; M. Papoušek et al., 1985). Parents in higher socioeconomic strata also change more flexibly and more rapidly in response to changes in developmental theory than do parents in lower socioeconomic strata (Bronfenbrenner, 1958). Lower-SES parents believe they have less control over the outcome of their children's development than do higher-SES parents (Elder, Eccles, Ardelt, & Lord, 1995; Luster, Rhoades, & Hass, 1989). Kohn (1963, 1969, 1979) hypothesized that social class differences in fathers' goals and expectations for their children, for example, were related to differences in the requirements and expectations fathers needed to succeed in their jobs.

Overall, financial and social stresses adversely affect the general well-being and health of parents and demand attention and emotional energy from them (Magnuson & Duncan, 2002). In McLoyd's (1998) analysis, great stresses on impoverished parents stemming from the day-to-day struggle to find the resources to pay for food and rent, and the stresses of trying to cope with living in crowded housing and deteriorated, dangerous neighborhoods undermine parenting skills and contribute to disorganizing family life. These circumstances, in turn, may reduce parents' attentiveness, patience, and tolerance toward children (Crnic & Low, 2002). McLoyd found that the deterioration of parenting is responsible for many of the adjustment difficulties of children growing up in

impoverished families (see Conger, Ge, Elder, Lorenz, & Simons, 1994). The effects of parental poverty appear to depend on the age and sex of the child, however (Elder, 1974), and parenting in the upper class is not immune from disadvantage either (Luthar, 2003).

Culture and Parenting

Like social class, culture pervasively influences how parents view parenting and how they parent (Bornstein, 1991, 2002c; Harkness & Super, 1996, 2002; LeVine, 2003). Cultural variation in beliefs and behaviors is always impressive, whether observed among different ethnic groups in one society or among groups in different parts of the world. In some cultures, children are reared in extended families in which care is provided by many relatives; in others, mothers and babies are isolated from almost all social contexts. In some groups, fathers are treated as irrelevant social objects; in others, fathers assume complex responsibilities for children. Baumrind's (1967, 1978, 1989) work defined a typology of middle-class European American approaches to parenting children as mixes of control and responsiveness and linked the approach to child outcomes. Other socioeconomic, ethnic, or cultural groups in the United States have different approaches to parenting and value different outcomes (Steinberg, Dornbusch, & Brown, 1992; Steinberg, Mounts, Lamborn, & Dornbusch, 1991). The majority of research in parenting refers to Western psychological traditions and has not situated parenting by specific ethnic groups or within specific cultural traditions. Parenting clearly varies in meaningful ways across ethnicity and culture, however.

Culture influences parenting and child development from very early in life in terms of when and how parents care for children, the extent to which parents permit children freedom to explore, how nurturant or restrictive parents are, which behaviors parents emphasize, and so forth (Benedict, 1938; Whiting, 1981). For example, Japan and the United States maintain reasonably similar levels of modernity and living standards and both are child-centered societies, but the two differ dramatically in terms of history, beliefs, and child-rearing goals (Azuma, 1986; Bornstein, 1989b; Caudill, 1973). Japanese mothers expect early mastery of emotional maturity, self-control, and social courtesy in their offspring, whereas American mothers expect early mastery of verbal competence and self-actualization in theirs. American mothers promote autonomy and organize social interactions with their children so as to foster phys-

ical and verbal assertiveness and independence, and they promote children's interest in the external environment. Japanese mothers organize social interactions so as to consolidate and strengthen closeness and dependency within the mother-child dyad, and they tend to indulge children (Befu, 1986; Doi, 1973; Kojima, 1986).

Culturally defined beliefs are so powerful that parents sometimes act on them as much as or more than on what their senses tell them about their own children. Parents in Samoa, for example, reportedly think of young children as having an angry and willful character, and, independent of what children might actually say, parents consensually report that their children's first word is *tae*, Samoan for "shit" (Ochs, 1988). Likewise, an investigation of expected developmental timetables in new mothers from Australia and Lebanon showed that culture shapes mothers' expectations of children much more than other factors, such as experiences observing their own children, comparing them to other children, and receiving advice from friends and experts (Goodnow, Cashmore, Cotton, & Knight, 1984).

Although social science sometimes succumbs to the mistaken tendency to lump ethnicity and culture, research shows that each is heterogeneous, and across cultures and across subgroups within the same society, different parenting cognitions, different parenting practices, and (not unexpectedly) different patterns of child outcomes prevail (Ogbu, 1993; Stevenson & Lee, 1990).

Ethnic and cultural differences notwithstanding, parents also show striking commonalities in interacting with their children. All must nurture and promote the physical growth of children if their children are to survive (Bornstein, 2002b; LeVine, 2003). Some similarities may reflect biological bases of caregiving, the historical convergence of parenting styles, or the increasing prevalence of a single child-rearing pattern through migration or dissemination via mass media. In the end, different peoples presumably wish to promote some similar general competencies in their young as well as some culture-specific ones. Even where ultimate goals may be similar, however, cultures may differ in proximal ways to achieve them (Bornstein, 1995).

Methodological Note

The literature concerning endogenous and exogenous sources of influence on parenting is rich (R. M. Lerner, Rothbaum, Boulos, & Castellino, 2002). Typically, however, antecedents to parenting have been studied in iso-

lation, and few investigations evaluate multiple influences simultaneously. Thus, the overlap of different antecedents vis-à-vis the unique contribution that any one may make to parenting remains essentially unexplored. For example, parent age may exert important effects on parenting and on children because people who have children at an early age are more likely to have preexisting problems that in turn affect their parenting and their children. Younger parents are likely to have less education (Baldwin & Cain, 1981; Elster, McAnarney, & Lamb, 1983; Luster & Dubow, 1990) and to come from poorer families (Haveman, Wolfe, & Wilson, 1997). With this in mind, family systems theorists have emphasized the importance of considering the possible independence *and* interdependence of organismic, environmental, and experiential determinants of parenting (see Belsky, 1984; Bornstein, 2002b; Bornstein & Sawyer, 2005; Bronfenbrenner & Morris, 1998; R. M. Lerner et al., 2002; Minuchin, 1985).

Summary

To understand variations in parenting, information about multiple domains is required (P. A. Cowan, Powell, & Cowan, 1998), including biological and psychological characteristics of each individual in the family, the quality of relationships in parents' families of origin, the quality of the relationship between parents, their division of roles, communication patterns, and coparenting, the quality of relationships between parents and each child, and relationships between nuclear family members and key individuals or institutions outside the family (friends, peers, work, child care, school, ethnicity, culture). Parenting stands at the confluence of many complex tributaries of influence; some arise within the individual, whereas others have external sources in the child, in the society, and in the culture.

PARENTING EFFECTS AND THEIR MULTICAUSAL CONTEXT

“As the twig is bent, so grows the tree.” “The apple does not fall far from the tree.” These sayings reflect the belief (some would say assumption) that parental ideas and actions, and the environments parents create, give rise to differences in children. (The agrarian metaphor for parenting is especially pervasive, stretching as it does from “kindergarten” to “culture.”) Much of the early lit-

erature on “parenting effects” built up as a natural consequence of this way of thinking, and much of it used parent-child correlations as its evidentiary base. However true it may be that parents influence children, we recognize that correlation does not prove causation, that the arrow of influence may run in the opposite direction (*viz.*, that children influence parents), and that children's characteristics could be a product of some third familial or extrafamilial factor. There follows next brief comment on parenting effects constructed on correlational designs and thereafter an extended discussion of more powerful and robust approaches to parenting effects. This section concludes with a review of complementary information from behavior genetics and group socialization theory.

Correlational Designs

By some reckoning, parenting is believed to account for 20% to 50% of the variance in child outcomes (Conger & Elder, 1994; Kochanska & Thompson, 1997; Reiss, Neiderhiser, Hetherington, & Plomin, 1999). For example, Patterson and Forgatch (1995) found substantial correlations between parents' disciplinary and monitoring practices and children's negative, coercive behavior both at home and in out-of-home contexts. Chilcoat and Anthony (1996) showed a significant increase in risk of drug sampling for every unit of decrease in parental monitoring after partialling age, sex, and ethnic status.

Most studies of parents and children are correlational in design, the resultant associations have usually been modest, and early advocates sometimes overstated their implications. In actuality, the sizes of zero-order correlations between parent cognitions or practices and child characteristics vary considerably depending on what parent and child variables are considered, the way they are measured, the length of time between predictive and outcome measurements, which analyses are used to investigate the questions, which kinds of children or families living in which circumstances are studied, and whether background variables are statistically controlled. For example, direct behavioral observations yield large effect sizes for environmental associations with social development, whereas parental reports yield small effect sizes. It is not reasonable to expect generalizations about the nature and effects of specific parent-child interactions to span all the ages/stages and domains of child development. Parents foster the development of specific talents (e.g., by providing sports

practices) and can influence some activities (e.g., religious beliefs), but may have less influence on others. Research that includes a broader array of parenting attributes and focuses on parenting processes tends to show more robust findings.

Gene-Environment Interactions

Contemporary parenting research has moved beyond a focus on main effects of parenting toward understanding more complex interactions between individuals and their environments. Interactions emerge when a given environment has different effects on an organism depending on the organism's traits. Tienari, Wynne, Moring, Lahti, and Naarala (1994) contrasted children with a schizophrenic biological parent with adopted children who did not carry this risk factor to illustrate how a predisposition can either manifest itself or not, depending on whether certain triggering environmental conditions are present. Adoptees who had a schizophrenic biological parent were more likely to develop a range of psychiatric disorders (including schizophrenia) than adoptees not at risk, but only if they were adopted into dysfunctional families. Bohman (1996) studied adopted children whose biological parents did or did not have a history of criminality. Among adoptees who carried a risk factor from their biological parents, those who had been adopted into dysfunctional homes were much more likely to become criminals than those whose adoptive parents provided stable and supportive environments.

An implicit assumption in parenting studies is that the effects of equivalent parenting are similar for all children. However, studies that pool parenting effects across children with different temperaments might obscure parental effects. There is no reason to expect that a given parenting cognition or practice exerts the same effect on every child. A given parental cognition or practice might have different effects on children with different temperaments. For example, Kochanska (1995, 1997) found that maternal responsiveness and the formation of a close emotional bond with the child fostered the development of conscience in bold, assertive children, whereas maternal gentle child-rearing techniques that de-emphasized power assertion were more effective with shy, temperamentally fearful children.

Experiments

Experimental manipulations help to advance beyond parent-child correlations and interactions to reveal

causality. The strongest statement that could be made about parenting effects would be based on experimental treatments or interventions in which parents are assigned randomly to treatment/intervention versus control groups, with resulting changes in the behaviors of both the parents and their otherwise untreated children in the experimental groups. Such experiments show (a) that the intervention alters parenting in the experimental group, (b) that there are no changes in the comparison group, and (c) that change in the mediating mechanisms in the parent effects change in the child.

Animal Studies

When young rhesus monkeys with different reactivity patterns are cross-fostered to mothers that are either reactive or nonreactive, their adult behavior differs from that shown by the biological offspring of reactive and nonreactive mothers (Suomi, 1997). Genetically reactive young animals that are raised by nonreactive mothers for the first 6 months of their lives and then placed in large social groups made up of peers and nonrelated older adults develop normally and rise to the top of their dominance hierarchy. These cross-fostered animals are also adept at avoiding stressful situations and at recruiting social support that enables them to cope with stress. By contrast, reactive animals that are raised by reactive mothers are socially incompetent when placed in the larger living group at 6 months of age and are particularly vulnerable to stress.

Natural Experiments with Human Beings

Studies of children with genetic backgrounds that differ from those of their nurturing families provide a means of simultaneously evaluating the impacts of heredity and experience on child development (H. Z. Ho, 1987; Plomin, 1990; Plomin & DeFries, 1985). In (ideal) natural experiments of adoption, one child shares genes but not environment with biological parents, and another child shares environment but not genes with adoptive parents. In France, children were located who had been given up in infancy by their low-SES parents and adopted by upper-middle-SES parents. These children all had biological siblings or half-siblings who remained with their biological mother and were reared by her in impoverished circumstances. No selective factors differentiated the two groups. When tested in middle childhood, the adopted children's IQs averaged significantly higher than those of their natural siblings, and children who remained with their biological mother were more likely to exhibit failures in school performance (Duyme, Dumaret, & Stanis-

law, 1999; Schiff, Duyme, Dumaret, & Tomkiewicz, 1982). Similarly, the Colorado Adoption Project included assessments of rates of communicative development in groups of children either born or adopted into intact families. The language competencies of children correlated with their biological mother's verbal intelligence even though they had not seen their mother since birth. However, adoptive mothers' parenting activities, especially imitating their children's vocalizations and vocalizing contingently to their children's vocalizations, also predicted child language competencies (Hardy-Brown, 1983; Hardy-Brown & Plomin, 1985; Hardy-Brown, Plomin, & DeFries, 1981). These results point to roles for *both* genetics and parenting in child development.

Parenting Interventions

Forgatch (1991) advocated the interpretation of intervention trials as experimental manipulations that test theoretical models of parenting. In interventions to improve the behavioral-training skills of parents of non-compliant children, Forehand and colleagues (Forehand & King, 1977; Forehand, Wells, & Griest, 1980) demonstrated both improvements in parental behavior and behavioral changes in children, as well as increased parental perceptions of improved child behavior and decreased parental depression. Similarly, Belsky, Goode, and Most (1980) found that interventions to increase mothers' didactic interactions with their young children during play resulted in significantly higher exploratory play among children compared to a no-treatment control group. Van den Boom (1989, 1994) demonstrated that an intervention to train lower-class mothers to respond sensitively to their children modified both their negative responses to child irritability and reduced the extent of avoidant attachment in distress-prone children. Dishion, Patterson, and Kavanagh (1992) showed that the reduction of parent-to-child coercive behavior, brought about by a parent-training intervention with a randomly assigned experimental group, produced declining levels of antisocial behavior in aggressive children. P. A. Cowan, Cowan, Ablow, Johnson, and Measelle (2005) observed that parents' participation in classes on effective parenting just prior to their children's kindergarten entry resulted in better school adjustment and higher academic achievement for children in kindergarten and first grade, compared to the children of parents who attended a comparable series of discussion groups without the effective-parenting emphasis. The relative advantage for the children of intervention-group parents persisted through age 10, a period of 6 years.

Studies that randomly assign families to treatment or control groups and that intervene with the parents but do not simultaneously treat the children are rare, but several have shown that, when treatment is able to change parental behavior toward children in specified ways, the behavior of children changes correspondingly. Such experimental studies document that changes in parenting predict changes in children's school adjustment (Forgatch & DeGarmo, 1999), aggressive behavior (Patterson, Dishion, & Chamberlain, 1993), behavior management (Webster-Stratton, 1990), and attachment (P. A. Cowan et al., 1998; Heinicke, Rineman, Ponce, & Guthrie, 2001).

With these sources of data in mind, it is surprising that some critics contend that there is still little compelling evidence that parents influence the psychological functioning of children or adolescents but, rather, that heredity and peers do so. It is illogical and non-scientific to assert the preeminence of one cause over another when each in its own way contributes to an effect. The enterprise is really to understand how these several forces work in concert to shape the developing individual. The following discussion cumulates over the hard-won knowledge of several critiques (see Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; R. M. Lerner et al., 2002; Maccoby, 2000; Vandell, 2000).

The arguments for genetic and social influences on child development complement our understanding of parenting and the effects of parenting.

Behavior Genetics

Behavior genetics seeks to understand biological sources of variation in human characteristics. By studying individuals of varying genetic relatedness (identical and fraternal twins, biological and adopted siblings who live or do not live in the same households), behavioral geneticists attempt to estimate the amount of variation (the heritability; h^2) in characteristics explained by genetic factors. They assume that sources of variation in a characteristic can be separated into independent genetic (G) and environmental (E) components that together (with error variance) add to 100% of the variance in a characteristic. (Note: E is often not directly measured, but estimated as the residual variance not accounted for by G; Caspi, Taylor, Moffitt, & Plomin, 2000.) However, G and E do not play a zero-sum game (Block, 1995; Feldman & Lewontin, 1975; Gottlieb, 1995; Rose, 1995; Turkheimer, 1998).

Furthermore, some behavioral genetic research contends that (a) genetic endowment accounts for child characteristics better than socialization; (b) children with different genetic predispositions elicit different reactions from their parents; and (c) nonshared environments (conceptualized as experiences in and out of the family that result in differences among individuals) play a greater part in child development than shared factors (such as parenting). However, a full consideration of this literature reveals limits on its claims.

1. Heritability can be high at the same time environmental forces are at work. Some environmental factors affect a group or population without altering the rank order of individuals within the group. The prevailing ecological perspective on human development “stresses the interactive and synergistic, rather than additive and competitive, nature of the links between the family and other influences” (Collins et al., 2000, p. 227). Everything that human beings are or do is a joint function of both their genes and their life experiences (Elman et al., 1996).
2. Correlations between child characteristics and parenting reflect genetic linkages between parent and child characteristics but also bidirectional interactive processes. Behavior genetics assigns both child and parent parts of parent-child covariances to the genetic component in the $G + E = 100\%$ equation. It may be that the child’s part in parent-child covariance (i.e., evocative effects) is genetic, but assigning the parent contribution to genetics is questionable (Maccoby, 2000). Behavior genetics ignores parent-child reciprocal influences. In a developing and unfolding relationship such as the one between a parent and a child, the child influences the parent and the parent influences the child. Parenting is influenced by child characteristics, but parents contribute to child characteristics as well.
3. Behavior genetic designs show parenting effects. Horn (1983) reported that the mean IQ of adopted children was the same as the mean IQ of their adoptive parents, and significantly higher than the mean IQ of their biological parents. This effect presumably follows from how adoptive parents caregive. O’Connor, Deater-Deckard, Fulker, Rutter, and Plomin (1998) identified two groups of adoptees: one at genetic risk for antisocial behavior (i.e., a history of antisocial behavior in the biological mother) and the other not at risk. At several points during the adoptees’ childhood, they assessed both the children’s characteristics and the adoptive parents’ child-rearing methods. Children carrying a genetic risk for antisocial behavior were more likely to receive negative socialization inputs from their adoptive parents, but parental negative behavior made an independent contribution to children’s externalizing, over and above the children’s genetic predispositions. Neiss and Rowe (2000) found that parents’ education was significantly (if modestly) associated with adopted adolescents’ verbal IQ.
4. Behavior genetics assumes that parenting is a shared experience for siblings, and because shared environment effects have sometimes proven to be small, parenting effects must be small. However, parents do not behave toward all their children in the same way, parenting is not perceived by all children in the same way, and parenting does not affect all children in the same way. Twin data support the hypothesis that family environments make a substantial contribution to the child’s development (Plomin, 1994; Reiss, 1997). Nonshared environmental effects refer to the influence of events specific to an individual’s life, such as illness or particular friends, which are not shared by other family members. Behavioral geneticists have offered two suggestions to account for individual variation among siblings. The first is within-family environmental differences (Dunn & Plomin, 1990; Hoffman, 1991), and the second is differential experience outside the home (J. R. Harris, 1995, 1998; Rowe, 1994). To the extent that siblings perceive differential parental treatment, they experience different environments, which increases the likelihood that they also develop differently in important aspects of intellect and personality compounding genetic dispositions. Genes contribute to making siblings alike, but (as we all recognize) siblings are normally very different from one another, and it is widely held that siblings’ different experiences (their nonshared environments) in growing up contribute to making them distinctive individuals (Dunn & Plomin, 1990; Plomin & Daniels, 1987). Even within the same family and home setting, parents (and other factors) help to create distinctive and effective environments for their different children (Stoolmiller, 1999; Turkheimer & Waldron, 2000).
5. Heritability estimates are themselves often indeterminate and variable:

- The genetic contribution might be greater for some human attributes (intellect) than for others (religion).
 - Estimates of the size of the genetic contribution vary depending on the source of information for measuring a trait. Cadoret, Leve, and Devor (1997) reported a range of heritability coefficients for aggressive behavior from .00 for observational studies to .70 for parent-report measures. In a meta-analysis of 24 twin and adoption studies, Miles and Carey (1997) reported substantially greater h^2 values based on parent reports than for those based on adolescent self-reports.
 - Genes function differently in different environments.
 - Meta-analyses show that heredity rarely accounts for as much as 50% of the variation among individuals in a particular population (McCartney, Harris, & Bernieri, 1990).
 - Estimates derived from twin studies might overestimate the genetic contribution because identical twins have more similar environments than do with same-sex fraternal twins.
6. The child outcomes that are the focus of most heritability studies are intelligence and personality, but contemporary parenting studies are concerned with a much broader range of questions. The case for parental influence may be great, for example, for aspects of children's learned behavior. Children's fruit and vegetable consumption is shaped not just by children's taste preferences, but also by their mother's nutritional knowledge, her attitudes about the health benefits of eating more produce, and by her own consumption of fruit and vegetables (Galloway, Fiorito, Lee, & Birch, 2005).
 7. Parents' concerns are not only the "final product" of their parenting. They live with their children and are involved in quotidian processes of parenting and cope with a constantly changing set of child-rearing challenges. The upbringing of children is also highly emotional for both parents and children (Pomerantz, Wang, & Ng, 2005). These concerns of parenting are not addressed by behavioral genetics or other approaches to parenting that look only at child outcomes.
 8. In behavior genetic twin and adoption studies, degree of biological relatedness between individuals, not specific markers of genetically linked char-

acteristics in the two individuals, is often the primary focus, and variations in environments are infrequently assessed.

Group Socialization Theory

Many researchers have observed that peers exert a strong environmental influence on individual psychological functioning in children.

Lewin (1947) theorized that we change when we participate in peer group interaction, and J. R. Harris (1995, 1998) used this view as a platform from which to assert that experience outside the home, and especially within the peer group, constitutes the major environmental source of influence on development in children. According to J. R. Harris (1995, p. 463), group socialization affects children's behavior, language, cognitions, emotions, and self-esteem, whereas dyadic relationships with parents, teachers, and mentors have minimal effects on these psychological characteristics or functioning in adulthood. However, several counterarguments to this radical proposition mitigate its claims:

1. Parents and peers actually exert joint influences on the developing child (Brown, Mounts, Lamborn, & Steinberg, 1993; Cairns & Cairns, 1994; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Fuligni & Eccles, 1993; Mounts & Steinberg, 1995).
2. The proclivity in individuals to select like-minded peers (Berndt, 1999; Berndt, Hawkins, & Jiao, 1999) might account for observed similarities between children and their friends across a wide array of variables, including school achievement (Epstein, 1983), aggression (Cairns, Cairns, Neckerman, Gest, & Garipey, 1988), internalized distress (Hogue & Steinberg, 1995), and drug use (Kandel, 1978). Children are not randomly assigned to peer groups; rather, parents and parent-child relationships influence which peers children select.
3. Group socialization may apply to some everyday behaviors and transient attitudes but not to enduring personality traits or values (Brown, 1990).
4. Children vary in their susceptibility to peer influence, and parenting might be a major source of their differential susceptibility. Of course, infants and very young children are hardly exposed to meaningful peer influence.

Social relationship theory posits that multiple relationships are important to children because they meet

different developmental needs (Howes, Hamilton, & Phillipson, 1998; Ladd, Kochenderfer, & Coleman, 1997; MacKinnon-Lewis, Starnes, Volling, & Johnson, 1997; Vandell & Wilson, 1987; Vondra, Shaw, Swearingen, Cohen, & Owens, 1999; Wentzel, 1998). Parents may serve as a source of love, affection, security, protection, advice, and limit setting. Siblings may offer opportunities related to social understanding, conflict management, and differential status. Peer friendships provide mutual commitment, support, and trust. Teachers and nonparental caregivers of young children often act similarly to parents, whereas teachers of older children may be influential for their expertise and access to opportunity. In the end, J. R. Harris (1995) conceded:

It is important to note that [group socialization theory] does not imply that children can get along without parents. Children are emotionally attached to their parents (and vice versa), are dependent on them for protection and care, and learn skills within the home that may prove useful outside of it; these facts are not questioned. (p. 461)

In short, many individuals in children's lives influence their development, parents prominently included.

Summary

Even parenting's most strident critics acknowledge that parents serve important functions in children's lives: "Parents are the most important part of the child's environment and can determine, to a large extent, how the child turns out" (J. R. Harris, 1998, p. 15). Of course, biological mothers and fathers contribute directly to the nature and development of their children by passing on heritable characteristics (Plomin, 1999). At the same time, all prominent theories of development put experience in the world as either the principal source of individual growth or as a major contributing component (R. M. Lerner, Theokas, & Bobek, 2005; Wachs, 2000). Thus, evidence for heritability effects and peer influences neither negates nor diminishes equally compelling evidence for effects of parenting.

Parenting research today is guided by a developmental contextual perspective. The size of reported parenting effects reflects the fact that parenting is part of a complex developmental system that includes children's own capacities and proclivities, children's and parents' multiple social relationships (with siblings, friends, peers, teachers, and neighbors), and multiple developmental contexts (homes, schools, neighborhoods, so-

cioeconomic class, and culture). Within complex developmental systems like the parent-child, it is unlikely that any single factor will account for even substantial amounts of variation. Parenting effects are conditional and not absolute (i.e., true for all children under all conditions). Finally, given the variance related to the number of independent variables, more complex theories that incorporate larger numbers of variables can be expected to account for effects better than simpler theories with fewer variables. Multiple sources of shared and nonshared environmental influences affect the child's life.

PARENTING COGNITIONS AND PRACTICES

What defines parenting? What about parenting affects children? Parenting is instantiated in cognitions and practices. Parenting is also multidimensional, modular, and specific (see Bornstein, 1989a, 2002b), supporting empirical focus on multiple specific cognitions and practices (De Wolff & van IJzendoorn, 1997; MacDonald, 1992; Tamis-LeMonda, Chen, & Bornstein, 1998). Furthermore, the child-rearing cognitions and practices of one's own group may seem natural but may actually be rather unusual when compared with those of other groups.

Parenting Cognitions

When their children are only 1 month of age, 99% of mothers believe that their babies can express interest, 95% joy, 84% anger, 75% surprise, 58% fear, and 34% sadness (Johnson, Emde, Pannabecker, Stenberg, & Davis, 1982). These judgments may reflect children's expressive capacities, or contextual cues, or mothers' subjective inferences. In response to specific questions, mothers describe children's vocal and facial expressions, along with their gestures and arm movements, as the bases of their judgments (H. Papoušek & Papoušek, 2002). Because mothers commonly respond differently to different emotional messages they perceive in their children, they have frequent opportunities to have their inferences fine-tuned or corrected depending on how their children respond in turn. There is therefore good reason to invest confidence in maternal cognitions.

Parenting cognitions include their goals, attitudes, expectations, perceptions, attributions, and actual

knowledge of child rearing and child development (Goodnow, 2002; Holden & Buck, 2002; Sigel & McGillicuddy-De Lisi, 2002). Parenting cognitions are generally believed to serve many functions. They affect parents' sense of self, mediate the effectiveness of parenting, and help to organize parenting (Darling & Steinberg, 1993; Dix & Grusec, 1985; Goodnow & Collins, 1990; Harkness & Super, 1996; S. G. Miller, 1988; Murphy, 1992; K. H. Rubin & Mills, 1992; Sigel & McGillicuddy-De Lisi, 2002). Cognitions form a framework from which parents perceive and interpret their children's behaviors. In addition, many theorists reason that because parents' cognitions generate and shape their practices, they in turn shape children's development (Conrad et al., 1992; Darling & Steinberg, 1993; Goodnow, 2002; Holden & Buck, 2002; Hunt & Paraskevopoulos, 1980; Wachs & Camli, 1991). Unfortunately, fewer than a handful of studies have examined the three-term relation among parenting cognitions, parenting practices, and child development completely, although those that have tend to support expected pathways (McGillicuddy-De Lisi, 1982; Seefeldt, Denton, Galper, & Younoszai, 1999). Benasich and Brooks-Gunn (1996), for example, using the prospective longitudinal study data set of a low-birthweight preterm cohort from the multisite Infant Health and Development Program, found that maternal knowledge of child development and child rearing conditioned the quality and structure of the home environment mothers provided, which in turn affected child cognitive and behavioral outcomes.

How parents see themselves vis-à-vis children generally can lead to their expressing one or another kind of affect, thinking, or behavior in child rearing. According to the Zero-to-Three (1997) survey, for example, 90% of new parents in the United States have confidence in their abilities and think of themselves generally as good parents. Mothers who feel efficacious and competent in their role as parents tend to be more responsive, more empathic, and less punitive and have more appropriate developmental expectations (East & Felice, 1996; Parks & Smeriglio, 1986; Schellenbach, Whitman, & Borkowski, 1992). How parents construe childhood in general functions in the same way: Parents who believe that they can or cannot affect children's characteristics modify their parenting accordingly. Zero-to-Three also found that one in four parents in America thinks that a baby is born with a certain level of intelligence that cannot be increased or decreased by how parents interact

with the baby. Mothers who feel effective vis-à-vis their children are motivated to engage in further interactions, which in turn provide them with additional opportunities to understand and interact positively and appropriately with their children (Teti, O'Connell, & Reiner, 1996). Last, how parents see their own children has its specific consequences. Mothers who regard their child as being difficult, for example, are less likely to pay attention or respond to their child's overtures. Their inattentiveness and nonresponsiveness can then foster temperamental difficulties and cognitive shortcomings (Putnam, Sanson, & Rothbart, 2002). In this way, parents' cognitions foster further temperamental problems because they can lead parents to treat children more negatively.

Although it is arguably the case that all parents seek some of the same accomplishments and achievements for their children, notably social adjustment, educational achievement, and economic security, they may do so in substantially different ways. Considerable attention in the parenting literature has focused on variation in parents' cognitions with SES, ethnicity, and culture (see Bornstein & Bradley, 2003; Harwood, Handwerker, Schoelmerich, & Leyendecker, 2001; Kohn, 1963, 1969, 1979; Schulze, Harwood, Schoelmerich, & Leyendecker, 2002). "Beliefs are like possessions" (Abelson, 1986, p. 223), and parents cling to theirs beliefs about parenting and children equally dearly.

A Taxonomy of Parenting Cognitions

Parents' *goals* for their own parenting and for their children arise, in part, out of society's expectations of its adult members (LeVine, 2003). For example, many Western societies encourage independence, self-reliance, and individual achievement among their children, whereas many Asian and Latin cultures encourage interdependence, cooperation, and collaboration (Triandis, 1995). These general values are associated with differences in the socialization goals of parents (Harwood, 1992; Ogbu, 1981). According to D. Y. F. Ho (1994), for example, Confucian ethics emphasize obligation to others rather than individual rights and provide a foundation for parent-child relationships through the notion of filial piety. Among such filial precepts are obeying, honoring, and providing for the material and mental well-being of one's parents, performing the ceremonial duties of ancestral worship, taking care to avoid harm to one's body, ensuring the continuity of the family line, and in general conducting oneself so as to bring honor

and not disgrace to the family name. These underlying values are reflected in parents' goals for what it means to be a good parent and what constitutes a good or virtuous child.

Attitudes are a component of social cognition that refer to a tendency, internal state, or explicit evaluation of some object (Eagly, 1992). Some children are relatively relaxed when confronted with an unfamiliar situation and show little indication of distress. Other children react to novel objects and situations with anxiety and try to remain close to their mother. They do not readily explore novel objects or easily interact with unfamiliar people. These actions indicate behavioral inhibition. X. Chen et al. (1998) found cultural differences in mothers' attitudes toward such behavioral inhibition in children. Chinese mothers, who traditionally value mutual interdependence, view behavioral inhibition in toddlers as a positive trait. Behavior inhibition was positively associated with maternal acceptance of the child and maternal belief in encouraging children's achievement. In contrast, for Canadian parents of European origin, who traditionally hold a more individualistic orientation, behavioral inhibition is negatively associated with maternal acceptance and encouragement of children's achievement. Among Chinese families, children who displayed higher levels of behavioral inhibition had a mother who was less likely to believe that physical punishment is the best way to discipline the child and who was less likely to feel angry toward the child. However, maternal punishment orientation was positively correlated with behavioral inhibition in Canadian families; mothers whose children displayed higher levels of behavioral inhibition were more likely to believe that physical punishment was the best discipline strategy. In short, behavioral inhibition in children was associated with positive attitudes in Chinese mothers and negative attitudes in Canadian mothers.

Expectations about developmental norms and milestones—when a child is expected to achieve a particular developmental skill—affect parents' appraisals of their child's development and of child development per se. Adult caregivers—parents, teachers, or others—normally harbor ideas about when children should be capable of certain achievements (Becker & Hall, 1989), and these ideas can themselves affect development. For example, Hopkins and Westra (1989, 1990) surveyed English, Jamaican, and Indian mothers living in the same city and found that Jamaican mothers expected their children to sit and to walk earlier, whereas Indian moth-

ers expected their children to crawl later. In each case, children's actual attainment of developmental milestones accorded with their mother's expectations. Higher-SES mothers generally give earlier age estimates for children's attainment of developmental milestones than lower-SES mothers (Mansbach & Greenbaum, 1999; von der Lippe, 1999). When Filipino mothers of preschool-age children were asked to estimate the age at which their child would acquire a variety of cognitive, psychosocial, and perceptual-motor skills (Williams, Williams, Lopez, & Tayko, 2000), mothers with higher educational attainment had earlier expectations for children's cognitive and psychosocial development (e.g., emotional maturity, independence).

Especially salient *self-perceptions* of parenting have to do with parents' feelings of competence in the role of caregiver, satisfaction gained from caregiving relationships, investment in caregiving, and ability to balance caregiving with other social roles. These distinctive self-perceptions function in child rearing and child development in unique ways. Most is known about parenting competence (Bornstein, Hendricks, et al., 2003; Teti & Candelaria, 2002). Functionally, perceptions of competence in parenting are associated with parents' use of effective child-rearing strategies (Johnston & Mash, 1989; Teti & Gelfand, 1991). Self-efficacy theory posits that adults who evaluate themselves as competent, who know what they can do, and who understand the likely effects of their actions will, as parents, more likely act as constructive partners in their children's development (Bandura, 1986, 1989; Coleman & Karraker, 1998; Conrad et al., 1992; King & Elder, 1998). Feelings of competence relate to behavioral choice and help to determine how much time, effort, and energy to expend in parenting. Eccles and Harold (1996) reported that parents' confidence in their ability to influence their children's academic performance and school achievement was associated with parents' school involvement and predicted parents' helping with children's academic interests (see, too, Hoover-Dempsey & Sandler, 1997).

Investment in, involvement with, and commitment to children is integral to child rearing; indeed, Baumrind and Thompson (2002, p. 3) defined ethical parenting "above all [as] requiring of parents enduring investment and commitment throughout their children's long period of dependency." High-investment parents believe that they can meet their children's needs better than other adults; they hold higher maturity expectations, are more responsive, and view their children more positively

(Greenberger & Goldberg, 1989). In turn, parental involvement relates to developmental outcomes in children (Bogenschneider, 1997; E. V. Clark, 1983; Eccles & Harold, 1996). Parental investment in children's lives and parental responsibility for children's care ensure that children receive the preventive medical attention, physical activity, and proper nutrition they require (Cox & Harter, 2003).

How individuals balance their roles in life, such as parent, spouse, and employee, reflects on their effectiveness in those diverse roles (Perry-Jenkins, Repetti, & Crouter, 2000). People who maintain greater balance score lower on measures of role strain and depression and higher on measures of self-esteem and other indicators of well-being (Marks & MacDermid, 1996). J. V. Lerner and Galambos (1985, 1986) found that mothers' role balance had more of an impact on child development than did mothers' work status per se. Mothers who are unhappy with their roles are more rejecting of their children (Stuckey, McGhee, & Bell, 1982; Yarrow, Scott, DeLeeuw, & Heinig, 1962). Thus, research supports a positive association between the balance struck by employed mothers and their parenting behaviors (Harrell & Ridley, 1975; Stuckey et al., 1982).

In certain circumstances, parents will tend to believe their children are behaving intentionally in one or another way, when the child's behavior may in fact be developmentally typical (K. H. Rubin & Mills, 1992). Thus, parents' *attributions* about their children (often vis-à-vis developmental norms) help to shape parents' caregiving practices, which in turn affect children's lives. Numerous studies have documented that Asian American parents as compared to European American parents attribute the effort the child directs toward school work as most important contributor to the child's academic success (Hess, Chang, & McDevitt, 1987; Okagaki & Sternberg, 1993; Stevenson & Lee, 1990). Cultural variation also characterizes parents' attributions about successful parenting. For example, mothers from Argentina, Belgium, Italy, Israel, Japan, and the United States were asked if being able to successfully comfort their child when the child cries was due to their parenting ability (e.g., "I am good at this."), effort (e.g., "I have tried hard."), mood (e.g., "I am in a good mood."), task difficulty (e.g., "This is easy to do."), or a child characteristic (e.g., "My child makes this easy to do."). Among the culturally differentiated patterns of findings that emerged, Japanese mothers were less likely than mothers from all other nations to attribute success to

their own ability and more likely to indicate that, when they were successful, it was because of the child's behavior (Bornstein et al., 1992).

Parenting *knowledge* encompasses understanding how to care for children, how children develop, and the diverse roles parents play in children's lives. Studies of parents' knowledge of child rearing and child development investigate what kinds of knowledge parents have, how accurate their knowledge is, how parents of different social statuses, ethnicities, or cultures vary in their knowledge, where parents acquire their knowledge, and what factors are related to differences in knowledge. The general state of knowledge that parents possess constitutes a frame of reference from which they interpret their children's behaviors, and knowledge about children's development affects parents' everyday decisions about their children's care and upbringing (Conrad, Gross, Fogg, & Ruchala, 1992; Holden & Buck, 2002; S. G. Miller, 1988; Murphy, 1992). Knowledgeable parents have more realistic expectations and are more likely to behave in developmentally appropriate ways with their children (Grusec & Goodnow, 1994), whereas parents who harbor unrealistic developmental expectations that are not informed by accurate knowledge experience greater stress as a result of mismatches between expectations and actual child behaviors (Teti & Gelfand, 1991).

Parents' knowledge of children's health and safety is measured in terms of awareness of health care, the identification and treatment of illnesses, and accident prevention. These cognitions guide parents' decisions about how to maintain child health and when to seek care if children manifest symptoms (Hickson & Clayton, 2002; Melamed, 2002). For example, sudden infant death syndrome (SIDS) is the leading cause of reported neonatal deaths in the United States (C. A. Miller, 1993), and sleeping prone or on too soft bedding that may cover the child's mouth and nose increases the likelihood of asphyxiation (Scheers, Rutherford, & Kemp, 2003). Yet approximately 20% of infants ages 1 to 3 months are still placed on their stomachs during sleep (Gibson, Dembofsky, Rubin, & Greenspan, 2000).

Parenting knowledge includes understanding the various approaches appropriate to fulfilling the physical and biological and socioemotional and cognitive needs of children as they develop (Goodnow & Collins, 1990). Proper parenting practices follow knowledge of principles related to early experience, bidirectionality of social influences, atypical development, individual

differences, instrumental beliefs, management of the child through tuition or modeling, and the responsibilities of being a parent.

Extant research points to definite individual variation in parenting knowledge (Young, 1991; Zero-to-Three, 1997). Parenting researchers have also identified multiple antecedents of parenting knowledge (Belsky, Youngblade, & Pensky, 1989; Cochran, 1993; Goodnow & Collins 1990; MacPhee, 1981). Clarke-Stewart (1998), for example, reported that books and magazine articles were a popular source of advice about general child development, and their most frequent users were first-time and middle-class parents (Deutsch et al., 1988). Friends and relatives constitute a major base of information for younger parents with little child-rearing experience (Belsky et al., 1989). Pediatricians are a resource for all social classes and ages of parent, but they appear to be turned to most often for advice about current or specific problems (Hickson & Clayton, 2002). Mothers' own knowledge tends to relate to their formal, objective experience—exposure to books and manuals, pediatricians, and courses about child rearing—whereas previous informal or subjective experience with children (through babysitting or professional services alone) has been found to correlate not at all or negatively with parenting knowledge (Frankel & Roer-Bornstein, 1982; MacPhee, 1981).

Of course, differences in parents' cognitions may reflect differences in children's prior performance (Entwisle & Hayduk, 1988; Seginer, 1983). A hierarchical regression in which the previous year's grades and parents' perceptions of their child's ability were used to partial out differences in actual and perceived school performance still resulted in group differences in parents' expectations for their child's school attainment. This finding supports the hypothesis that differences in parental cognitions are not simply a response to children's prior achievements, but reflect differences in broader cultural values.

Parenting Practices

In the 1983 *Handbook*, Maccoby and Martin reasoned that parenting style could be assessed along two separate broad dimensions, responsiveness (child-centeredness and warmth) and demandingness (control), which they combined to produce four parenting types: authoritative, authoritarian, permissive, and disengaged. Baumrind's

(1967, 1978, 1991) categories of parenting involve just such an emphasis on style and content. She hypothesized that these practices contribute differentially to child identity formation and cognitive and moral development. Her findings show that some parenting practices facilitate growth (social competency), whereas others do not. An authoritative style combines high levels of warmth with moderate to high levels of control. In middle-class European American children, it is associated with achievement of social competence and overall better adaptation. Authoritarian parenting, by contrast, contains high levels of control but little warmth or responsiveness to children's needs, and it is generally associated with poorer developmental outcomes. In different social classes or ethnic groups, however, different outcome patterns appear to obtain. For example, adolescents from European American and Latin American authoritative homes perform well academically, and better than those coming from nonauthoritative households. However, school performance is similar for authoritatively and for nonauthoritatively reared Asian Americans and African Americans (Dornbusch, Ritter, Leiderman, Roberts, & Fraleigh, 1987).

A small number of domains of parenting practices has been identified as a common core of parental care (Bornstein, 1989a, 2002b; LeVine, 1988; for other componential systems, see Bradley & Caldwell, 1995). They have also been studied for their variation, stability, continuity, and covariation, as well as for their influences on child development.

A Taxonomy of Parenting Practices

In infrahuman primates, the majority of maternal behaviors consist of biologically requisite feeding, grooming, protection, and the like (Bard, 2002; Rheingold, 1963). Some related acts focus on examining offspring and assessing and monitoring their behavioral and physical state. Perhaps these mothers also encourage motor development with physical exercise. Other residual activities among higher primate parents include playing with offspring.

The contents of human parent-child interactions are more dynamic, varied, and discretionary. Moreover, like cognitions, parenting practices tend to be multidimensional, modular, and specific. Several categories of human parental caregiving can be identified: They are nurturant, physical, social, didactic, verbal, and material. Together, these modes are perhaps universal

among human beings in different societies, even if their instantiation or emphases (in terms of frequency or duration) vary across groups. These categories capture the most prominent of human parents' activities with children. For their part, human children are reared in, influenced by, and adapt to a social and physical ecology commonly characterized by this parenting taxonomy and its elements.

When parents *nurture*, they meet the biological, physical, and health requirements of their offspring. From a biological evolutionary stance, survival and reproduction are the ultimate criteria of adaptation. After reproduction, survival is achieved through protection of the child and provision of nourishment, but also through processes that involve sharing information and maintaining social order (Wilson, 1975). Child mortality is a perennial parenting concern, and parents are centrally responsible for promoting children's wellness and preventing their illness from the moment of conception, or even earlier. Parents in virtually all higher species nurture their young, providing sustenance, protection, supervision, grooming, and the like. Parents shield children from risks and stressors. Nurturance is a prerequisite for children's survival and well-being; seeing a child's survival to reproductive age enhances parents' probability of passing on their genes (Bjorklund et al., 2002).

Parents promote children's *physical development*, that is their gross and fine motor skills. Parents foster their children's physical growth in many direct and indirect ways. Parents physically move and manipulate babies to reach or step, and they set goals and place rewards for children to achieve. In turn, child growth and maturation affect the ways parents treat a child. How parents organize the physical environment and interact with and speak to children who vary in their physical abilities differ substantially (Campos et al., 2000; Campos, Kermoian, Witherington, & Chen, 1997). Parents talk to the walking as opposed to the crawling toddler differently, just as they interact with the pubertal adolescent differently from the prepubertal.

Parenting in the *social* domain includes the variety of visual, verbal, affective, and physical behaviors parents deploy in engaging children in loving interpersonal exchanges. Through positive feedback, openness and negotiation, listening, and emotional closeness, parents make their children feel valued, accepted, and approved of. Social caregiving includes all the ways parents help and direct children to regulate their own affect and emotions

and influence the communicative styles and interpersonal repertoires that children use to form meaningful and sustained relationships with others. Early in life, dyadic organization is a foundation for an intricate system of communication and interpersonal interaction. Later in childhood, parents mediate and monitor their children's social relationships with others, such as peers (Ladd & Pettit, 2002; K. H. Rubin, Bukowski, & Parker, 1998; Stattin & Kerr, 2000).

Parenting also consists of a variety of *didactic* strategies used to stimulate children to engage and understand the wider natural and designed environments. Didactics organize the young child's attention to properties, objects, or events in the surroundings; introduce, mediate, and interpret the external world; describe and demonstrate; as well as provoke or provide children with opportunities to observe, to imitate, and to learn. Education is a vital and fundamental human parenting function.

Language in parenting is fundamental to child development and to the parent-child bond in itself. The motivation to acquire language is social and is born in interaction, usually with parents (Bloom, 1998). Language also cross-cuts the foregoing domains, as speech to children supports and enriches all domains of child development (Hoff, 2003).

Finally, caregiving includes those ways in which parents *materially* provision and organize the child's world, especially the home and local environments (Wachs, 2000). Parents influence their children not only by what they do but also by the role they play in structuring the physical and social surround. Adults are responsible for the number, variety, and composition of inanimate objects (toys, books, tools) available to the child, the level of ambient stimulation, the situations and locales children find themselves in, the limits on their physical freedom, and the overall physical dimensions of children's experiences. The amount of time children spend interacting with their inanimate surroundings rivals or exceeds the time children spend in direct social interaction with parents or others.

Together, these categories encompass virtually all of parents' important activities with their children. Although these modes of caregiving are conceptually and operationally distinct, in practice parent-child interaction is dynamic, intricate, and multidimensional, and parents regularly engage in combinations of them. Taken as a totality, this constellation of parenting practices constitutes a varied and demanding set of caregiving

tasks, and adults differ considerably in terms of how they recognize, esteem, and engage in components of the caregiving repertoire, as well as in how successful they are in executing different components. Traditionally, the mechanisms asserted to convey intergenerational transmission of beliefs and behaviors amongst human families include socialization, teaching, and scaffolding, conditioning and reinforcement, and modeling. Elements of the parenting taxonomy via these means constitute direct parenting experience effects on children's development.

Certain characteristics of this parenting taxonomy merit brief comment:

1. From an evolutionary adaptive view, nurturant and physical parenting seem compulsory; by contrast, social, didactic, language, and material elements appear more discretionary.
2. Nurturant, physical, social, didactic, and verbal parenting are active forms of interaction; physical and material parenting may be active or passive.
3. No one category of parenting is the most prominent all the time, although any one may best characterize a given parent-child interaction at a given time.
4. There is initially asymmetry in parent and child contributions to parenting. As childhood progresses, children play more active and anticipatory roles in their upbringing, whereas initial responsibility for nurturing, promoting physical growth, sociability, teaching, language, and material provisions in child development appear to lie more unambiguously with parents.

Some Prominent Principles of Parenting Cognitions and Practices

For parent-provided experiences to play a meaningful role in child development, they need to meet some psychometric criteria and the mechanism of their action should be explained.

Psychometric Characteristics of Parenting Cognitions and Practices

Four significant psychometric characteristics help to further define and distinguish parenting cognitions and practices. The first has to do with *variation* among parents. Adults vary among themselves in terms of how tenaciously they cling to various parenting cognitions and how often and long they engage in various parenting practices, even when they come from socioeconomically

homogeneous groups and from the same culture. For example, the amounts of language which parents address to children varies enormously: Some mothers talk to their infants during as little as 3% and some during as much as 97% of a naturalistic home observation, even when the mothers are sampled from a relatively homogeneous population in terms of education and SES (Bornstein & Ruddy, 1984). As a consequence, the range in amount of language that washes over babies is virtually as large as it can be. This is not to say that there are not also systematic group differences by SES or culture; there are.

The second psychometric feature of parenting has to do with developmental stability and the third with continuity. *Stability* is consistency in the relative ranks of individuals in a group over time, and *continuity* is consistency in the mean level of group performance over time; the two are independent developmental constructs (Bornstein, Brown, & Slater, 1996; McCall, 1981). Summarizing over a variety of samples, time intervals, and types of home assessments, A. W. Gottfried (1984) concluded that parent-provided experiences tend to be stable. Holden and Miller (1999) analyzed the short-term reliability of attitude questionnaires and behavioral observations of parents (mothers) in 11 studies and arrived at a median correlation of .59. The fact that parenting is stable (in some degree) implies that cognitions and practices assessed at one point can be assumed to reflect past as well as future parenting. It also means that indices of parenting can be related systematically to concurrent or future parent and child behavior or performance. Mothers' behavior toward their first- and second-borns when each child was 1 and then 2 years of age shows similar stability (Dunn, Plomin, & Daniels, 1986; Dunn, Plomin, & Nettles, 1985).

Individual parents do not vary in themselves much from day to day. Over longer periods, of course, parenting changes, and it certainly does in response to children's development. The ratio of adult-directed speech to child-directed speech increases across just the first postpartum year (Bornstein & Tamis-LeMonda, 1990); more generally, there is a reduction in time devoted to parenting activities (Fleming, Ruble, Flett, & Van Wagner, 1990), especially caregiving (Holden & Miller, 1999), as children grow and develop. Parents also adjust their behaviors relative to both child age and child capacity or performance (Bellinger, 1980): Sensitive parents tailor their parenting to match their children's developmental progress (Adamson & Bakeman, 1984; Carew, 1980), for example, by providing more didactic

experiences as children age (Bornstein & Tamis-LeMonda, 1990; Bornstein et al., 1992; Klein, 1988). They do so as well to children's changing capacities. The mean length of mothers' utterances tends to match the mean length of those of their 12- to 32-month-olds (McLaughlin, White, McDevitt, & Raskin, 1983).

The fourth characteristic of parenting assesses *covariation* among parenting domains. Despite the wide range of activities parents naturally engage in with children, classical authorities, including notably psychoanalysts, personality theorists, ethologists, and attachment theorists, historically and theoretically conceptualized maternal behavior as traitlike and more or less unitary, often denoted as "good," "good enough," "sensitive," "warm," or "adequate" (Ainsworth et al., 1978; Brody, 1956; Brody & Axelrad, 1978; Hunt, 1979; MacPhee, Ramey, & Yeates, 1984; Mahler, Pine, & Bergman, 1975; Rothbaum, 1986; Schaefer, 1959; Symonds, 1939; Wachs & Gruen, 1982; Winnicott, 1957). This view is that parents package the variety of their beliefs and behaviors together into a monolithic set and show the self-same beliefs or behaviors across domains of interaction, time, and context. Operationally, that is, a parent who engages the child in more emotional and interpersonal exchanges is also the parent who engages the child in more teaching and learning experiences and does so across situations. This trait conceptualization projects parenting as more or less fixed in recurrent patterns, so that the particular pattern embodied by a parent represents the essence of that parent's child rearing.

However, trait approaches have led to erroneous conclusions about the nature of parenting. For example, Thomas and Chess (1977) observed that trait formulations assume an all-or-nothing character and are credited with exclusive significance in determining the child's development; they argued (pp. 78–79) that it is insufficient and inaccurate to characterize a parent in an overall, diffuse way as rejecting, overprotective, insecure, and so on. Rather, a parent's behavior may vary relative to the situation. Moreover, the trait approach to parenting does not invite more differentiated developmental questions or allow for bidirectionality, the fact that different child characteristics may affect or interact with particular factors of parenting. Yet, the child effects position recognizes the manifest behavioral adjustments parents make to children's age and gender, behavior and appearance, temperament and activity. Child-rearing practices reflect the interaction of child, parent, and context. Thus, parent cognition or practice is

a joint product of multiple parent and child characteristics based on a history of shared interactions and transformations over time.

Parents naturally engage their children in a range of diverse activities, and parents do not only or necessarily behave in uniform ways. Research has shown that, rather than employing one broad style, parents are adaptable (Smetana, 1994). They change their approach to children of different ages and temperaments and in response to situational constraints such as time available or whether they are in public or in private. In a similar way, Mischel and Shoda (1995) delineated a unified view of personality in which there is consistency across contexts as well as situational specificity (see Fleeson, 2004).

Different domains of parenting are conceptually and operationally distinct, but in practice parents regularly engage in combinations of domains. Positions alternative to the trait conceptualization are that frequently performed activities are not necessarily or rigidly linked psychologically, and that individuals vary in the constellation and pattern of their activities so as to call into question any monistic organization of parenting. The different domains of parenting children constitute coherent but distinctive constructs (Bornstein, 1989a, 2002b). In shorter words, parenting is multidimensional, modular, and specific, and individual parents may possess particular cognitions and emphasize particular practices with their children.

Direct and Indirect Effects of Parenting Cognitions and Practices

Empirical research attests to the short- and long-term influences of parent cognitions and practices on child development. Maternal attentiveness and mood during feeding in the first months predict 3-year child language (Bee et al., 1982). Mothers' affectionately touching, rocking, holding, and smiling at their 6-month-olds predict cognitive competencies at 2 years (Olson, Bates, & Bayles, 1984). Mothers who speak more, prompt more, and respond more during the 1st year have 6-month-olds to 4-year-olds who score higher in standardized evaluations of language and cognition (Bornstein, 1985; Bornstein, Tamis-LeMonda, & Haynes, 1999; Nicely, Tamis-LeMonda, & Bornstein, 1999). Even features of the parent-outfitted physical environment appear to influence child development directly (Wachs & Chan, 1986): New toys and changing room decorations influence child language acquisition in and of themselves, and independent of proximal parenting.

Indirect effects are more subtle and perhaps less noticeable than direct effects, but no less meaningful. One primary type of indirect effect is marital support and communication. Effective coparenting bodes well for child development (McHale et al., 2002), and mothers who report supportive relationships with “secondary parents” (grandparents and the like) are more competent and sensitively responsive to their children than are women lacking such relationships (Grych, 2002). In the extreme, conflict between spouses may reduce the availability of an important source of support in child rearing, namely, one’s partner. Short of that, parents embroiled in marital conflict may miss the sometimes subtle signals children use to communicate their needs. Children in these homes may learn that their caregivers are unreliable sources of information or assistance in stressful situations. For example, even 1-year-old children are less likely to look to their maritally dissatisfied father for information or clarification in the face of stress or ambiguity than are like-age children of maritally satisfied fathers (Parke, 2002).

Specificity, Transaction, and Interdependence in Parenting Cognitions and Practices

Parents’ cognitions and practices each can influence children via different paths. A common assumption in parenting is that the overall level of parental involvement or stimulation affects the child’s overall level of development (see Maccoby & Martin, 1983). An example of this simple model suggests that the development of language in children is determined (at least to some degree) by the amount of language children hear (Hart & Risley, 1995). Indeed, mothers’ single-word utterances are just those that appear earliest in their children’s vocabularies (Chapman, 1981), and specific characteristics of maternal speech appear to play a part in children’s specific styles of speech (E. Bates, Bretherton, & Snyder, 1988).

Increasing evidence suggests, however, that more sophisticated and differentiated mechanisms need to be brought to bear to explain parenting effects (Collins et al., 2000). First, specific (rather than general) parental cognitions and practices appear to relate concurrently and predictively to specific (rather than general) aspects of child competence or performance (Bornstein, 1989b, 2002b; Bradley, Caldwell, & Rock, 1988; Hunt, 1979; Wachs, 2000). It is not the case that overall level of parental stimulation directly affects children’s overall level of functioning and compensates for selective deficiencies: Simply providing an adequate

financial base, a big house, or the like does not guarantee, or even speak to, children’s development of healthy eating habits, an empathic personality, verbal competence, or other valued capacities. The *specificity principle* states that specific cognitions and practices in specific parents at specific times exert specific effects in child development in specific children in specific ways (Bornstein, 1989a, 2002b).

The specificity principle helps to explain numerous observations and discrepancies in the parenting literature. For example, “Parents who are highly effective at one stage in the child’s life [are] not necessarily as effective at another. . . . Similar practices do not necessarily produce the same effects at successive stages in [a] child’s life” (Baumrind, 1989, p. 189). Mothers’ responses to their children’s communicative overtures are central to children’s early acquisition of language, but exert less influence on the growth of motor abilities (Tamis-LeMonda & Bornstein, 1994).

The specificity principle is apparently counterintuitive because, according to the Zero-to-Three (1997) national survey, 87% of parents simplistically think that the more stimulation a baby receives, the better off the baby is. In fact, parents need to carefully match the amount and kinds of stimulation they offer to a specific child’s specific level of development, specific interests, temperament, and mood at the moment. The specificity principle accords with a situational contextual view of parenting. It is not that there do not exist consistent parenting styles, but parenting is best conceptualized as multidimensional, modular, and specific, reflecting the interactional context. Parenting undergoes frequent adjustments and represents the product of multiple transactional processes. This is person-situation interaction brought to parenting (Dix, 1992; Grusec & Goodnow, 1994; Luster & Okagaki, 2005).

One implication of this position for parenting is that estimates of the strength of parental effects are likely specific to particular parenting cognitions or practices in specific circumstances for specific children at specific points in time. To detect regular relations between antecedents in parenting, experience, and environment on the one hand and outcomes in child characteristics and values on the other, we need to seek and to find precisely the right combinations of independent and dependent variables.

Consider timing as one key term of the specificity formulation. Ethological and attachment theories of parenting posit a special role for early experience in child

development. Early parenting influences the child at a particular time point in a particular way, and the consequence for the child endures, independent of later parenting and of any other contribution of the child. This early experience model is consonant with a sensitive period interpretation of parenting effects (Bornstein, 1989c), and data derived from ethology, attachment, psychoanalysis, behaviorism, and neuropsychology support this model with regard to some child outcomes. Wakschlag and Hans (1999), for example, found maternal responsiveness in infancy was related to a decreased risk of behavioral problems in middle childhood after controlling for concurrent parenting.

Early childhood may be a period of plasticity and adaptability to transient conditions, but early effects may not persist or they may be altered or supplanted by subsequent conditions that are more consequential. On this argument, some theorists have questioned the importance of early experience (Kagan, 1998; Lewis, 1997). Alternatively, they argue, parents exert unique influences over their children at points in development that override the effects of earlier experiences and independent of whatever individual differences children carry forward. Empirical support for contemporary experience models typically consists of recovery of functioning from early deprivation and failures of early interventions to show sustained effects (Clarke & Clarke, 1976; Lewis, 1997; Rutter and English and Romanian Adoptees Study Team, 1998).

Third, a cumulative/additive/stable environment model, which combines the first two views, contends that, with repeated and successful experiences, children develop important associations as they assimilate information from one learning experience and apply it to information gained in the next (Rovee-Collier, 1995). That is, a parent-provided experience at any one time does not necessarily affect the child, but meaningful longitudinal relations are structured by similar parenting interactions continually repeating and aggregating through time (Bornstein & Tamis-LeMonda, 1990; Coates & Lewis, 1984; Landry, Smith, Swank, Assel, & Vellet, 2001; Olson et al., 1984). Although longitudinal data provide evidence for unique early, unique contemporary, and cumulative experiential effects between parents and children, for the most part children are reared in stable environments (Holden & Miller, 1999), so that cumulative experiences are very likely.

Furthermore, concurrent and predictive correspondences begin to define the mutual influences that parent

and child continuously exert on one another. The *transactional principle* in development acknowledges that the characteristics of an individual shape his or her experiences and, reciprocally, that experiences shape the characteristics of the individual through time (Sameroff, 1983). Bell (1968; Bell & Harper, 1977) was among the first to emphasize the key role that bidirectional effects play in the socialization process. Biological endowment and experience mutually influence development from birth onward, and each life force affects the other as development proceeds to unfold through the life span (R. M. Lerner et al., 2002; Overton, 1998). By virtue of their unique characteristics and propensities—state of arousal, perceptual awareness, cognitive status, emotional expressiveness, and individuality of temperament and personality—children actively contribute, through their interactions with their parents, to producing their own development. Children influence which experiences they will be exposed to, and they interpret and appraise those experiences, and so (in some degree) determine how those experiences will affect them (Scarr & McCartney, 1983). Child and parent bring distinctive characteristics to, and each is believed to change as a result of, every interaction; both parent and child then enter the next round of interaction as changed individuals. For example, child temperament and maternal sensitivity operate in tandem to affect one another and eventually the attachment status of babies (Cassidy, 1994; Seifer, Schiller, Sameroff, Resnick, & Riordan, 1996).

In addition, parents and children are embedded in complex social systems marked by strong forms of *interdependence* associated with responsibilities and functions of family members through time. Interdependence means that to understand the responsibilities and functions of any one family member necessitates recognizing the complementary responsibilities and functions of other family members (Bornstein & Sawyer, 2005). When one member of the family changes in some way, all members of the family are potentially affected. Beyond the nucleus family system, all families are also embedded in, influence, and are themselves affected by larger social systems. These include both formal and informal support systems, extended families, community ties with friends and neighbors, work sites, social, educational, and medical institutions, and the culture at large.

To fathom the nature of parenthood and parent-child relationships within families, therefore, requires a *multivariate* and *dynamic* stance. Only by taking multiple circumstances into consideration simultaneously can we

appreciate individual-, dyadic-, and family-level aspects within the family and the embeddedness of the family within its many relevant extrafamilial systems. The multiple pathways and dynamics of parenting and child development present really quite messy facts of life, and it makes everyone's job harder: Researchers are challenged to develop new paradigms and methodologies to accommodate this chaos; similarly, the use of this perspective in the development and implementation of parenting interventions as well as policy is made problematic. Yet, it is only out of this complexity and chaos that we can possibly understand more about the reality of families and children and parenting.

Cognition-Practice Relations in Parenting

Are parents' cognitions about their own practices accurate and valid? Intuitively, parents' child-rearing beliefs might be expected to relate to their child-rearing behaviors. Indeed, parents' cognitions are hypothesized by many to direct parents' child-rearing practices (Darling & Steinberg, 1993; Sigel & McGillicuddy-De Lisi, 2002). Nonetheless, the relation between beliefs and behaviors is historically an unsettled area in social psychology (Festinger, 1964; Green, 1954; LaPiere, 1934), and relations between parental beliefs and behaviors specifically are equally problematic (Okagaki & Bingham, 2005; Goodnow & Collins, 1990; Holden, 2002; S. G. Miller, 1988; Sigel & McGillicuddy-De Lisi, 2002). Coordinate relations between parents' beliefs and behaviors have often proven elusive (S. G. Miller, 1988), with many researchers reporting no relations between mothers' professed parenting attitudes and their activities with their children (Cote & Bornstein, 2000; McGillicuddy-De Lisi, 1992). In many cases, those parenting beliefs and behaviors that have been studied have been general and have not been conceptually corresponding, and so there has been little reason to expect covariation. Other studies have reported correlations between parents' beliefs and behaviors that are relatively weak or positive but nonsignificant (Coleman & Karraker, 2003; Mantzicopoulos, 1997; Sigel & McGillicuddy-De Lisi, 2002).

When more circumscribed and corresponding domains are studied, some maternal beliefs relate to some self-reported or observed maternal child-rearing behaviors (Kinlaw, Kurtz-Costes, & Goldman-Fraser, 2001; Stevens, 1984). Thus, the strength of the association between parents' cognitions and practices appears to depend, at least in part, on the closeness of the conceptual

match between the contents of the beliefs and the types of behaviors that are measured (DeBaryshe, 1995), for example, between mothers' authoritative attitudes and discipline strategies (Kochanska, Kuczynski, & Radke-Yarrow, 1989), beliefs about child-rearing practices and actual caregiving behaviors (Wachs & Camli, 1991), and beliefs about parenting effectiveness and caregiving competence (Teti & Gelfand, 1991). The degree to which mothers believe that children's development can be facilitated by their social environment is positively correlated with the amount and type of language that mothers use during mother-child interactions (Donahue, Pearl, & Herzog, 1997). Harwood, Miller, and Irizarry (1995) found that European American mothers underscore the importance of values such as independence, assertiveness, and creativity when asked to describe their ideal child, whereas Latina mothers underscore the importance of obedience and respect for theirs. In line with these expressed values, U.S. mothers foster independence in their children; for example, in naturalistic mother-child interactions during feeding, U.S. mothers encourage their children to feed themselves at 8 months of age. In contrast, Latina mothers hold their children close on their lap during mealtimes and take control of feeding them meals from start to finish.

Of course, associations between parents' cognitions and practices could, also in part, be a methodological artifact of shared source variance: Much of the research that has reported significant correlations between parents' cognitions and practices has utilized parents' self-reports to measure both, inflating relations between the variables being studied (S. G. Miller, 1988).

Summary

Biological parents endow a significant and pervasive genetic makeup to their children, with its beneficial or other consequences for children's proclivities and abilities. Beyond parents' genes, prominent theories of human development put experience in the world as either the principal source of individual growth or as a major contributing component. It falls to parents (and other caregivers) to shape most, if not all, of young children's experiences, and parents directly influence child development both by the beliefs they hold and by the behaviors they exhibit. Parenting cognitions include, for example, perceptions about, attitudes toward, and knowledge of all aspects of parenting and childhood. Out of the dynamic range and complexity of individual

activities that constitute parenting, major domains of parent-child interaction have been distinguished. These domains are conceptually separable but fundamentally integral, and each is developmentally significant.

Caregiving behaviors and styles constitute direct experience effects of parenting. Indirect effects are more subtle and less noticeable than direct effects, but perhaps no less meaningful. Parents indirectly influence their children by virtue of their influence on each other, for example, by marital support and communication and the multiple contexts in which they live. Whether direct or indirect, parental influences on children operate on several noteworthy principles. The specificity principle states that specific experiences specific parents provide specific children at specific times exert effects over specific aspects of child growth in specific ways. The transaction principle asserts that the experiences parents offer their children shape the characteristics of the child through time, just as, reciprocally, the characteristics of the child shape his or her experiences. Thus, children influence which experiences they will be exposed to, as well as how they interpret those experiences, and therefore ultimately how those experiences affect them.

PREVENTION AND INTERVENTION IN PARENTING

Infanticide was practiced historically, and although it is rare today, it is not unknown (Hrdy, 1999). Short of that, children are common victims of abuse and neglect, babies are born drug addicted, and many youngsters are never immunized. It is a sad fact of everyday life that parenting children does not always go as planned. Almost two in five parents (37% in the Zero-to-Three, 1997, survey) say that one of the chief reasons they need to improve as parents is that they do not spend as much quality time with their children as they would like. Modern parents typically complain that they have too many balls in the air already: working, errands, multiple commitments. This is not to trivialize the daunting problems that parents face: In the 1940s and 1950s, chewing gum and talking out of turn were the classroom problems listed by teachers as most prominent; today drug abuse and violence—witnessed in its most extreme form in the school shootings at Pearl, Peducah, Edinboro, Jonesboro, and Columbine High Schools—top their list. A significant proportion of parents need assistance to find more effective strategies to create more satisfying relationships with children, but

only a fraction of parents who need such services receive them (Saxe, Cross, & Silverman, 1988). When parents suffer from individual, marital, and parenting problems, children are more likely to have academic and behavior problems and difficulty relating to their peers.

Strong secular and historical trends operating in modern society—industrialization, urbanization, poverty, increasing population growth and density, and especially widespread dual parental employment—constitute centrifugal forces on parenting. Society at large is also witnessing the emergence of striking permutations in parenthood and the constellation of the family structure, notably in the rise of single-parent households, divorced and blended families, and teenage and 50s first-time parents. In short, the family generally, and parenthood specifically, are today in an agitated state of question, flux, and redefinition. Because these societywide changes exert many unfortunately debilitating influences on parenthood, on interactions between parents and children, and consequently on children and their development, organizations at all levels of society increasingly feel the need to intercede in child rearing and to right some of society's ills through parenting preventions and interventions. For these and other reasons, contemporary parenting has witnessed an explosive growth in information and support programs. This trend also leads away from a focus on parents as the proximal protectors, providers, and proponents of their own progeny. In reality, however, parents are children's primary advocates and their frontline defense. Parents are the corps available in the greatest numbers to lobby and labor for children. Few ethical or sentient parents want to abrogate their child-rearing responsibilities. Insofar as parents can be enlisted and empowered to provide children with experiences and environments that optimize children's development, society can obviate after-the-fact remediation.

Prevention and Intervention

Little wonder that a one-time U.S. commissioner of education opined that every child has a right to a trained parent. Preventions are concerned with identifying risk and protective factors that ultimately lead to empirically based interventions (Coie, Watt, West, & Hawkins, 1993; Mrazek & Haggerty, 1994). Contemporary parenting prevention and intervention programs are normally guided by several assumptions. Parents are usually the most consistent and caring people in the lives of their children. If parents are provided with knowledge,

skills, and supports, they can respond more positively and effectively to their children. Parents' own emotional and physical needs must be met if they are to rear children optimally.

Certain tools can help to address these parenting requirements successfully. First, parents benefit from knowledge of how children develop. Therefore, the normative patterns and stages of children's physical, verbal, cognitive, emotional, and social development, as well as their nutritional and health needs, should be part of the knowledge base for parenthood. Second, parents need to know how to observe children. Informed child watching helps to clarify a child's level of development in relation to what parents want children to learn and to accomplish. Observing also allows parents to spot potential trouble early and may help them respond to a child's daily frustrations more skillfully. Third, parents need all manner of skills for managing their children's behaviors. Knowledge of alternative methods of discipline and problem avoidance are basic. Parents need to understand the tremendous impact they have on their children's lives through the simplest things they do: their attention, expressed pleasure, listening, and interest. Fourth are supports for development. Knowing how to take advantage of settings, routines, and activities to create learning and problem-solving opportunities enhances parenthood and childhood. Finally, parents need to be patient, flexible, and goal-oriented—to call on their personal sources of support—and they must command an ability to extract pleasure from their encounters with children.

Positive prevention and intervention programs for parents are guided by beliefs in the consummate role of families in rearing their own children and the importance of family participation in defining its priorities and identifying appropriate prevention and intervention strategies. The responsibility for determining the child's best interests rests first and foremost with parents. Therefore, the doctrine of parental rights remains a fundamental premise of parent education efforts.

Contemporary parents from families all along the continuum from low risk to serious distress can and do seek assistance to become more effective parents. Preventions and interventions designed to help parents come in a variety of venues (psychotherapy, classes, print and broadcast media), settings (homes, schools, health clinics, houses of worship), and formats (individual, family, groups). Child-focused programs are based on theories

that emphasize biological and psychological change mechanisms within the child; parent-focused programs relate primarily to changing parents' cognitions and practices; transactional programs combine child- and parent-focused perspectives to improve the quality of parent-child relationships (P. A. Cowan et al., 1998).

Experimental designs yield the best causal evidence on what works in a prevention or intervention. Early reviewers of parenting programs arrived at the unhappy conclusion that research results were often confusing and failed to demonstrate support for program effectiveness (Dembo, Switzer, & Lauritzen, 1985; Levant, 1988; Powell, 1998). To overcome design and measurement flaws in existing studies, prevention and intervention studies require large samples, inclusion of fathers as well as mothers, recruitment of no-treatment or alternative treatment controls and comparisons, random assignment to conditions, and multimeasure, multimethod assessments that include parent self-reports, parents' reports about children, and independent observations of parents' and children's behavior. Researchers also need to be mindful of the specificity principle and its implications. Researchers rarely find problem-free organizational settings to host programs, consistently uniform program implementation, or consensus among staff on a program's theory of change (Cook & Payne, 2002). With sufficient sample sizes, however, such variability in implementation can be systematically examined as part of outcome research. Many parenting preventions and interventions aimed at at-risk populations have failed to produce anticipated or desired effects on parents or children (St. Pierre & Layzer, 1999), leading to a closer examination of process. For example, small effects from randomized trials of six prominent home visiting programs led one group of analysts to call for research "crafted to primarily help programs improve quality and implementation: for example, to explore which families are most likely to engage in and to benefit from the services . . . and to determine the threshold levels of intensity and duration of services" (Gomby, Culross, & Behrman, 1999, p. 22).

Interest in what works for parenting reflects the general desire to ensure that resources are well spent and, more specifically, coincide with governmental efforts to use findings from scientifically based research (Powell, 2005). For example, the U.S. Department of Education's Institute of Education Sciences established a What Works Clearinghouse (WWC) to provide educators, pol-

icymakers, and the public with high-quality reviews of scientific evidence of the effectiveness of replicable educational interventions, including programs, practices, products, and policies.

Program research has generally focused on three categories of variables in searches for what works in parenting: program features, population characteristics, and program participation (Powell, 2005). Program features have been considered in relation to outcomes and have also been studied as a context of program participation. There are structural characteristics such as the mode of delivery (group, home-based); the onset, duration, and frequency of program services; and whether the parenting program is part of a larger effort that includes other services (early childhood education). A related characteristic is program staffing. For example, in a review of 15 randomized trials of home visiting programs aimed at promoting the cognitive and verbal development of young children in low-SES families, Olds and Kitzman (1993) found that only six produced significant overall program benefits for children. Five of the six successful programs employed professionals or highly trained staff: nurses, teachers, or psychology graduate students. In total, compared with randomized controls, 71% of the interventions that employed professionals, but only 29% of the programs staffed by paraprofessionals, produced significant positive outcomes for children. However, employing professional staff did not guarantee program success, nor were intervention failures attributable solely to the lack of professional training. Goals and content represent other critical sets of program features. Last, parenting programs differ in the pedagogical or clinical strategies they employ to support change in parents.

Contemporary studies also use randomized trials and repeated measures of family processes and child outcomes over long-term follow-up intervals (Forgatch & DeGarmo, 1999; Kellam, Rebok, Ialongo, & Mayer, 1994; Reid, Eddy, Fetrow, & Stoolmiller, 1999). With improved design features, positive effects of programs often prove stronger over time, sometimes more than a year or two after the conclusion of the program (C. P. Cowan et al., 1985; Markman, Renick, Floyd, & Stanley, 1993; Olds, Henderson, Kitzman, & Cole, 1995). A program may stimulate initial disequilibria of organized systems, which may result in replacing disorganization with reorganization at a new structural level only with some delay. Also, treatment groups might remain intact

or at the same level or they may show positive gains, whereas control groups decline. Even small effects of parenting have the potential to become large effects over time (Abelson, 1985). Because parenting has been shown to be stable (Holden & Miller, 1999), specific parental influences, consistently experienced, could accumulate to produce larger meaningful outcomes in childhood.

Case History of a Parenting Intervention

The Center for Child Well-being (CCW; 2004), a branch of the Task Force for Child Survival in Atlanta, Georgia, recognizes that the healthy development of children is not simply a result of eliminating health problems that occur in childhood, but requires proactive nurturing of strengths and positive behaviors, skills, characteristics, and values that promote physical growth and health, cognitive development, and social and emotional well-being. The CCW undertakes projects that engage diverse groups of parents, policymakers, scientists, practitioners, and advocates in synthesizing their knowledge and experience in child health and development. To meet these goals, the CCW has created five networks: Parenting, Early Child Care and Education, Health and Safety, Early Child Development, and Community Support. Each network consists of approximately one dozen geographically dispersed core members who represent a wide range of disciplines, professions, sectors of society, perspectives, ethnicities, and cultural viewpoints.

The Parenting Network and Its Work

The Parenting Network (PN) was recruited by the CCW to apply science and experience to strengthen parenting skills by creating and disseminating practical products that would make a difference for parents. Topics of interest to the PN included parenting stress (time management, setting priorities, work/family issues, social support networks, and parenting skill development); effective parental relationships with caregivers, pediatricians, teachers, and bosses/supervisors; regulating environmental influences on children (media and peers); parental education (recognizing and promoting strengths in children and coping with weaknesses); and nontraditional parenting (single parents, divorced parents, foster parents, and grandparents). The PN has generated a number of products: books, pamphlets, book lists, Web

postings, and the like (e.g., Bornstein, Davidson, Keyes, Moore, & Center for Child Well-Being, 2003).

For one project, the PN reviewed the scientific literature concerned with supporting parents, conducted an online survey of parents and parenting professionals, and evaluated more than 1,000 parenting products (in terms of consumer cost, publication, ease of acquisition, endorsement by official organizations, the organizations responsible for product development, and intended audiences). It observed that very few products were developed for parents of low SES or for minority parents. Rather, approximately 75% of available parenting products were primarily geared to general audiences; the majority were literature-based materials, but more than 100 videos were developed for parents or for use in parenting classes. Of those, only a handful were developed for low-SES parents and only a dozen for minority parents, at an average cost per video of over \$100. Evident throughout the PN's initial review was the thread of awareness that they were to create a product that would serve as a medium—through which knowledge would pass—and that their challenge was to create a vehicle that would effectively deliver their work into the hands of parents who would benefit from this conveyance.

The PN decided to pursue the issue of stress-related parenting, including stress related to normal child development, selection and supervision of child care, balancing work and family, child temperament, discipline and daily hassles, illness or disability, stress associated with intrafamilial conflict, coping with stress, cultivating social support, and building parenting strengths to counteract stress. Parenting is inherently stressful. Decreasing parental stress promises to improve the parent-child relationship as well as the well-being of both parties. Economic stress, for example, has a negative impact on parents, erodes parenting skills, and also undermines children's development (Conger et al., 1994). Connections exist between parental stress and child abuse (Holden, Willis, & Foltz, 1989), harsh parenting styles (Emery & Tuer, 1993), and decreased sensitivity to child cues and more negative feelings toward children (Crnic et al., 1983).

Parental stress that occurs in everyday interactions with children also relates to normal child development. Lack of knowledge about child development often leads to inappropriate expectations, which in turn lead to negative interactions between parents and children. This logic became a central theme of a planned intervention project. If parents better understood normative develop-

mental issues, then they would have more realistic expectations for their children's behavior. The presence of unrealistic expectations, based on a lack of understanding of normal child development, for example, leads to frustrated interactions and increased daily stressors. Increasing parents' knowledge of their children's development would then decrease stress, which would directly benefit both parents and children. *Zero-to-Three* (1997) conducted a survey of 3,000 adults regarding what parents know about child development. Specific areas of misinformation included expectations of young children at different ages and stages, and spoiling and spanking. A report from the Commonwealth Fund, "Child Development and Medicaid: Attitudes of Mothers with Young Children Enrolled in Medicaid," indicated that mothers want simple and easily accessible materials about their child's development and about easing pressures of child rearing (Kannel & Perry, 2001).

The PN conducted two focus groups at Head Start programs. Taking an emic approach, the PN endeavored to learn about the intended audience: what topics interested this audience, by which channels this audience preferred to receive messages, which product formats might most appeal to it, and what barriers prevented it from accessing and using existing information about child development.

One message the PN heard repeatedly was that parents wanted to participate in groups where they could talk to other parents and learn more about how to improve their parenting skills. On this basis, the PN decided to develop a parenting intervention for young African American parents in low-SES circumstances. The PN determined that starting at a local level would increase the likelihood of success.

The culmination of planning led the PN to propose that the CCW develop a "Community Kit" to help these parents reduce parent-related stresses and improve their parenting skills. The proposed kit would be used in a group setting to foster a support network for parents and would include videos and complementary multimedia materials for facilitators and participants. The information included in the kit would address general categories: child development specific to age/stages, stage-specific parenting, and coping with stresses specific to those stages.

The final proposal was the result of a dynamic exchange between parents and parenting experts. The PN had sought and received input directly from parents representative of the ultimate target audience to discover what those parents felt they most needed, how

that information would best be received, and how the information to be contained in the Community Kit could reflect the members' own child development, experiences, and parenting expertise.

Partnerships

The CCW also initiated partnerships with organizations that agreed to field-test, fine-tune, and implement the Community Kit. Expert interviews and focus groups were used to obtain information from African American cultural authorities and behavior change theorists, service providers, and parents. In particular, four critical pieces of information about content and delivery of messages were sought and obtained:

1. *Message style:* How messages about child development and child rearing, stress and coping, should best be formulated to meet with the highest level of recognition and understanding?
2. *Messenger:* Who should present those messages?
3. *Barriers:* What impediments stand between recognition and understanding of such messages and behavior change related to child development and child rearing, stress and coping?
4. *Success:* What are the best ways to overcome barriers to recognition and understanding of target messages?

Findings indicated that low-SES African American parents were most concerned with stresses related to finding time for self, finances, balancing work and family, and ensuring quality child care. Parents reported that they needed to learn more about their child's development and talked about issues such as discipline, attachment, and establishing a routine as being important. Parents also preferred parenting classes held in a support group setting, and wanted to see videos with real-life parents, with whom they could identify, instead of celebrities or white-coated child development experts. Parents stressed the importance of authenticity and avoiding a judgmental tone. Many parent education programs have been criticized for attempting to impose middle-SES values on all types of families and failing to acknowledge the strengths and values of minorities. Furthermore, many parenting education materials undermine parents' feelings of efficacy (C. Smith, Perou, & Lesesne, 2002).

These parents' focus groups provided the framework for the design of the main CCW parenting intervention.

Based on comments from parents, several features of the intervention were considered vital to its success:

1. *Support:* Group formation should be used to increase support networks that also constitute a product of the project.
2. *Appropriateness:* The intervention should be primarily focused on low-education/low-income African American mothers and fathers, but can be modified to fit various languages, racial and ethnic norms, and generations.
3. *Incentives:* The work focused heavily on addressing both barriers and incentives to participation.
4. *Reinforcement:* In addition to messages discussed and reinforced in the group setting, participants would be provided with materials to take home to reinforce messages at the time when they need the information to achieve behavior change.

Parenting in the Real World

On the basis of findings from the background research and focus groups, the PN developed a targeted intervention for parents of children from birth through 3 years of age called Parenting in the Real World: Kids Don't Come with Instructions (a name generated by focus group participants). Parenting in the Real World (PRW) is a system of parenting classes for low-income African Americans that addresses the most critical aspects of parenting young children, as identified by the PN and in focus groups of actual parents. The main goals of PRW are to help parents reduce their parenting stress and improve their parenting knowledge and skills. PRW consists of seven 90-minute sessions, including an introductory session, five topic sessions, and a graduation. Topics covered are knowledge of child development; discipline; attachment; juggling work, school, and family; and taking care of self. The PRW tool kit was developed for group facilitators, such as Early Head Start family support coordinators, and consists of a video, facilitator's guide, a parent handbook, marketing material, and message reinforcement materials, such as pens and key chains imprinted with key concepts.

Each PRW session begins with a short video clip designed to trigger discussion among the participants. Parenting stresses and coping techniques are identified and discussed. Sessions also contain exercises designed to

build parents' skills and improve their understanding of child development. These exercises include a judicious mix of role-play, quizzes, and peer education. At the end of each session, parents are given take-home materials and asked to identify one area to work on during the following week. Parents are asked to report on their activities at the next session. One important goal of each session is to have parents build on their strengths to improve their parenting skills and increase their feelings of competence. The intervention was also designed to foster connections among participants.

Assessment

Three groups of parents participated in an initial assessment of PRW: (1) Parents whose children were enrolled in Early Head Start and who took part in the PRW intervention served as the treatment group; (2) parents whose children were enrolled in Early Head Start, but who did not participate in the PRW intervention, served as the first control group; and (3) parents whose children were not enrolled in Early Head Start served as the second control group. (Sample sizes were small due to limited funding for the evaluation phase of the project.) All parents were African American, and most were mothers. On average, parents were about 30 years of age, had two children, and almost half had never been married. Over a quarter of parents had a high school diploma or less education, about half had completed either partial college or specialized training, and another quarter had completed a 4-year college degree. Reported annual income ranged from under \$10,000/year to between \$40,001 and \$50,000/year. The parents in the three groups did not significantly differ in age, education, or income levels.

To test the feasibility of the kit, parents and facilitators in the PRW program completed ongoing evaluations of each of the seven sessions. Almost all parents reported that the number of sessions was appropriate and that the length of the sessions (90 minutes) was appropriate. Parents' evaluations of program content and structure were very positive. Upon graduation, parents were asked a variety of questions, including whether the program helped to improve their parenting skills and their confidence about their parenting skills, and if they would recommend the program.

Parent perceptions of the program's effects were overwhelmingly positive. Parents agreed that the information presented across the seven sessions was understandable and interesting and that the video

segments were informative and entertaining. The topics covered in the program were deemed relevant to parenting. They reported a good balance among lecture, discussion, and activities, and that the facilitator did a good job of teaching the sessions. Parents reported having learned new parenting skills or strategies across the seven sessions. Similarly, they reported that the sessions had reduced their parenting stress. Overall, parents agreed that the PRW program helped to improve their parenting, made them feel more confident about their parenting, and reduced their parenting stress. The treatment group also reported less depression than the control groups at posttest, controlling for pretest levels of depression. All parents reported that they would recommend the program to a friend.

Facilitators were asked similar questions about the comprehensibility of the material; balance among lecture, discussion, and activities; and video segments. They were also asked whether the facilitator's guide was easy to use, helpful, clear, and thorough; whether parents were interested in the topics; and whether it was easy to get parents to participate. Like the parents, the facilitators reported that the information presented across the seven sessions was understandable to the parents and maintained parents' interest, and they found it easy to get parents to participate. They agreed that the video segments were informative and entertaining and that they achieved a good balance among lecture, discussion, and activities. Facilitators found the teaching guide easy to use and thorough.

The final stage of the evaluation process included focus groups for parents who participated in the classes, conducted within 2 weeks after the sessions were completed and facilitated by an independent consultant. These exit focus groups gave participants the opportunity to talk about their experiences in the classes and how the classes impacted their parenting beliefs and behaviors. Parents had the opportunity to offer suggestions about the sessions and provide feedback to be used to revise the contents of the PRW kit. Facilitators also participated in a focus group. They were asked about the sessions and whether or not they felt that the structure and content were likely to improve parenting and child development. Issues such as attendance, time of sessions, incentives, and facilitator characteristics were also discussed.

Transcriptions from these focus groups were analyzed for themes. For parent focus groups:

1. The group discussions and the support group setting were deemed very helpful. Interacting with other parents and being able to come to the session and talk helped to relieve parenting stress.
2. Parents agreed that the sessions had the appropriate amount of information and found the information to be understandable and relevant to their lives.
3. Participants reported learning new information and using new skills that helped to reduce their stress: establishing a routine, yelling at their children less, reassessing their beliefs about child development, becoming more patient with their children, and learning that all children are different.
4. Parents enjoyed the take-home items and found them to be useful reminders of the main messages.
5. Parents formed support networks with one another. Some exchanged phone numbers and helped one another with babysitting.
6. All parents would recommend the PRW course to their friends.

For facilitator focus groups:

1. Each facilitator found the PRW kit easy to use. They liked the organization of the topics as well as the content in each section.
2. The facilitators felt that the participants could relate to the parents in the video.
3. Facilitators found the content to be understandable and relevant (although they wanted to see more time spent covering discipline).
4. Facilitators suggested that homework assignments be made more user-friendly and simpler.
5. Facilitators agreed that they would continue to use the PRW kit for their parent education classes.

Ongoing Efforts

Based on feedback from both parents and facilitators, the PRW kit was revised. Obtaining real-world feedback throughout each stage of development and refinement was essential to making the CCW parenting intervention both accessible and relevant to the target population. Further dissemination and continued evaluation of the PRW kit are aimed at improving parental involvement, and at the same time arming Early Head Start centers with a valuable tool for parent education. The topics covered in PRW are issues that all parents face, and par-

ents who took part in PRW classes reported that the support group atmosphere was extremely helpful, the topics especially relevant, and the information contained in the classes effective in reducing their stress and affording them strengths and strategies to be more available and consistent with their children. Furthermore, participation in the PRW classes ameliorated depression in parents, and many parents reported that they changed their parenting behaviors, which increased their feelings of competence and improved their relationships with their children.

CONCLUSIONS

Parents intend much in their interactions with their children: They promote their children's mental development through the structures they create and the meanings they place on those structures, and they foster their children's emotional regulation, development of self, and social sensitivities and participation in meaningful relationships and experiences outside of the family through the models they portray and the values they display. The complex of parent cognitions and practices with children is divisible into domains, and parents tend to show consistency over time in certain of those domains. Some aspects of parenting are frequent or significant from the get-go and wane thereafter; others wax over the course of childhood. Parenting, along with other forces, exerts powerful influences on children's psychological development. Although not all parenting is critical for later development, and single events are rarely formative, parenting certainly has long-lasting effects. Little and big consistencies of parenting aggregate over childhood to co-construct the person. The interactive and intersubjective aspects of parent and child have telling consequences for development. Researchers and theoreticians today do not ask *whether* parenting affects child development, but *which* parent cognitions and practices affect *which* aspects of development *when* and *how*, and they are interested also to learn the *ways* in which individual children are so affected, as well as the ways individual children affect their own development.

Children bring unique social styles and an active, physical, social, and mental life to everyday interactions with adults that shape their caregiving experiences. Children alter the environment as they interact with it, and they interpret their experiences and environment in idiosyncratic ways. In addition, biology, personality,

and contexts all play important roles in determining the nature and function of parenting. A full understanding of what it means to parent children depends on the several ecologies in which parenting takes place. Family composition, social class, and cultural variation all exert salient influences on the ways parents rear their children and what they expect of children as they grow.

Of course, human development is too subtle, dynamic, and intricate to maintain that parenting alone determines the course and outcome of ontogeny; stature in maturity is shaped by the actions and vicissitudes of individuals themselves across the life span. Parenthood does not fix the route or the terminus of the child's development. Parent and child convey distinctive characteristics to every interaction, and both are changed as a result. In short, parent and child actively construct one another through time.

Parents have central roles to play in children's physical survival, social growth, emotional maturation, and cognitive development. A better understanding of the nature of the human being is afforded by examining parents' cognitions, practices, and their consequences—the unique and specific influences of parents. As children achieve autonomy, parenthood ultimately means having facilitated a child's self-confidence, capacity for intimacy, achievement motivation, pleasure in play and work, friendships with peers, and continuing academic success and fulfillment. Within-family parenting experiences exercise a major impact over growth in each of these spheres of development. In parenting, we sometimes don't know what to do, but we can find out; we sometimes do know what to do, but still don't get into the trenches and do it.

So, parenting is a peculiar kind of life's work, marked by challenging demands, changing and ambiguous criteria, and all too frequent evaluations. Principles such as specificity, interdependence, and transaction, and indirect and direct effects, do not make it easy. Successful parenting entails both affective components—in terms of commitment, empathy, and positive regard for children, for example—as well as cognitive components—the how, what, and why of caring for children. Moreover, the path to achieving satisfaction and success in parenting is not linear or incremental, but tends to meander. Different tasks are more or less salient and challenging at different periods in the course of child rearing. It is obvious that parenthood is central to childhood, to child development, and to society's long-term investment in children. Parents are fundamentally com-

mitted to the survival, socialization, and education of young children. But parenthood is also a critical component of adulthood. So we are motivated to know about the meaning and importance of parenthood as much for itself as out of the desire to improve the lives of children and society. Parenting is a process that formally begins before pregnancy and continues through the balance of the life span. Practically speaking, *once a parent, always a parent*.

INTRODUCTION

What type and how much care do young children receive from adults other than their parents? What effects do such care arrangements have on their development? Although the latter question has been the focus of heated ideological debate for more than 30 years, the issues are actually more complicated than the shrill polemics suggest, and interpretation of the burgeoning literature is often difficult. In addition, researchers have learned in recent years to be wary of facile generalization across cultures or circumstances when studying such issues. It is naive to ask whether nonparental child care is good or bad for children or whether center care is better for chil-

dren than home-based child care. Instead, researchers must examine children's development in the context of the rich array of people, experiences, and settings to which children are exposed, recognizing that the effects are likely to differ from child to child, from one phase of life to the next, and from setting to setting.

Most of the published research on the effects of child care has been conducted in the United States, where ideologically driven passions have been most intense, but we have tried in this chapter to report and evaluate relevant research conducted in other countries as well. Such studies help place in context and perspective the results of research conducted in the United States and should foster caution about the universality, generalizability, and interpretability of the research literature. Unfortunately, social scientists tend to have a very myopic view of human history, often treating popular or widespread practices as basic species-typical givens

The authors gratefully acknowledge the many constructive comments and suggestions offered by Jay Belsky.

without analyzing their origins and history. Because formal schooling has been mandatory in most developed countries for several generations, for example, the potential effects of schooling on child-parent relationships are largely ignored, and concerns are raised about the potential effects of nonparental care on younger children. By contrast, the fact that formal education (or productive labor away from family members) is a much more recent and culturally restricted innovation than nonparental child care is seldom recognized. The transition to school is viewed as normal and normative; enrollment in child care, by contrast, has been widely questioned, popularly and professionally. Hrdy (1999, 2002, 2005) has argued persuasively, however, that humans evolved as cooperative breeders and thus that human child rearing has always been characterized by extensive involvement by multiple relatives and conspecifics.

Of course, preoccupation with the potentially harmful effects of nonparental care in early childhood is not accidental; it reflects the belief, partially attributable to psychoanalysis and its incorporation into popular North American belief systems, that early experiences have disproportionately powerful influences on child development. Fortunately, commitment to the early experience hypothesis is not as profound today as it was as little as 4 decades ago, when psychologists implied that major early experiences had long-lasting effects that were nearly impossible to overcome. Many researchers and theorists have since come to believe that all developmental periods are critical and that development is best viewed as a continuing process in which successive experiences modify, modulate, amplify, or ameliorate the effects of earlier experiences on remarkably plastic individuals (J. S. Kagan, 1980; Lerner, 1984; Lewis, 1998). This life span view of development undeniably complicates efforts to study longer-term effects on child development—particularly the effects of less salient and significant events—but appears to represent better the determinants and course of human development.

Over the past decade, researchers have also come to recognize the diversity and complexity of child care arrangements and their effects on children. Children grow up in a heterogeneous array of cultural and family circumstances, and many also experience multiple types of nonparental care. The diversity of family circumstances, the disparate array of nonparental care arrangements that exist, and the complex effects of en-

dogenous differences among children all ensure that nonparental child care per se is unlikely to have clear, unambiguous, and universal effects, either positive or negative, when other important factors are taken into account (Lamb & Sternberg, 1990). Instead, researchers must focus on the nature, extent, quality, and age at onset of care, as well as the way these factors together affect children with different characteristics, from different family backgrounds, and with different educational, developmental, and individual needs. In this endeavor, contemporary researchers will need to focus increasingly on the crucial intersection between home and out-of-home care settings and their complementary impact on children.

In the first substantive section of this chapter, we attempt to place contemporary patterns of child care in their broader sociocultural and historical context. Nonparental care is a universal practice with a long history, not a dangerous innovation representing a major deviation from species-typical and species-appropriate patterns of child care (Hrdy, 2005; Lamb & Sternberg, 1992). Specific patterns of child care vary cross-culturally, of course, with different nations emphasizing different goals and mechanisms. These differences are revealing to the extent that they underscore the need to view any research on the “effects” of “child care” in the context of the goals, values, and practices of particular cultures at specific points in time.

We next sketch changing patterns of child care in the United States and other industrialized countries. Over the past 3 decades, nonparental care has become a normative experience for preschoolers in the industrialized countries, although there are broad inter- and intracultural differences in the types of care received and in the ages at which most children begin receiving such care.

The effects of day care on child development then become central. In the past 15 years, most researchers have emphasized the need to evaluate the quality of care when assessing effects on children, and the parameters of this debate, as well as the popular indices of quality, are introduced in the third section. The increasing belief that the quality of care plays a crucial role in determining how children are affected by nonparental care has fostered efforts to understand *how* care providers behave and how they should be trained to provide growth-promoting care for children (Bredekamp, 1987a, 1987b).

Unfortunately, “high-quality” alternative care is difficult to define, measure, and promote comprehensively,

even though some simple and concrete measures—including adult-child ratios, levels of care provider training and experience, staff stability and pay, and the adequacy of the physical facilities—can be used to assess structural aspects of the quality of care. These dimensions are most likely to be emphasized by state standards, which set the minimal acceptable standards on a state-by-state rather than federal basis (Phillips & Zigler, 1987). Structural characteristics affect the likelihood of high-quality care, but they do not guarantee it: Centers that are characterized by good adult-child ratios and are staffed by well-trained providers may still provide care of poor quality. Extensive training, education, and experience, like generous adult-child ratios, have to be translated into sensitive patterns of interaction, displays of appropriate emotion, and the intuitive understanding of children that make the experiences richly rewarding for them. The ease with which and the extent to which structural factors are translated into quality clearly vary depending on the culture, the context, and the alternative opportunities available to children, care providers, and parents. Furthermore, even the benefits of high-quality care may be compromised when the demands of the parents' work roles result in excessively long periods of nonparental care. It is thus impossible to write a recipe for high-quality care that is universally applicable. High-quality care needs to be defined with respect to the characteristics and needs of children and families in specific societies and subcultures rather than in terms of universal dimensions.

Debates about the effects of child care on children's development, which are the focus of the fourth section, have varied over time in response to a multitude of social, economic, and scientific factors. Initially, research efforts were focused on 3- and 4-year-old children in an attempt to address the implicit question "Is out-of-home care bad for young children?" Anxieties about the effects of nonmaternal care on child-mother attachment predominated, with professionals warning that damaged attachments would in turn lead to maladaptation in other aspects of development. Only in discussions regarding the benefits of compensatory education for impoverished children were these concerns submerged, presumably because the risks were viewed as less serious than the potential gains. By the early 1980s, however, the results of several studies, most conducted in high-quality day care centers, had fostered a widespread consensus that, contrary to the dire predictions of attachment theo-

rists, nonparental care begun in the 3rd year of life or later need not have adverse effects on psychosocial development (Belsky & Steinberg, 1978; Belsky, Steinberg, & Walker, 1982; Clarke-Stewart & Fein, 1983). This conclusion had to be qualified, however, because most of the studies involved atypically good programs, ignored home-based child care and in-home sitter arrangements, and paid no attention to group differences in parental values or attitudes prior to enrollment in nonparental care.

These limitations notwithstanding, public concerns about child care changed in the 1980s, by which time out-of-home care had become a normative and manifestly nonharmful experience for preschoolers. Instead, concern was focused on the many infants and toddlers who began receiving nonparental care before they had time to establish and consolidate attachments to their parents. Intensive and contentious research has since established that infant day care does not typically harm infant-mother attachment, but uncertainty persists concerning the interpretation, universality, and implications of the established effects. Focus on infant-mother attachment has also fostered research concerned with the effects of infant child care of varying quality on other important aspects of development, such as compliance with adults, peer relationships, behavior problems, and cognitive/intellectual development.

Unfortunately, recent preoccupation with the way the quality of care mediates the effects of nonparental child care on young children has led researchers to overstate the demonstrated importance of quality of care. Just as quality clearly makes a difference, so, too, is it clear that the effects of quality are considerably less profound than expected. Whether this reflects difficulties measuring quality or the reality that human development is shaped by so many factors that any one factor seldom has a large and dramatic effect is not clear, but both policymakers and researchers need to address this point much more forthrightly than they have in the past.

Public and professional concerns about the effects of nonparental care have been focused on infants, toddlers, and preschool-age children, but human children remain dependent on adults through adolescence and into early adulthood. The effects of the educational system and school personnel are discussed elsewhere in this *Handbook*, but the effects of before- and afterschool care on elementary, middle, and high school students have attracted some attention recently as well. As with younger

children, increases in the rates and extent of maternal employment have forced many parents to arrange supervision and care for their children by others. The diverse effects of self-care and various forms of afterschool care are summarized in the fifth section. The chapter ends with an integrative summary and conclusion.

CHILD CARE IN CULTURAL CONTEXT

Recent media hyperbole notwithstanding, arrangements regarding nonparental child care do not represent a new set of problems for the world's parents. In fact, decisions and arrangements about children's care and supervision are among the oldest problems faced by human society. The fact that they were not discussed frequently in the past may reflect the failure of the men with political and intellectual power to discuss a "women's issue" as well as the fact that maternal care at home has been the dominant mode of early child care in the groups and eras most familiar to contemporary social and political scientists.

Unfortunately, the long history of attempts to make child care arrangements has not reduced the complexity of the issues faced by parents and policymakers today, although it has ensured that a diverse array of solutions have been tried. In this section, we sketch some of the arrangements that have developed in various parts of the world. Our goal is to provide a framework for analyzing these individual solutions and for making cautious and informed comparisons among them. In the first subsection, we place child care in the context of species-typical behavior patterns and needs. We then discuss the various purposes that nonparental child care can be designed to serve in industrial societies. In the third subsection, we describe the ideological dimensions along which countries can be arrayed and the resulting dangers of superficial generalization from one country to another. Finally, we summarize implications for policymakers, researchers, and practitioners, which we revisit later in the chapter after examining the empirical literature.

Human Evolution and Ecology

Our species is one for whom decisions about child care arrangements and the division of time and energy among child care, provisioning, and other survival-relevant ac-

tivities have always been necessary (Lancaster, Rossi, Altmann, & Sherrod, 1987). Humans are born at a much earlier stage of development than are the young of any other mammalian species, and a larger proportion of development takes place outside of the womb in humans than in any other mammal (Altmann, 1987). The period of dependency, and thus the process of socialization, is extremely prolonged among humans, with offspring dependent on conspecifics into adulthood, whereas the young of most mammals become nutritionally independent at the time of weaning. As a result, parental investment in each child is extremely high, and recent scholarship makes clear that other conspecifics typically make invaluable contributions as well (Hrdy, 2002, 2005). Humans have long been forced to develop complex and extended alliances and arrangements with others to ensure the survival of both themselves and their offspring; studies in many contemporary cultures underscore the survival value of these contributions (Hewlett & Lamb, 2005; Hrdy, 2002, 2005). Many theorists believe that pair-bonding represents one adaptation to the basic needs of human parents to cooperate in the provisioning, defense, and rearing of their offspring (Lancaster & Lancaster, 1987). In many environments, multifamily units developed to maximize individual survival in circumstances where, for example, hunting or gathering required cooperative strategies.

Studies of modern hunter-gatherers provide insight into the social organizations that might have developed in circumstances such as these (contributors to Hewlett & Lamb's, 2005, anthology describe child care practices in several foraging societies). In many such societies, within-family divisions of responsibility between men and women are paralleled by cooperative hunting strategies among men and cooperative gathering strategies among women. Depending on the task, the season, the children's ages, the availability of alternatives, and the women's condition, children accompany one or other parent at work or are left under the supervision of alloparents, often older children or adults.

Prior to weaning, mothers assume the heaviest portion of child care responsibilities in most societies, although alloparents are active long before weaning in many cultures where weaning is delayed and nursing coexists alongside other forms of feeding (Fouts, Hewlett, & Lamb, 2005; Fouts, Lamb, & Hewlett, 2004). Although the strategies of provisioning, protection, and child care are different in industrialized countries and

in those societies where pastoral or agricultural traditions have replaced nomadic hunting and gathering, similar choices must always be made. Exclusive maternal care throughout the period of dependency was never an option in what Bowlby (1969) called “the environment of evolutionary adaptedness” and was seldom an option in any phase of human society even through early childhood; it emerged as a possibility for a small elite segment of society during one small recent portion of human history. Infants in 40% of the cultures sampled by Weisner and Gallimore (1977) were cared for more than half the time by people other than their mother, for example, and rates are surely higher where toddlers, preschoolers, and young children are concerned. It is thus testimony to the power of recent mythology and ignorance of the dominant human condition throughout history that exclusive maternal care came to be labeled as the “traditional” or “natural” form of human child care, with all deviations from this portrayed as unnatural and potentially dangerous. Braverman (1989) decries this “myth of motherhood,” and Silverstein (1991) has bemoaned the way the historically recent “essentializing” of maternal care has shaped the popular and scholarly approach to conceptualizing and studying various forms of nonmaternal care. Nonmaternal child care is portrayed as deviant, even though it is universal and normative. Only the need for parents in industrialized countries to leave their children in the care of paid care providers, rather than neighbors or kin, is novel, and the possible implications of this situation have received little attention from researchers or theorists (see Daly & Wilson, 1995).

Economic Influences on Child Care Practices

In contemporary industrial societies, the availability of nonparental child care is determined by economic circumstances, local social demography, history, and cultural ideology. Of these, economic factors often play the major role in determining whether and what types of nonparental care arrangements are available. To complicate matters, however, economic, demographic, ideological, and historical factors often exert inconsistent and contrasting pressures. In North America, for example, employed parents began to seek help caring for their infants and young children before such practices were popularly endorsed. Economic circumstances thus forced families to make nonmaternal care arrangements, of which many family members and neighbors disapproved.

The central prominence of economic forces can be illustrated with many examples. In agricultural societies, for example, infants are typically left in the care of siblings, relatives, or neighbors while their mothers work in the fields (e.g., Fouts, 2002; Hewlett, Lamb, Shannon, Leyendecker, & Schölmerich, 1998; Leiderman & Leiderman, 1974; Nerlove, 1974; Weisner & Gallimore, 1977). Economic factors are also important in more developed countries. Mason and Duberstein (1992) have shown that the availability and affordability of child care influences maternal employment in the United States. Similarly, Sweden’s family policy was developed because rapid industrialization produced a national labor shortage. To increase the number of women who were employed and to increase the willingness of young families to bear and rear future workers, it was necessary to develop a comprehensive system in which women were paid well, in which early child care could be accomplished without professional or financial sacrifices, and in which the assured availability of parental leave and high-quality nonparental child care facilities motivated parents to have and rear children (Broberg & Hwang, 1991; Gunnarsson, 1993; Haas, 1992; Hwang & Broberg, 1992; Lamb & Levine, 1983).

The communist countries of Eastern Europe likewise made child care facilities widely available to facilitate the increased participation of women in the paid labor force (Ahnert & Lamb, 2001; Kamerman & Kahn, 1978, 1981). Similarly, the U.S. and Canadian governments became involved in the financial support and supervision of nonmaternal child care facilities during the Second World War to encourage women to work in war-time industries while male potential workers were away at war (Griswold, 1993; Tuttle, 1993).

Meanwhile, in what is now Israel, small agricultural settlements called *kibbutzim* were established in the early part of the twentieth century by Jewish socialists from Eastern Europe (Infield, 1944). The malaria-infested swamplands and rocky desert soils posed severe problems for the idealistic and inexperienced farmers, and the need for female labor made it expedient to have one person, usually a woman, take care of several children rather than have mothers individually care for their own children. To maximize productivity and minimize the amount of housing needed, the original *kibbutznikim* (inhabitants of the *kibbutz*) also decided that children should live in collective dormitories, visiting their parents only for several hours every day (Neubauer, 1965). Over the ensuing decades, the emer-

gence of the communal child care system has been attributed to ideological commitment (gender equality), and the role played by economic necessity has been downplayed.

The tendency to develop post hoc ideological explanations for popular behavior patterns tends to obscure the central role of economic circumstances in the development of nonparental care arrangements. Lamb, Sternberg, Hwang, and Broberg (1992) could identify no country in which the introduction of nonmaternal child care policies was not driven primarily by economic forces, although subgroups (e.g., the British upper class) occasionally sought child care assistance (e.g., nannies) for other reasons.

Other Goals and Purposes of Nonparental Child Care

Nonparental child care serves a variety of additional purposes, the most prominent of which include fostering equal employment opportunities, acculturation and ideological indoctrination, the encouragement of economic self-sufficiency, and the enrichment of children's lives.

Fostering Female Employment

As mentioned earlier, child care policies in many countries have been designed at least in part to promote female employment and to equalize the potential employment opportunities of men and women (Cochran, 1993; Lamb, Sternberg, Hwang, et al., 1992). The formerly communist countries of Asia and Eastern Europe, for example, made this a central feature of their family policies (Ahnert & Lamb, 2001; Foteeva, 1993; Kameron & Kahn, 1978, 1981; Korczak, 1993; Nemenyi, 1993; Zhengao, 1993). Unfortunately, equality of opportunity has never been achieved anywhere despite the costly and extensive investment in child care facilities, and women do not enjoy equitable pay, whether or not their professions are integrated.

Influencing Demographic Patterns

The limited availability of high-quality child care also appears to have affected fertility rates in European countries such as Germany, with an especially dramatic effect on well-educated women (Ahnert et al., 2005; Kreyenfeld, 2004). Concerns about these demographic trends have led the government of reunified Germany not only to strengthen the child care system in the east that it had initially attempted to dismantle but also to

improve the underdeveloped child care infrastructure in the west (Ahnert & Lamb, 2001).

Acculturation and Indoctrination

Child care facilities have frequently been used to facilitate acculturation or ideological indoctrination. In northern Italy, for example, the number of children in preschools nearly doubled in the 1960s because the educational philosopher Ciari believed that preschools could be used to provide cultural foundations for children from different backgrounds (Corsaro & Emiliani, 1992). In Israel, meanwhile, the speed with which successive waves of Jewish immigrants have risen to positions of economic and political power can be attributed in the main to the participation of immigrant children in preschool programs where they learn Hebrew and the norms of Israeli culture (M. K. Rosenthal, 1992). The children in turn socialize and teach their parents. In the People's Republic of China, child care was made available in the early 1950s ostensibly to help children learn the importance of hard work and individual sacrifice (Lee, 1992). Universal day care also permitted parents to participate in reeducation programs, sponsored by the new communist government as part of its plan for the reconstruction of China. Finally, Shwalb and his colleagues (Shwalb, Shwalb, Sukemune, & Tatsumoto, 1992) point out that preschool education was made widely available to 4- and 5-year-old Japanese children in 1941 in part because the government wanted to use kindergarten as a means of fostering nationalism.

Encouragement of Economic Self-Sufficiency

Child care facilities have also been provided to encourage women to seek job training or paid employment and thus to cease being the beneficiaries of welfare; in the United States, pursuit of this goal led politicians to completely reshape the welfare system in the mid-1990s (National Academy of Science, 2003). Ironically, this goal was promoted with greatest vigor by conservative politicians who opposed governmental involvement in child care and emphasized the importance of maternal care and the "traditional family" while instituting policies that required parents to become economically self-sufficient and promoted this by subsidizing nonparental child care (Knitzer, 2001).

Enrichment of Children's Lives

The impetus to develop and invest in intervention or enrichment programs grew in the late 1950s and early

1960s, following the determination by experts that poor children experienced understimulation, overstimulation, or inappropriate stimulation, which in turn led them to perform poorly in school and on achievement tests (Clarke-Stewart, 1977; Fein & Clarke-Stewart, 1973; Hess, 1970). The development in the United States of the Head Start program in 1965 exemplified such a motivation to enrich the lives of children from the poorest and most disadvantaged families (Zigler & Valentine, 1979). Likewise, despite its strong opposition to nonmaternal care, the Catholic Church in Italy came to view preschools as a medium for socializing children from impoverished homes whose parents were considered incapable of effective socialization (Corsaro & Emiliani, 1992; New, 1993). Only later was preschool deemed acceptable for children in better socioeconomic circumstances. Until very recently, similarly, child care was widely viewed in Great Britain as a service for children at risk because their parents could not cope (Melhuish & Moss, 1992) and government funding was largely channeled to centers serving disadvantaged, troubled, and disabled children. In Canada, meanwhile, it took the recommendations of a government task force in the mid-1980s to recast day care as a service of potential value to all Canadian families, rather than as a service for disadvantaged and immigrant children (Goelman, 1992; Pence, 1993).

Exemplary programs like Head Start notwithstanding, a desire to enrich the lives of children did not motivate the initial development of nonparental care facilities in most countries. Parents and their government representatives may hope for care of adequate quality, but there is ample evidence that parents often accept care of lower quality because they simply have no choice (National Academy of Science, 1990, 2003). Where parents, groups, and societies have seriously considered the needs and best interests of children, these have often been secondary considerations. Many politicians and social commentators argue further that few societies, whether industrialized or nonindustrialized, have addressed children's needs satisfactorily.

Dimensions of Cross-Cultural Variation

Cultures clearly differ with respect to the goals—other than supervising children while their parents are employed—that nonparental child care is expected to serve. In addition, there are four major philosophical

or ideological dimensions along which contemporary societies can be compared. The first is one that has already been broached: the ideology concerning *equality between men and women* and how the availability of nonmaternal care programs increases female labor participation and allows women to advance themselves economically and professionally.

Consider international variations in the extent to which the provision of child care is viewed as a *public responsibility* rather than a *private or individual concern*. The United States probably represents the extreme among the industrial societies holding that decisions about child care should be left to individual families, that the cost and quality of care should be set by competition between the unregulated forces of supply and demand, and that governmental intrusions of all kinds should be resisted on the grounds that they would simply reduce efficiency (Blau, 2000; B. Cohen, 1993; Lamb, Sternberg, Hwang, et al., 1992; Spedding, 1993). Since 1997, the United Kingdom has moved from a position alongside the United States to one in which the role of the state is ensuring access to high-quality child care has been embraced and major investments have been made in building up the child care infrastructure. At the other extreme stand the democratic socialist countries of Scandinavia and the formerly communist countries of Eastern Europe, in which society as a whole is believed to share responsibility for the care and welfare of all children (Ahnert & Lamb, 2001; Hwang & Broberg, 1992; Kameron & Kahn, 1978, 1981; Stoltenberg, 1994). The child care systems that evolved in each country necessarily reflected that society's position regarding public and private responsibilities. Contributors to Lamb, Sternberg, Hwang, et al.'s volume suggested that the best quality nonparental care was provided or regulated by governmental agencies in the context of comprehensive family policies. By contrast, countries or regions that have failed to develop comprehensive family policies tend to provide care of much poorer average quality.

Third, societies vary with respect to whether child care is viewed as a *social welfare program* or an *early education program*. Because all industrialized countries and most developing countries regularly assign responsibility for children older than 5 or 6 years to educational authorities, many countries have expanded the availability of care settings for young children by emphasizing the educational value of preschool care. Higher percentages of preschoolers are in nonparental

care settings when societies attribute educational rather than custodial goals to them (Olmsted, 1992). Because public education is a widely accepted concept, it has also proven relatively easy to direct public finances to the support of preschool nonparental care when such facilities are represented as the early stages of a universal educational process, as they are in France, Belgium, Italy, Iceland, New Zealand, and Spain (see next section). By contrast, when nonparental care is viewed as a custodial babysitting service addressing the goals of social welfare, it has proven harder to obtain public support and harder yet to make quality of care a relevant dimension. Thus, the presumed character of nonparental care has major and far-reaching implications for the quality, type, and public support for nonparental care services. In Italy, the United Kingdom, France, and the Netherlands, for example, the portrayal of day care or nursery schools as an educational service rather than a welfare service altered perceptions of its value by middle- and upper-class families and thus legitimized its utilization (Clerkx & van IJzendoorn, 1992; Corsaro & Emiliani, 1992; Lamb, Sternberg, Hwang, et al., 1992; Melhuish & Moss, 1992). Analogously, whereas day nurseries and kindergartens both emerged in St. Louis at the start of the twentieth century, the latter came to be seen as part of the educational process and flourished, whereas day nurseries experienced the struggle for support that continues to this day. Cahan (1989), too, has chronicled the emergence of separate child care and early childhood education pathways in the nineteenth and twentieth centuries.

The last, infrequently considered, factor concerns *basic conceptions of childhood and developmental process*. Many inhabitants of the Western industrialized countries are steeped in the Freudian and post-Freudian belief that early experiences are crucially important. Endogenous tendencies may directly affect development, too, of course and, perhaps more important, interact with and alter the impact of diverse experiences on developmental processes and outcomes. Variations in the conceptualization of developmental processes have major implications for child care practices and the seriousness of concerns about the quality of care.

Students of comparative child care practices and policies need to consider these four dimensions (ideologies concerning male and female roles, perceptions of private and public responsibilities, educational and custodial goals, and conceptions of developmental

processes) when evaluating the policies and systems of diverse countries because international differences on these dimensions make it difficult and often inappropriate to generalize from one country to another and to use any country's social policies as models for adoption by others. Only when we fully understand the social structures and the ideologies that led to the development of a particular child care system are social scientists likely to learn from the experiences of other societies.

In addition, differences in parental and national goals lead to differences in the implementation of programs and in the effects of child care, and the evaluation of those outcomes differs from society to society. In some of the Western industrial countries, for example, assertiveness is viewed as a desirable goal, whereas others view it as one manifestation of undesirable aggression. Everywhere debate persists over the relative values of individualism and cooperation: Is compliance an index of passive acquiescence or of being well socialized? As long as disagreements persist concerning these values, it becomes impossible, for example, to state objectively that any given pattern of child care has positive or negative effects on behavioral adjustment.

Few countries have actually developed integrated child care systems that address all the functions of child care equally well. Even the best-developed and most carefully integrated systems must deal with the contradictory impulses created by pursuit of these different goals, and in most countries a patchwork array of solutions has emerged over time, with different and often contradictory policies designed to address each of these needs. At its best, pursuit of the highest possible quality of care forces ideologically liberal governments into a dilemma. Better quality care almost invariably involves more adults taking care of fewer children, and this becomes expensive. In fact, it is cheaper to provide infant care at home than to provide out-of-home care of good quality. As a result, successive Swedish governments gradually extended the duration of paid parental leave permitting parents to stay at home with their children—a generous resolution that may strengthen parent-child relationships at the expense of other worthy goals for both parents and children. Does high-quality nonparental care provide some unique and valuable formative experiences of which children in exclusive parental care will be deprived? What happens to the goals of gender equality and salary equity when families almost invariably conclude that mothers rather than fathers

should withdraw from paid work to care for their children? What values are conveyed by the assignment of child care to members of an immigrant lower class (Wrigley, 1995)? How can one satisfy the competing agendas that child care policies must address?

Summary

Clearly, individuals and societies have developed a large number of solutions to age-old needs for child care. The variety and diversity of these solutions illustrate the ways historical, economic, ideological, and demographic realities shape the context in which individuals, families, and societies operate and constrain the solutions or policies they can develop. Employed parents need to obtain care for their children, and this chapter is concerned largely with the circumstances in which they make these decisions as well as with their effects on child development.

The development of child care policies has become increasingly important to governments around the world. As a result, new policies, plans, and practices are being developed worldwide. But despite the development of family policies and child care facilities, the demand for child care far outstrips the available supply in almost every country. This in turn maintains the pressure on governments, private agencies, and parents to make arrangements that are not optimal.

Interestingly, discussions of the needs for child care have, with few exceptions, portrayed child care as a women's issue, even though decisions about how and where children will be raised should concern both mothers and fathers. Swedish sociologists and policymakers recognized more than 4 decades ago (e.g., Dahlström, 1962) that major changes in maternal employment and paternal child care were unlikely unless they were preceded by changes in the underlying expectations about the appropriate roles and responsibilities of men and women and without changes in the opportunities available to men and women within the home as well as in the world of paid employment. Reformers hoped that group care settings might instill greater concern for the community and a commitment to less sexist values, but the near exclusive reliance on female care providers makes it unlikely that child care gives children a less sexist view of adult responsibility, whether or not their mother is employed.

Decades of research have made clear that one cannot make blanket statements about the superiority of any

particular form of child care (Lamb, 1986; Lamb & Sternberg, 1990). In each case, the development of most children is affected by the quality of care received both at home and in out-of-home care facilities and by the extent to which the care is sensitively adjusted to children's developmental and individual needs. The implication is that societies need to provide an array of options that allow parents to choose child care arrangements that are most appropriate given their children's ages and individual styles, their economic and social circumstances, and the values and attitudes they hold.

Furthermore, nonparental child care must be viewed in the context of the whole ecology of socialization, because child care patterns are manifestations of the wider social structure. Development is a complex, multifaceted process, and thus we are only likely to understand it if we look, not simply at patterns of nonparental care, but at these patterns of care in the context of other experiences, ideologies, and practices. Nonparental child care arrangements do not exist in social vacuums and are likely to have relatively small, discrete, and direct effects on development, though they may be important parts of the web of influences and experiences that shape children's development. Because development is such a multifaceted and complicated process, it is essential to understand the role played by each of those experiences in shaping the course of human development. With that in mind, we next consider evidence concerning the extent to which children in the major industrial countries experience nonparental care in the first few years of their lives.

CHANGING PATTERNS OF CARE IN THE UNITED STATES AND EUROPE: PARENTING AND ALLOPARENTING

In this section, we review statistics concerning changing patterns of early child care in developed countries over the past few decades. As we show, these decades have been marked by the availability of increasingly detailed social statistics as well as by dramatic secular changes in marital, fertility, and employment practices that have had powerful and tangible effects on patterns of child care. Broadly similar changes and trends have been evident in most of the developed countries, although meaningful and significant international differences are evident as well. Changes in the utilization of nonparental child care of course affect the extent to which

children in these countries may be affected by non-parental child care experiences.

Patterns of Shared Care

Most is known about pattern of child care in North America and Western Europe. As a result, we begin our analysis by considering statistics concerning patterns of child care in the United States.

The United States

In the United States, child care was once viewed as a service valued primarily by single mothers and disadvantaged Black families, whereas middle-class families supplemented maternal care by sending their children to part-day nursery schools and child development centers (Phillips, 1989). The proportions of employed Black and White mothers of preschoolers were the same by 1995, however, with a larger proportion of White than Black mothers in the workforce when they had school-age children. By the mid-1990s, similarly, 48% of single mothers whose youngest child was 3 or under and 52% of those with children age 5 and under were employed, compared with 57% and 59% of married mothers, respectively (Casper & Bianchi, 2002; H. Hayghe, personal communication, October 17, 1995). By 2001, however, these groups had diverged again: 64% of single mothers with children of 3 and under and 67% of those with children age 5 or under were employed, compared with 56% and 58% of married mothers, respectively (Casper & Bianchi, 2002). Overall, most of the 22 million under-5s in the United States had an employed father and 12.2 million had an employed mother by 2000 (U.S. Bureau of the Census, 2003). Employed mothers averaged 36 hours of paid work per week in 2001, mean-

ing that the majority of employed parents had full-time paid responsibilities (Casper & Bianchi, 2002). Perhaps most important, the majority of new mothers now return to paid work before their child’s 1st birthday, whereas mothers formerly remained out of the workforce for considerably longer (U.S. Bureau of Labor Statistics, 2000).

Because the majority of the parents who live with their children are now employed, formal nonparental care arrangements are experienced by almost all children, although the industrial countries differ with respect to when these arrangements tend to be initiated, with the United States distinguished as the country where nonparental home-based day care, care by relatives, in-home babysitters, nursery schools, and child care centers for anywhere between 5 and 55 hours per week is initiated earliest.

The Census Bureau’s annual reports, entitled *Who’s Minding the Kids?* which use survey of income and program participation (SIPP) data, provide the most extensive and up-to-date information about child care patterns drawn from nationally representative samples of the U.S. population. Information about child care has been collected as a supplement to the SIPP since 1984, and the most recently published census data on child care were collected between April 1999 and July 1999 in the 10th interview with the 1996 SIPP panel. Initially, the SIPP collected child care information only when the mothers were employed, but the data gathered in the spring of 1999, released in January 2003, are informative regarding care arrangements for all children. The 1999 National Survey of American Families also provided valuable information regarding the child care arrangements made by employed parents (Sonenstein, Gates, Schmidt, & Bolshun, 2002).

As indicated earlier, and as shown in Table 23.1, the majority of children in the United States were receiving

TABLE 23.1 Child Care Arrangements for 0- to 5-Year-Olds in the United States (1999 SIPP), Expressed in Percentages

| Age of Child | Parents | Grandparents | Other Relatives ^a | Child Care Centers ^b | Family Day Care | Own Home | No Regular Arrangement | Multiple |

care regularly from persons other than their parents in 1999. The number for whom the parents were the primary designated care providers fell modestly from nearly a quarter of children under 1 to around a fifth of those over 3 years of age. Home-based nonparental care arrangements were used for about one-seventh of the children, regardless of age, and the number attending some kind of center increased from just over 20% for 1-year-olds to a remarkable 72% of 3- to 4-year-olds.

Table 23.2, which summarizes information only concerning the children whose mother was employed (and thus excludes children who lived alone with their father and those whose mother was unemployed or was a full-time student) makes clear that many of the children received care from centers on a part-time basis, although the proportion of children for whom it was the primary form of care doubled between the ages of 1 and 4 years. Notwithstanding this increase, it is noteworthy that the majority of infants and toddlers were cared for primarily by relatives, and another 20% received care from an individual nonrelative. Evidently, formal or institutional forms of care are not widely utilized by American parents with children age 4 and under. The tendency to seek care providers related to the child was most marked in Native American (73%), Asian and Pacific Islander (64%), and Black (61%) families, and less common in White (54%) and Hispanic (53%) families (see also National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2004). In every group, however, the majority of children received care regularly from relatives. Of course, many children have more than one child care arrangement, and Table 23.2 documents only the most important for each child.

As one might expect, child care arrangements vary depending on the mother's employment status and work schedule (U.S. Bureau of the Census, 2003), and changes in maternal employment are the best predictor of changes in child care arrangements (Han, 2004), which are extremely frequent (NICHD Early Child Care Research Network, 2004). Mothers working full time in 1999 were more likely than those employed part time to use child care centers or schools (86% versus 25%) or home-based child care (24% versus 15%), although both of these differences were less marked than they had been in 1991 (U.S. Bureau of the Census, 2003). As in 1991, however, fathers were more likely to be the regular nonmaternal care providers when mothers were employed part time (38%) rather than full time (25%; U.S. Bureau of the Census, 2003), with both figures representing increases from 1991. Fathers were also more likely to be the regular nonmaternal care providers when mothers worked a nonday shift (39%) rather than a day shift, and these percentages would undoubtedly be higher if the sample was limited to children living with both of their parents; not surprisingly, fathers are less involved in care when separated from or never married to the mothers.

When mothers are not employed, families make less use of nonparental care, although it is clear from Table 23.1 that the vast majority of 3- to 4-year-olds are enrolled in some kind of center-based care, with minimal differences between families with nonemployed and employed mothers (U.S. Bureau of the Census, 1993, 2003). As would be expected, however, children of nonemployed mothers spent much less time in care than peers whose mothers were employed: According to the 1993 Census Bureau report, about 80% of children with

nonemployed mothers spent less than 20 hours a week in child care, whereas 55% of the children with employed mothers spent 35 or more hours a week at child care facilities. A decade later, 63% of 3- to 5-year-olds with employed mothers were in center-based programs, compared with 67% of those with nonemployed mothers (NCES Early Child Care Research Network, 2002). Participation in educationally oriented center programs continued declining among 3- to 5-year-olds through 2001 (Child Trends, 2003).

Examination of Table 23.3 reveals that, between 1977 and 1999, primary care arrangements made by employed mothers in the United States changed remarkably little in the intervening quarter-century, despite dramatic increases in the number of employed mothers with young children and concomitant increases in the proportion of young children who were thus receiving nonparental as opposed to exclusive parental care. Between 20% and 25% of contemporary families rely on parental care, and as the proportions of women who can care for their children while working have declined (from 11% to 3%), the population of children cared for by their fathers while mothers work has increased from 14% to 19%. Care by grandparents has increased by about 25%, whereas care by other relatives has remained stable at around 8%. The popularity of child care centers and nursery schools initially increased but has declined since the mid-1990s, perhaps in response to well-publicized but exaggerated concerns about the adverse effects of center care, especially on infants and toddlers (see later discussion). By contrast, the utilization of informal and formal home-based child care arrangements has increased, although it

is unclear how much of this increase may reflect changes in the way information was solicited since 1995.

Whatever the reason for the dramatic apparent increase in 1995, reliance on home-based child care has steadily declined by about 33% since that time. In-home care by nannies and babysitters was never very common, and its importance has declined over the last quarter-century.

Other Industrial Countries

As suggested in the previous section, the nonparental care picture looks quite different in most other industrial countries than it does in the United States (Tietze & Cryer, 1999). Principally, this is because most industrial countries other than the United States offer various incentives to allow or encourage new parents, particularly new mothers, to remain at home to care for their infants throughout the 1st year of life. Parental leave has only recently (1993) been mandated in the United States, but even though half the private sector workers and all public sector workers are now entitled to 12 weeks of job-protected leave, few can afford to remain out of work long because the mandatory leave is unpaid (Asher & Lenhoff, 2001). In other industrial countries, by contrast, new mothers (and, in some countries, new fathers) are entitled to extended periods of paid leave. In countries of the Organization for Economic Cooperation and Development (OECD), for example, the average paid leave is 10 months (the minimum outside the United States is 6 months), with pay levels ranging from a basic daily stipend to as much as 90% of the parent’s regular salary (Kamerman,

TABLE 23.3 Historical Changes in Primary Child Care Arrangements for U.S. Children under 5 Years of Age with an Employed Mother (Percentages)

| | 1977 | 1985 | 1988 | 1990 | 1991 | 1993 | 1995 | 1997 | 1999 |
|--------------------|------|------|------|------|------|------|-------------------|------|------|
| Mother | 11 | 8.1 | 7.6 | 6.4 | 8.7 | 6.2 | 5.4 | 3.3 | 3.1 |
| Father | 14 | 15.7 | 15.1 | 16.5 | 20.0 | 15.9 | 16.6 | 19.0 | 18.5 |
| Grandparents | N/A | 15.9 | 13.9 | 14.3 | 15.8 | 17.0 | 15.9 | 18.4 | 20.8 |
| Other relatives | N/A | 8.2 | 7.2 | 8.8 | 7.7 | 9.0 | 5.5 | 7.4 | 8.0 |
| Day care/school | 13 | 23.1 | 25.8 | 27.5 | 23.1 | 29.9 | 25.1 | 21.6 | 22.1 |
| In child’s home | 7 | 5.9 | 5.3 | 5.0 | 5.4 | 5.0 | 4.9 | 4.0 | 3.3 |
| Family day care | 22 | 22.3 | 23.6 | 20.1 | 17.9 | 16.6 | 46.0 ^a | 36.3 | 33.8 |
| Other ^b | N/A | 0.8 | 1.6 | 1.3 | 1.6 | 1.1 | 2.9 | 8.1 | 7.3 |

^a In 1995, the Census Bureau first distinguished between all forms of care in the providers’ home, family day care, and other forms of care by nonrelatives. Changes in the questions used may account for the dramatic increase in the number of children in various forms of “family day care.”

^b Includes self-care, no regular arrangement, and other arrangements.

2000; Waldfogel, 2001). Whereas the statistics reported earlier show that the majority of infants in the United States begin nonmaternal care during the 1st year of life, therefore, enrollment can be delayed until the 2nd and even 3rd year of life in other industrial countries. Because maternal or parental care is thus nearly universal in the 1st year, good statistics documenting the enrollment of European children in nonparental child care

facilities in the first 2 to 3 years of life are not widely available. The statistics shown in panel a of Figure 23.1 refer only to enrollment in publicly subsidized settings (Waldfogel, 2001), and these figures vastly understate the number of children in private facilities, particularly in countries like the United States, where publicly subsidized facilities are scarce. The figures for the other listed countries are probably more representative and

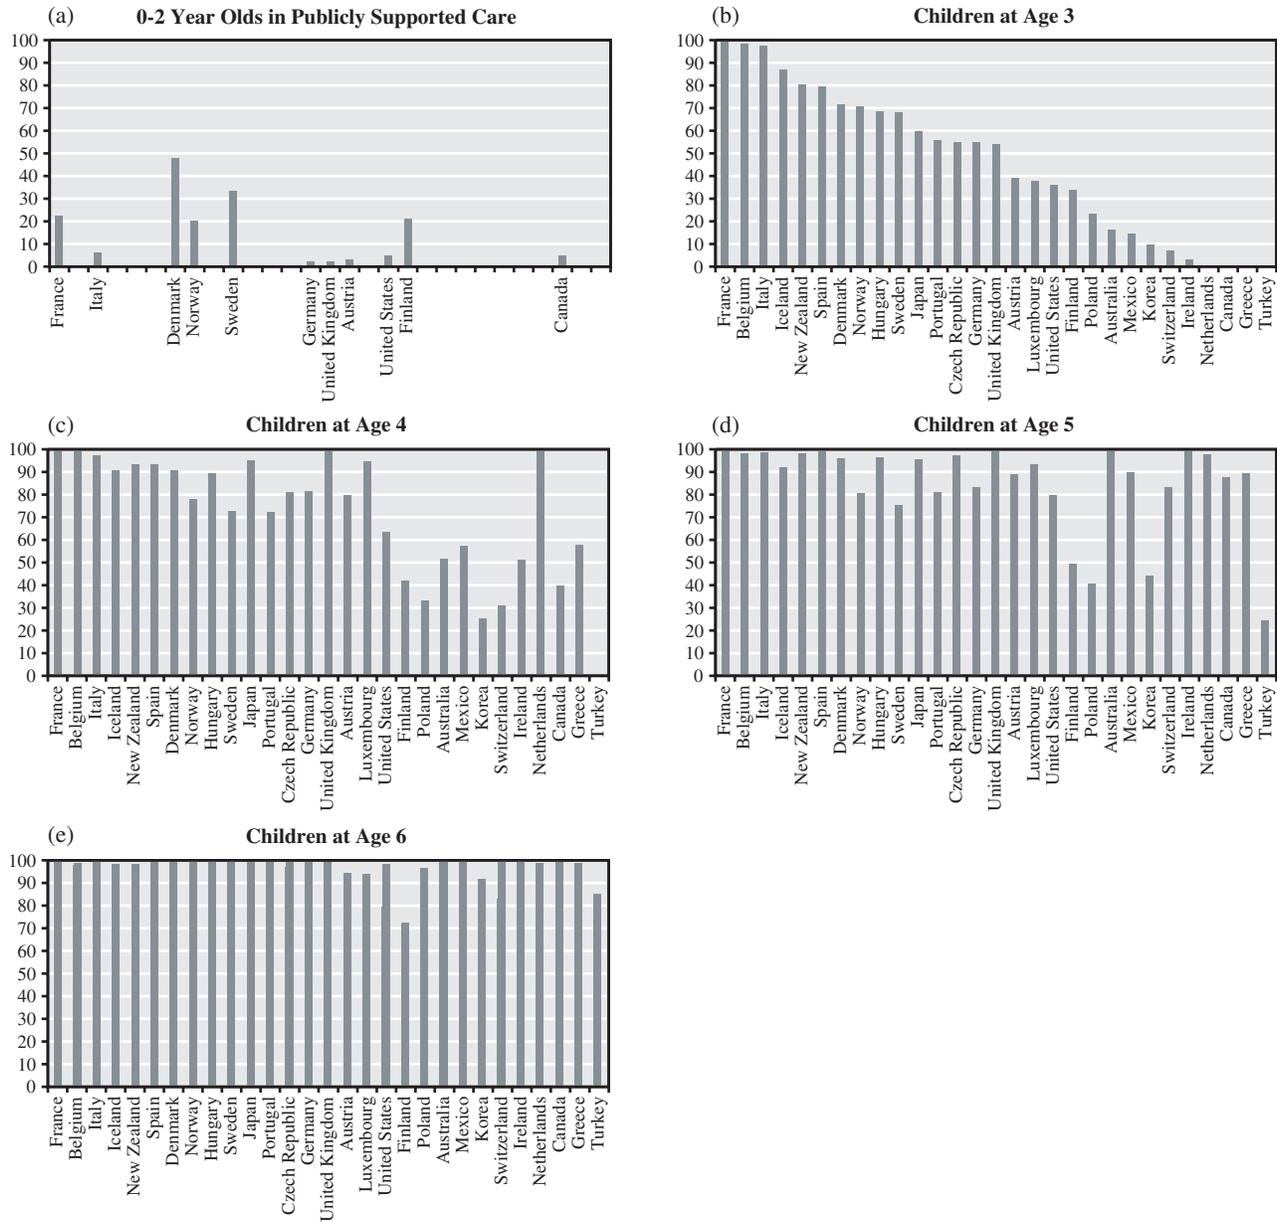

Figure 23.1 (a) 0- to 2-year-olds in publicly supported care, (b) Children at age 3, (c) Children at age 4, (d) Children at age 5, (e) Children at age 6.

underscore how few infants and toddlers in these countries are enrolled in formal child care facilities.

The panel b of Figure 23.1 shows dramatic cross-national variations in the number of 3-year-old children enrolled in educationally oriented programs (OECD, 2002). Notice that, by the age of 3, almost all children in Belgium, France, and Italy are already enrolled in such programs (which are formally affiliated with the public education systems), as are two thirds or more of the children in Denmark, Hungary, Iceland, New Zealand, Norway, Spain, and Sweden. (The comparable figure for the United States is 37%.) By the age of 4 (Figure 23.1, panel c), two-thirds or more of the children in Austria, the Czech Republic, Germany, Japan, Luxembourg, The Netherlands, Portugal, the Slovak Republic, and the United Kingdom are enrolled as well, along with 65% of the children in the United States. Children in the remaining countries become enrolled as either 5- or 6-year-olds (see panels d and e). Thus, whereas nonparental child care is much more common in the United States than elsewhere in the first years of life, educational programs in several Western countries embrace most children much earlier than they do in the United States. The programs themselves are also viewed and funded as part of the educational system in these countries, thereby fostering care of more homogeneous quality that is more easily regulated, administered, and publicly funded (Tietze & Cryer, 1999).

Parental Decisions about Nonparental Care

A variety of factors, including role conflicts, anxieties about daily separations, and fears that children may have difficulty adapting to settings with unfamiliar or undesirable characteristics, and fears that children might develop closer relationships to care providers than parents, influence parents' child care decisions (e.g., Fein, Gariboldi, & Boni, 1993; Hock, McBride, & Gnezda, 1989; Stifter, Coulehan, & Fish, 1993). Furthermore, perhaps because many parents in the United States prefer within-family care when they return to paid work early in their children's lives (Sonenstein & Wolf, 1991), more than half the children with employed parents are initially cared for by their mother, father, or other relatives, mostly grandparents (see Tables 23.1 and 23.2). Such families are characterized either by concerns about the effects of nonparental care on their infants or have limited resources that constrain their ac-

cess to more costly nonparental care arrangements (NICHD Early Child Care Research Network, 1997c). Not surprisingly, American families with annual incomes exceeding \$54,000 in 2003 were more apt to use center care than those whose incomes were either less than \$18,000 or between \$18,000 and \$36,000 per annum (28%, 19%, and 18%, respectively; U.S. Bureau of the Census, 2003).

Reliance on care by fathers is more common when parents have less traditional child-rearing beliefs, marital intimacy is greater, and fathers want to be involved in care (NICHD Early Child Care Research Network, 2000b), whereas the avoidance of paternal care is associated with elevated emotional problems (Vandell, Hyde, Plant, & Essex, 1997). Father care is also higher when mothers work nonstandard hours and is highest when both parents have nonstandard work schedules (Han, 2004). Care by grandparents is more likely in families of color, when grandparents live in the household, and when mothers are very young, work nonstandard hours, or have extended workdays (NICHD Early Child Care Research Network, 2004; Vandell, McCartney, Owen, Booth, & Clarke-Stewart, 2003). Unfortunately, care by grandparents also tends to be quite unstable.

The heterogeneity of family circumstances in the United States leads many parents to rely on more than one child care arrangement during the first years of life (see Table 23.1) and probably explains why children in the United States experience such frequent changes in child care arrangements (NICHD Early Child Care Research Network, 2004). Interestingly, the extensiveness of maternal employment does not predict the type or number of child care arrangements, even though the availability of nonparental child care facilitates the simultaneous pursuit of both child-rearing and career goals (NICHD Early Child Care Research Network, 1997c).

Some professionals have been especially skeptical about the ability of young parents to pursue these two goals simultaneously, but associations between maternal age and either the types or extent of child care usage have seldom been studied. Older German mothers seemed better able to limit the time that their children spent in center-based care than younger mothers with similar working schedules, however (Ahnert, Rickert, & Lamb, 2000).

Since the late 1980s, parents in the United States have been increasingly willing to utilize center-based rather than home-based care by nonrelatives (Haber &

Kafka, 1992; Kisker & Silverberg, 1991). Perhaps this trend reflects increased understanding of children's needs for intellectual and social stimulation and of the possible disadvantages associated with more informal care arrangements, as well as improvements in the available quality of center care (e.g., Johansen, Leibowitz, & Waite, 1996; NICHD Early Child Care Network, 1997a). Over the past decade, these associations between parental education and child care preferences have increasingly been moderated by child age, however: Regardless of their educational backgrounds, parents of infants and toddlers (as opposed to parents of preschoolers) emphasize health and well-being and thus seek environments likely to minimize stress rather than those that maximize educational opportunities (e.g., Britner & Phillips, 1995; Cryer & Burchinal, 1997).

Furthermore, because many families, especially in Europe, have two or fewer children, parents may fear that exclusive family care may deprive children of enriching and diverse social experiences, especially with other children (Sturzbecher, 1998). In this context, parental decisions about child care may reflect the parents' willingness to offer their children opportunities to develop additional close relationships outside the family, with some mothers feeling particularly threatened when their children develop close relationships with others.

Relationships between Parents and Other Care Providers

Within-family and out-of-home care environments obviously differ in many important ways. To what extent do parents and care providers understand the differences between their roles and these environments? Parents and child care professionals value the same care characteristics, but, perhaps because they have difficulty monitoring it, parents tend to be poorly informed about the quality of care that their children receive. Nevertheless, parents who provide solicitous, stimulating care clearly tend to select child care arrangements with these characteristics (Bolger & Scarr, 1995). Relief at finding much needed child care and anxiety about the possible risks associated with nonparental care may also prevent some parents from evaluating their children's placements accurately and lead them to deny obvious problems. This may explain why parents of all education and income levels tend to overestimate the quality of their children's programs and relationships with their care

providers, reporting that these are satisfactory even when trained observers recognize that the quality of care is poor (e.g., Brown Miller, 1990; Clarke-Stewart, Gruber, & Fitzgerald, 1994; Cryer & Burchinal, 1997). Not surprisingly, parents also tend to report that they have positive relationships with care providers even when the partnerships may not be as good as they claim.

For their part, care providers seldom see parents as partners, perhaps perceiving themselves as professionals who have greater expertise regarding child care. In addition, they may be somewhat judgmental about parents, attributing children's perceived difficulties to inadequacies on the part of the parents, for example (Kontos & Dunn, 1989; Shpancer, 1998). Care providers also believe that parents need opportunities to develop their caregiving skills (Elicker, Noppe, Noppe, & Fortner-Wood, 1997).

Even when parents and care providers are mutually appreciative and respectful, they often have divergent views of one another's confidence and collaboration. Instead of developing the types of friendships that care providers would prefer, for example, parents often decline to share information about their families or to use care providers as sources of information and guidance (Elicker et al., 1997; Kontos & Dunn, 1989). As a result, parent-care provider conversations tend to be brief, infrequent, and nonsubstantive. The two partners also tend to be most available at different times: Whereas care providers are more accessible at drop-off times in the mornings, parents are more accessible during pick-up times in the afternoons (Endsley & Minish, 1991).

The notion that parent-care provider partnerships are formatively important is intuitively appealing, but empirical data have accumulated slowly. For example, Owen, Ware, and Barfoot (2000) reported that more communication between mothers and care providers (based on mothers' and care providers' reports) was significantly associated with more sensitive and supportive interactions between care providers and children. Van IJzendoorn, Tavecchio, Stams, Verhoeven, and Reiling (1998) reported that better communication was associated with indices of child well-being. In addition, Kontos and Dunn (1989) found that care providers tended to have the lowest regard for the parenting abilities of parents who communicated less; the children of these parents were also less advanced developmentally. This underscores the difficulties that may arise when the relationships between parents and care providers are not

adequately bridged and the need for professional care providers to foster improved relationships with parents. Ghazvini and Readdick (1994) reported a positive correlation between the quality of center care and the frequency of parent-care provider communication.

Summary

Nonparental care during the preschool years has become normative in the United States and other industrialized countries. Children outside the United States often begin nonparental care as toddlers because more generous parental leave policies allow them to be cared for by their parents in infancy, whereas the majority of children in the United States begin nonparental care as infants, typically some time before their 1st birthday. American mothers often attempt to arrange for early care to be provided within the family by fathers, grandparents, or other relatives when exclusive maternal care is not possible, although care provided by relatives tends to be unstable and changing care arrangements are very common. Children who begin nonparental care before their 1st birthday and experience three or more different nonparental care arrangements may be at special risk because the instability of infant care predicts behavioral maladjustment (see later discussion). From a policy perspective, it is thus important to determine why so many young children have unstable patterns of care and why the child care available in the United States is of such uneven quality.

Parents have limited insight into their children's child care experiences even when they monitor their children's responses closely, so it is misleading to assume that market forces will regulate the available quality of child care. Instead, quality of care tends to be best when it is evaluated and regulated by professionals, as in most European countries.

QUALITY OF CARE

Just as researchers have come to appreciate the diverse array of care arrangements that children experience and the possible importance of wide variations in their preenrollment characteristics and backgrounds, so, too, have they come to acknowledge vast differences in the quality of care that children experience both in and outside their homes. This realization led researchers to develop mea-

asures that have, in turn, advanced efforts to understand how quality of care affects children's development.

Process Measures of Quality

Researchers have developed both process and structural measures of quality. Process measures are observational measures of the settings and interactions between care providers and children, although some emphasize the experiences of individual children, whereas the majority assess the experiences of groups of children. The best known of these are standardized measures developed by Thelma Harms and Richard Clifford. The latest versions of the Infant/Toddler Environment Rating Scale (ITERS; Harms, Cryer, & Clifford, 2003) and the Early Childhood Environment Rating Scale (ECERS; Harms, Clifford, & Cryer, 1998) contain 39 and 43 items, respectively, on which the quality of care is rated by trained observers; from these ratings, scores on seven highly intercorrelated scales can be computed (see Table 23.4). Scores can also be reduced to two factors, Appropriate Caregiving and Developmentally Appropriate Activities, although scores on these two dimensions of the original measures tended to be highly intercorrelated as well (Phillips, Voran, Kisker, Howes, & Whitebook, 1994). The Family Day Care Rating Scale (FDCRS; Harms & Clifford, 1989) was developed to provide a six-factor assessment of the quality of home-based care using 32 items; a revision of this scale is currently in preparation. The FDCRS has been used much less than the ITERS and ECERS, not least because home-based care has been studied less extensively than center-based care. Harms, Jacobs, and White (1996) also developed a companion measure to use when evaluating the quality of afterschool programs.

Measures other than the ECERS, ITERS, and FDCRS have been used in major studies as well. Abbott-Shim and Sibley (1987, 1992) developed the Assessment Profile for Early Childhood Programs with over 150 items designed, like the measures developed by Harms and Clifford, to assess the entire setting. A briefer (26-item) Classroom Practices Inventory (CPI) was developed by Hyson, Hirsh-Pasek, and Rescorla (1990) to tap those aspects of quality subsumed under the National Association for the Education of Young Children's "Guidelines for Developmentally Appropriate Practices" (Bredekamp, 1987b). The CPI has not yet been

TABLE 23.4 Items on Some Popular Process Measures of Quality

| ECERS ^a | Global Rating Scale ^b | APECP ^c |
|---|---|---|
| Space and Furnishings | Positive Relationship | Safety and Health |
| 1. Indoor space | 1. Speaks warmly to children | 1. Classroom safe |
| 2. Furniture for routine care, play, and learning | 2. Listens when children speak | 2. Supplies and materials safe |
| 3. Furnishings for relaxation and comfort | 3. Seems to enjoy children | 3. Teacher prepared for emergencies |
| 4. Room arrangement for play | 4. Explains rule violations | 4. Personal hygiene encouraged |
| 5. Space for privacy | 5. Encourages new experiences | 5. Teacher responsible for basic health care |
| 6. Child-related display | 6. Seems enthusiastic | Learning Environment |
| 7. Space for gross motor play | 7. Attentive to individuals | 6. Physical layout encourages independence |
| 8. Gross motor equipment | 8. Talks at appropriate level | 7. Classroom respects individuality |
| Personal Care Routines | 9. Encourages prosocial behavior | 8. Outdoor materials support varied opportunities |
| 9. Greeting/departing | 10. Adopts children's level | 9. Teacher active outdoors |
| 10. Meals/snacks | Punitiveness | Scheduling |
| 11. Nap/rest | 11. Seems critical of children | 10. Scheduling occurs |
| 12. Toileting/diapering | 12. Values obedience | 11. Varied activities on written schedule |
| 13. Health practices | 13. Speaks with irritation | 12. Teacher-organized reasoning skills |
| 14. Safety practices | 14. Threatens | 13. Varied classroom activities |
| Language/Reasoning | 15. Punishes without explanation | Curriculum |
| 15. Books and pictures | 16. Finds fault | 14. Materials support varied experiences |
| 16. Encouraging children to communicate | 17. Prohibits many activities | 15. Materials encourage cultural awareness |
| 17. Using language to develop | 18. Unnecessarily harsh | 16. Alternative techniques used |
| 18. Informal use of language | Permissiveness | 17. Children active in learning |
| Activities | 19. Doesn't control | 18. Individualization |
| 19. Fine motor | 20. Doesn't reprimand misbehavior | Interacting |
| 20. Art | 21. Firm when necessary | 19. Teacher initiates positive interactions |
| 21. Music/movement | 22. Expects self-control | 20. Teacher is responsive |
| 22. Blocks | Detachment | 21. Teacher manages children positively |
| 23. Sand/water | 23. Seems distant/detached | 22. Food served in positive atmosphere |
| 24. Dramatic play | 24. Spends time in other activities | 23. Children happy and involved |
| 25. Nature/science | 25. Uninterested in children's activities | Individualizing |
| 26. Math/number | 26. Not close supervision | 24. Systematic child assessment |
| 27. Use of TV, video, computers | | 25. Assessments used in planning activities |
| 28. Promoting acceptance of diversity | | 26. Teacher identifies special needs |
| Interaction | | 27. Teacher cooperative with adults |
| 29. Supervision of gross motor activities | | 28. Provisions made for special needs |
| 30. General supervision | | 29. Conferences planned regularly |
| 31. Discipline | | 30. Parental activity encouraged |
| 32. Staff-child interactions | | |
| 33. Interactions among children | | |
| Program Structure | | |
| 34. Schedule | | |
| 35. Free play | | |
| 36. Group time | | |
| 37. Provisions for children with disabilities | | |
| Parents and Staff | | |
| 38. Provisions for parents | | |
| 39. Provisions for personal needs of staff | | |
| 40. Provisions for professional needs of staff | | |
| 41. Staff interactions and cooperation | | |
| 42. Supervision and evaluation of staff | | |
| 43. Opportunities for professional growth | | |

^a Early Childhood Environment Rating Scale-Revised (Harms, Clifford, & Cryer, 1998). All items are rated on a 7-point scale, anchored by definitions of Inadequate (1), Minimal (3), Good (5), and Excellent (7). Similar items, adjusted for age and context, appear on the Infant/Toddler Environment Rating Scale-Revised (Harms, Cryer, & Clifford, 2003). *Sources:* From *The Early Childhood Environment Rating Scale*, revised edition, by T. Harms, R. M. Clifford, and D. Cryer, 1998, New York: Teachers College Press. Reprinted with permission; and *Infant/Toddler Environment Rating Scale*, revised edition, by T. Harms, D. Cryer, and R. M. Clifford, 2003, New York: Teachers College Press. Reprinted with permission.

^b All rated on 4-point scale, with item scores combined into 4 factor scores. *Source:* From "Caregivers in Day Care Centers: Does Training Matter?" by J. Arnett, 1989, *Journal of Applied Developmental Psychology*, 10, pp. 541-552. Reprinted with permission.

^c Assessment Profile for Early Childhood Programs (Abbott-Shim & Sibley, 1987). Each of the 30 topics listed here subsumes several specific items (150 in all), each rated as "present" or "absent" on the basis of observations or reports. *Source:* From *Assessment Profile for Childhood Programs*, by M. Abbott-Shim and A. Sibley, 1987, Atlanta, GA: Quality Assistance. Reprinted with permission.

widely used, although L. Dunn (1993) reported that higher ECERS scores were associated with more developmentally appropriate practices, as assessed using the CPI. In addition, Arnett (1989) developed an observational measure of teacher sensitivity that has been used in several large-scale studies and can be used to assess the experiences of individual children. Items on the most widely used of these process measures are listed in Table 23.4.

Many recent reports concerned with the effects of nonparental child care have used data obtained in the NICHD Study of Early Child Care (1996), for which a new process measure of the quality of child care, the Observational Record of the Caregiving Environment (ORCE), was developed to permit comparable assessments of both home- and center-based care. The ORCE lists 18 specific types of interactions between the target child and the caregiver or other children (see Table 23.5) and is distinguished from other popular measures of quality because it emphasizes the experiences of individual children rather than those of the group as a whole. The observer observes each child for three 10-minute periods, during each of which the observer alternately observes and records descriptions of the child's experiences. In addition to recording these specific ex-

periences, the observers also take qualitative notes at the end of each 10-minute session and in a special 14-minute session after the three 10-minute sessions; these notes are used to make qualitative ratings of the care providers' behavior on the eight dimensions or scales displayed in Table 23.6. To maximize the reliability of the measures obtained in the NICHD Study of Early Child Care, furthermore, the observations described here (each comprising 44 minutes of observation, with both specific behavioral and qualitative ratings obtained) were repeated within 2 weeks. For purposes of analysis, scores on conceptually related items (e.g., those concerned with language simulation) can be combined or used individually to assess specific aspects of the quality, or the scores can be used to provide a more comprehensive assessment.

In the United States, scores on the various process measures are highly correlated with one another. This makes it possible to use composite measures of quality containing fewer items than the complete measures do (Scarr, Eisenberg, & Deater-Deckard, 1994). All of the standardized process measures have proven to be less useful as indices of the quality of care in Western Europe, however, perhaps because the quality of care available there is less variable and of higher average

TABLE 23.5 Behaviors Recorded on the Observational Record of the Caregiving Environment (Infant Version)^a

| Behavior | Definition |
|---|--|
| Share positive affect | Caregiver and infant laugh, smile, coo |
| Positive physical contact | Caregiver holds infant, touches warmly |
| Responds to vocalization | Caregiver responds verbally to infant's nondistressed vocalization |
| Asks questions | Caregiver directs a question to infant |
| Other talk | Caregiver makes declarative statement to infant |
| Stimulates cognitive development | Caregiver encourages a skill like rolling over or focuses infant's attention on something in the environment |
| Stimulates social development ^b | Caregiver plays social game with infant, moves infant so he or she can see, touch another infant |
| Reads | Caregiver reads aloud to infant |
| Facilitates behavior | Caregiver provides help, entertainment for the infant |
| Responds to negative affect | Caregiver responds when the infant fusses, cries (as proportion of infant fussing, crying) |
| Restricts infant's activities | Caregiver restricts infant's activity physically or verbally |
| Restricts in physical container | Infant is in a highchair, playpen, crib, etc. |
| Speaks negatively to infant | Caregiver speaks to infant in negative tone |
| Uses negative physical actions ^c | Caregiver slaps, yanks, pushes infant |
| Physical care | Caregiver provides physical care to the infant: feeding, bathing, diapering |
| Other activity | Caregiver involved in any activity with infant except physical care |
| Infant solitary | Infant playing or exploring alone |
| Infant watching or unoccupied | Infant is not involved in any activity |

^a Separate versions, with age-appropriate definitions, were available for each phase.

^b This behavior was not recorded reliably.

^c This behavior did not occur often enough for the frequency counts to be meaningful.

TABLE 23.6 Dimensions Rated on the Qualitative Portion of the Observational Record of the Caregiving Environment^a

| Dimension | Definition |
|---|---|
| Sensitivity/responsiveness to nondistressed communication | Caregiver responds to the infant's social gestures and is attuned to the infant's needs and moods |
| Detachment-disengagement | Caregiver is emotionally uninvolved, disengaged, and unaware of infant's needs |
| Intrusiveness | Caregiver is highly controlling and adult-centered in interactions with the infant |
| Stimulation of cognitive development | Caregiver engages in activities that can facilitate the infant's learning, such as talking to the infant or demonstrating a toy |
| Positive regard | Caregiver expresses positive feelings in interaction with the infant |
| Negative regard | Caregiver expresses negative feelings in interaction with the infant |
| Flat affect | Caregiver expresses no emotion or animation |
| Sensitivity/responsiveness to infant distress | Caregiver responds to the infant's distress signals consistently, promptly, and appropriately |

^aDefinitions provided here apply to infants; separate versions, with age-appropriate definitions, were prepared for each phase of the NICHD Early Child Care Study.

quality (e.g., Beller, Stahnke, Butz, Stahl, & Wessels, 1996; Tietze, Cryer, Bairrao, Palacios, & Wetzel, 1996). Recognizing the need for more systematic and comprehensive measures that could be used internationally, Pierrehumbert and his colleagues (Pierrehumbert, Ramstein, Krucher, et al., 1996) in Switzerland developed measures of quality that could be used in Switzerland, Sweden, and other countries characterized by high-quality child care. Subsequent research by Pierrehumbert, Ramstein, Karmaniola, Miljkovitch, and Halfon (2002) established the validity of this measure by way of correlates with outcomes that should be (and were) affected by the quality of care. Another measure, the Child Care Facility Schedule, was developed for use in countries outside the United States where quality is highly variable (Dragonas, Tsiantis, & Lambidi, 1995). Its predictive and construct validity have yet to be established, however. Neither Pierrehumbert's nor Dragonas's measures have been used widely enough to determine whether they might have broader utility.

Structural Measures of Quality

Instead of process variables, many researchers assess quality using structural indices: measures of teacher training and experience, group size, teacher-child ratios, crowding, staff turnover, and the like (e.g., Barnas & Cummings, 1994; Howes & Olenick, 1986). Most of these factors can be, and often are, regulated, although

such factors as stability and continuity obviously cannot be regulated. Conceptually, structural and process measures differ to the extent that factors indexed by the structural measures potentiate high-quality interaction and care but do not guarantee it, whereas process measures try to quantify the actual care received by children.

Group size and staff-child ratios are popular structural measures. The Panel on Child Care Policy of the U.S. National Research Council (1991) recommended group sizes of 6 to 8 for infants, 6 to 12 for 1- to 2-year-olds, 14 to 20 for 3-year-olds, and 16 to 20 for 4- and 5-year-olds, as well as staff-child ratios of 4 to 1 for infants and 1-year-olds, between 4 and 6 to 1 for 2-year-olds, between 5 and 10 to 1 for 3-year-olds, and between 7 and 10 to 1 for 4- and 5-year-olds. These standards were not very demanding, especially where infants were concerned, and ratios of 2 or at most 3 infants per adult are now considered more appropriate (American Academy of Pediatrics, American Public Health Association, & National Resource Center for Health and Safety in Child Care, 2002; American Public Health Association & American Academy of Pediatrics, 1992a, 1992b). Standards vary dramatically internationally and among states in the United States, not surprisingly, with only about half of the states even requiring that licensed care providers be trained (Morgan et al., 1993; Phillips, Lande, & Goldberg, 1990). Licensed care providers are also more likely to offer stimulating environments and nutritious food than unlicensed providers (Fosburg et al., 1980; Stallings, 1980).

Howes (1983) suggested more than 2 decades ago that the adult-child ratio and the extent of teacher training were the best structural indices of quality in centers, whereas group size, the degree of safety, and the appropriateness of care provider behavior best measured the quality of home-based care. Care providers' salaries have also proved to be valuable, if indirect, measures of the quality of care in a number of studies in the United States (Phillips, Howes, & Whitebook, 1992; Phillips, Mekos, Scarr, McCartney, & Abbott-Shim, 2001; Phillipsen, Burchinal, Howes, & Cryer, 1997; Scarr et al., 1994). Howes also introduced an important distinction between the conventional structural measures of quality (group size, adult-child ratio, care provider training) and more comprehensive and empirically derived measures, such as number of care providers present at any given time, staff turnover, number of settings experienced by each child, care provider sensitivity and involvement, and the provision of developmentally appropriate activities. Unfortunately, site- or care provider-specific measures of quality fail to take account of the substantial frequency of moves by children from one setting to another (NICHD Early Child Care Research Network, 1995a). These transitions may adversely affect children even when all facilities provide high-quality care.

Relations between Structural and Process Measures of Quality

Because the many structural measures of quality are all believed to reflect conditions conducive to high-quality interactions and experiences, one might expect at least modest relationships among them; this is usually, but not always, the case. Scarr et al. (1994) found that scores on various structural measures of quality were poorly correlated with one another and were not correlated with scores on the process measures of quality. In their large multisite study, only teachers' wages predicted the quality of care they provided, as indexed on process measures. Petrogiannis (1995), too, reported no significant associations among the observed quality of care provider-child interaction, ITERS scores, and structural indices of quality in his study of Greek child care centers.

Other researchers, including those participating in the multisite NICHD Study of Early Child Care, have reported clearer and stronger associations between scores on structural and process measures of quality:

The better the salaries, benefits, and level of training received by care providers, the better the quality of care they provide and the less they are likely to quit their jobs (Berk, 1985; Kontos & Stremmel, 1988; Phillips, Howes, & Whitebook, 1991; Ruopp, Travers, Glantz, & Coelan, 1979). The researchers in the NICHD Child Care Research Network (1995b, 2000a, 2002a) reported that the observed quality of care provider-child interaction was higher when group sizes were smaller, child-adult ratios were lower, and care providers were better trained. Howes, Phillips, and Whitebook (1992) reported that classrooms with appropriate teacher-child ratios were more likely than those with higher ratios to provide care of better quality and to promote secure child-teacher attachments.

In four large multisite studies (one of them multinational in scope and one conducted in the United Kingdom), the quality of child care—assessed using process measures of quality—was correlated with structural measures of quality, including higher staff-child ratios, better staff training and education, and higher teacher wages (*Cost, Quality, and Child Outcomes in Child Care Centers*, 1995; Cryer, Tietze, Burchinal, et al., 1999; Phillips et al., 2001; Sylva, Melhuish, Sammons, Siraj-Blatchford, & Taggart, 2004). In the two large U.S. studies, average levels of quality within the states sampled were related to the stringency of state standards: States with more demanding licensing standards had fewer centers providing care of poor quality, thereby underscoring the benefits of demanding and well-enforced standards (Vandell & Wolfe, 2000). In an interesting natural experiment, Howes, Smith, and Galinsky (1995) reported that the introduction of stricter standards of training and provider-child ratios statewide led to improvements in the quality of child-care provider interaction and higher scores on the ECERS scale. Similarly, the NICHD Early Child Care Research Network (1999b) reported that children in classrooms that met more of the recommended guidelines regarding ratio, group size, teacher training, and teacher education were less likely to have behavior problems and more likely to have better school readiness and language comprehension scores. Except in North Carolina, where licensing regulations are quite lax and for-profit centers provided care of significantly lower quality, the *Cost, Quality, and Child Outcomes in Child Care Centers* (1995) study revealed no difference in the quality of care provided by for-profit and not-for-profit centers, in part because nonprofit church-based

centers often provided care of such poor quality. Non-profit centers did have higher staff-child ratios, better educated, trained, and more experienced staff, and lower rates of staff turnover, however.

Similar findings were obtained in studies focused on family day care homes (Clarke-Stewart, Vandell, Burchinal, O'Brien, & McCartney, 2002). Galinsky, Howes, Kontos, and Shinn (1994) and Galinsky, Howes, and Kontos (1995) reported that home-based child care providers who received training were more likely to behave warmly, attentively, and responsively. Trained providers also received higher scores on Harms and Clifford's (1989) FDCRS, perhaps because the training enhanced their self-esteem and professionalism (Dombro, 1995; Dombro & Modigliani, 1995). In an independent sample of home-based child care providers, training was in fact the most powerful predictor of the observed quality of care as indexed on the FDCRS (Fischer & Eheart, 1991). Bollin (1993) reported that home-based care providers were most likely to continue providing care when they had held previous child care jobs and were not trying to combine paid child care work with care of their own young children. Quality of care provider-child interaction has also been linked to group size in home-based care (Kontos, 1994; Stith & Davis, 1984) and care provider-child ratios in both center and home-based care (Howes, 1983; Howes & Rubenstein, 1985). In Israel, however, M. K. Rosenthal (1991a) found little association between the quality of care provider-child interaction and the quality of the education that caregivers provided.

Overall, there is substantial evidence that scores on diverse structural and process indices of quality are intercorrelated, with Scarr et al.'s (1994) findings representing the exception rather than the rule. The convergence reported by most researchers validates the notion that structure affects function and underscores the substantial consensus regarding the components and nature of high- (or low-) quality care, despite the rather heterogeneous range of items considered as indices of quality. This consensus should also increase the amount of attention paid to reports that the average quality of care in the United States is barely adequate or mediocre (*Cost, Quality, and Child Outcomes in Child Care Centers*, 1995; Galinsky et al., 1994; Kontos, Howes, Shinn, & Galinsky, 1994; NICHD Early Child Care Research Network, 1995d, 2000a; Whitebook, Howes, & Phillips, 1989) and prompt efforts to narrow the gap between

parents' and researchers' evaluations of quality (Clarke-Stewart et al., 1994; Galinsky, 1992; Mason & Duberstein, 1992; Phillips, 1992).

The mean quality of care, as indexed by provider training and education level, improved during the 1980s in the United States, but average group size and turnover rates increased over this period (Hofferth, 1992). According to the NICHD Early Child Care Research Network (2000a, p. 116), "Positive caregiving was . . . very uncharacteristic" for 8% of children in the United States ages 1 to 3 years, "somewhat uncharacteristic" for 53%, "somewhat characteristic" for 30%, and "highly characteristic" for only 9%. This conclusion is especially alarming because the centers and care providers providing care of higher quality are likely to be overrepresented and those providing poorer quality care underrepresented in such studies, thanks to variations in their willingness to participate in research. Haskins (1992) and Clarke-Stewart (1992) have questioned the assumption that "adequate" day care quality represents a cause for concern, however, and the results of the NICHD Early Child Care Research Network (1995d) suggested that three-quarters of the infants studied had sensitive care providers.

Correlates of the Quality of Care

In the early 1980s, several researchers noted a disturbing tendency in both Canada and the United States for quality of care and social class to be confounded. Children from economically and socially disadvantaged backgrounds appeared to receive nonparental care of poorer quality than those from more advantaged backgrounds. This led researchers to fear that disadvantaged children were doubly handicapped, suffering the adverse effects of poor-quality care both at home and in their out-of-home care settings (Anderson, Nagle, Roberts, & Smith, 1981; Clarke-Stewart et al., 1994; Goelman, 1988; Goelman & Pence, 1987a, 1987b; Howes & Stewart, 1987; Kontos & Fiene, 1987). Although the NICHD Early Child Care Research Network (1995c) reported that children receiving better out-of-home care had superior home environments as well, most recent research has revealed a curvilinear rather than linear relationship between social class and the quality of out-of-home care (Phillips et al., 1994; Voran & Whitebook, 1991; Waite, Leibowitz, & Witsberger, 1991; Whitebook et al., 1989; Zaslow, 1991). Centers

serving children from advantaged backgrounds indeed seem to provide care of the highest quality (see also Holloway & Reichhart-Erickson, 1989; Kontos, 1991), but the worst care tends to be provided by centers predominantly serving children from middle-income families rather than the poorest families. Centers serving children from low-income families do not differ from those serving advantaged families on most measures of quality, although the teachers in centers serving poorer children tend to be less sensitive and harsher, perhaps because the children behave more poorly. According to the survey by Phillips and her colleagues, quality varies across an especially wide range in centers serving disadvantaged families. Community-based centers had smaller groups and better teacher-child ratios, although their teachers had obtained less education and were more poorly trained. Interestingly, children from middle-income families are especially likely to attend for-profit centers, where quality is often significantly poorer (Coelen, Glantz, & Calore, 1979; S. L. Kagan, 1991; Phillips et al., 1992). In the NICHD Early Child Care Research Network (1995b) study, however, the quality of observed care provider behavior was not predicted by family income level, although it was predicted by the quality of home care (NICHD Early Child Care Research Network, 1995c).

Family social status, parental income, and parental education are not the only factors correlated with indices of the quality of care children receive. Bolger and Scarr (1995) reported that authoritarian attitudes toward child rearing were also associated with lower-quality care, and that, at least in the middle-class sample they studied, variation in the state standards for child care quality did not attenuate the powerful association between family background and child care quality. Phillips, McCartney, and Scarr (1987) reported that parents who valued social skills tended to choose centers with higher quality than those who valued conformity. Children may also end up in centers of lower quality if their parents are too preoccupied with other problems to evaluate their child care options thoroughly (Howes & Olenick, 1986).

Much of the literature reviewed next confirms that quality of care is indeed an important consideration: Children perform better on many dimensions when they have received care of higher quality. Such findings raise obvious questions: How good is good enough? Is there a linear relationship between quality of care and chil-

dren's adjustment? Is there a threshold beyond which improvements in quality no longer have demonstrable effects? The results of the Goteborg Child Care Study provided an early answer to these questions (Broberg, Hwang, Lamb, & Ketterlinus, 1989; Hwang, Broberg, & Lamb, 1991; Lamb, Hwang, Bookstein, et al., 1988; Lamb, Hwang, Broberg, & Bookstein, 1988). In Sweden, nonparental care is government-subsidized and strictly regulated to ensure high quality (Broberg & Hwang, 1991; Hwang & Broberg, 1992). Despite limited variations in the quality of care across settings, however, quality of out-of-home care was one of the most important and consistent correlates of children's personality maturity, social skills, and compliance with maternal requests in the early assessments conducted as part of the Goteborg Child Care Study.

The results of the much larger and more comprehensive NICHD Early Child Care Study (2002a, 2003b) likewise revealed that the effects of quality were continuous across the wide range encountered in this study. Interestingly, however, careful analyses revealed no dose-response relations, meaning that the beneficial efforts of high-quality care and the adverse effects of poor-quality care were similar regardless of the amount of time spent in care. Similar findings were reported by Sylva et al. (2004) in the Effective Provision of Preschool Education (EPPE) Study.

Scarr and her colleagues (Scarr, 1992, 1998; Scarr, McCartney, Abbott-Shim, & Eisenberg, 1995) have not only reported poor intercorrelation among measures of quality, but were among the first to offer the more skeptical opinion that the quality of out-of-home care is much less significant than many advocates believe. Their research suggested that socioeconomic and family background variables were much more influential sources of variance than the quality of care, which explained statistically significant but small portions of the variance in behavioral adjustment. Measures of the quality of care also had small (but reliable) effects in the NICHD study: The NICHD Early Child Care Research Network and Duncan (2003) estimated that a 1 standard deviation increase in the quality of care between 36 and 54 months was associated with an increase of between .50 and 1.50 points on standardized cognitive test scores. Further research involving diverse samples and measures is obviously necessary to evaluate the merits of this argument, which has substantial implications for both parents and public authorities. Quality

matters, it seems, but not as much as researchers and policymakers hoped (Lamb, 2000). In addition, the type, quality, and extent of out-of-home care must be viewed in broader context: Child care does not replace home care and does not render family processes and family background irrelevant.

Summary

The results of both small- and large-scale studies over the past 2 decades have revealed substantial agreement among experts regarding the components of high-quality care, even though parents' assessments of quality and their appraisals of satisfaction seem to be determined very differently from experts' assessments. Researchers have distinguished between process indices of quality, which quantify development-promoting care provider behavior, and structural indices, which identify conditions in which such behavior should be more likely. Empirical evidence confirms that the many objective indices of high-quality care are highly intercorrelated, and that observable aspects of appropriate care provider behavior are more likely to be evident when the structural indices suggest auspicious circumstances for such high-quality care. Research reviewed later in this chapter also supports the assumption that high-quality care promotes adaptive development in a variety of developmental domains, although the effects of quality are much smaller than most researchers or policymakers typically acknowledge.

Unfortunately, the most popular indices of quality have proven less useful when employed in Western and Northern European countries. Their failure has been attributed to measurement insensitivity when levels of quality are very high, but cultural differences in the definition of quality may restrict the validity of these measures as well. Exploration and specification of these cultural differences would be extremely informative, not only to students of nonparental care but also to those who study cultural practices and beliefs. In addition, as noted earlier, repeated reports that the quality of care is correlated with various outcome measures often lead researchers to ignore the small size of the associations, especially in predictive analyses. At least in part, these disappointing findings can be attributed to the rather general way that quality is typically measured. In the next decade, researchers might profitably focus their efforts on attempts to identify more precisely the particular aspects of quality that promote or

impede development in specific domains, and for children with particular characteristics, thereby moving beyond global indices of quality and sharpening our understanding of quality and its effects (see Kontos, Burchinal, Howes, Wisseh, & Galinsky, 2002, for an example of such research).

CORRELATES AND CONSEQUENCES

With the exception of theorists such as Piaget (e.g., 1965) and Harris (1998), who have described how regular interactions with peers promote social and moral development, early childhood educators who have endorsed enrichment programs for children from impoverished backgrounds, and sociobiologists (e.g., Daly & Wilson, 1995) warning that biologically unrelated care providers are less motivated than relatives to meet children's needs, most contemporary theories of socialization focus almost exclusively on the ways parents (especially mothers) influence their children's development, largely ignoring the possible effects of nonparental care providers and extrafamilial environments. Only attachment theorists have conceptually analyzed the developmental consequences of nonparental care in any depth, proposing that care by a single care provider is needed to promote healthy social and emotional development (Bowlby, 1951, 1958, 1969–1973). Warnings that child-parent separations might damage child-parent relationships and thereby cause social maladjustment and pathological emotional development have in turn prompted researchers to examine the ways children cope with and are affected by nonparental care. For the most part, however, research on the effects of nonparental care has been surprisingly atheoretical rather than conceptually driven.

In this section, we review research designed to illuminate the effects of nonparental child care on children's development and adjustment. We begin with an analysis of the processes whereby children adjust to novel care providers and contexts, with emphasis on emotional reactions and factors associated with individual variations in the magnitude of children's responses. We then examine the effects of these transitions on the quality of child-parent interaction before turning to the issue that has been most contentious: the effects of child care on the security of infant-parent (especially child-mother) attachment relationships.

The initiation of nonparental care of course involves opportunities as well as stresses. In particular, children in care settings are able to form and be affected by meaningful relationships with other adults (care providers) as well as other children (peers). In fact, most children do establish such relationships, which range in quality and thus have the potential to affect children's development in positive as well as less desirable ways, as we show in our analysis of these developing relationships. Children in care settings are at increased risk of developing behavior problems, as we then show, noting that the magnitude and reliability of this effect appears to be a consequence of the time of enrollment and the quality of care, including the quality of the relationships with care providers. Effects on cognitive and linguistic development, in both community and special intervention programs, are discussed in the final subsection.

Processes of Adaptation to Nonparental Care

In this section, we discuss research on children's initial reactions to the start of out-of-home care, focusing first on separation responses and then on processes of familiarization with the new setting.

Separation Responses

Bowlby (1969, 1973) initially described children's reactions to extended maternal separations by reference to successive phases of protest, despair, and detachment similar to the observable stages of bereavement in adults. Passage through these phases was believed to proceed at a pace that varied depending on the length of the separations. Bowlby's theory was informed by observations of children in orphanages and residential homes during and after the Second World War, but comparable data were obtained by professionals working in East European child care centers during the 1970s. These educators and pediatricians reported sleeping and eating disorders, infectious diseases, and declines in levels of play and communication after enrollment (Schmidt-Kolmer, Tonkova-Jampolskaja, & Atanassowa, 1979). Bowlby's colleagues, Robertson and Robertson (1972, 1975), reported that a variety of factors modified children's emotional and physical reactions to extended separations, but little systematic research on factors affecting children's responses to repeated separations was conducted until much more recently (cf. Field, 1991b).

Most research on the transition from home to child care has been conducted in Europe, perhaps because national policies there encourage extended periods of subsidized parental care during the first years of life to ensure that most children enter nonparental care settings after child-parent relationships have already been established (Lamb, Sternberg, Hwang, et al., 1992). In Italy, Fein and her colleagues (Fein, 1995; Fein et al., 1993) observed that infants (ages ranged from 4.5 to 19.5 months) enrolled full time in high-quality centers continued to show despair-like behavior (negative affect, immobilization, and self-comforting) 6 months after enrollment. In Germany, Rauh and her colleagues (Rauh, Ziegenhain, Müller, & Wijnroks, 2000) found that infants who were enrolled in child care between 12 and 18 months of age (late entry) were more irritable and negative than those enrolled before 12 months (early entry), both at home and in child care centers. As children grow older, however, emotional reactions to child care entry become less intense, so that, for example, kindergartners regulate their emotions better and cope better with the first stressful days in child care than infants and toddlers do (Field et al., 1984).

Reactions to maternal separation may vary depending on the quality of the child-mother relationship prior to enrollment. According to attachment theorists, mothers who provide children with emotional security help children develop self-regulatory abilities that facilitate adaptation to separations (Ainsworth, 1979). Consistent with this view, infants from secure dyads appear less stressed (i.e., they have lower cortisol levels 30 minutes after the last separation) than infants from insecure dyads when observed in a setting (the Strange Situation) that involves brief mother-child separations (Spangler & Grossmann, 1993; Spangler & Schieche, 1998).

By comparison with the separations studied in the laboratory, however, nonparental child care involves longer, repeated separations which may violate children's expectations about their mother's return. The intensity of the stress involved may explain why cortisol levels were similarly elevated in securely and insecurely attached toddlers when the daily mother-child separations associated with child care began (Ahnert, Gunnar, Lamb, & Barthel, 2004). These findings suggest that enrollment in child care places a special stress on children who are too young to cope effectively with violations of expectations about the parents' availability, even when they have established attachments to their parents. M. K. Rosenthal (1994) found that Israeli toddlers in family

day care were most distressed when they had younger and more stressed mothers, when their coenrollees tended to be older than they, and when their care providers had age-inappropriate expectations.

Processes of Familiarization

Quite often, care providers can do little to modulate children's responses to stress. Fein et al. (1993) reported, for example, that the levels of negative affect 6 months after enrollment in child care were predicted by measures of immobility and reduced levels of positive affect at entry but not by variations in the care providers' behaviors, even though the care providers comforted, maintained proximity to, and initiated interactions with unhappy children more than with other children during the transitional period.

To help children adjust, many European child care centers have implemented adaptation programs in which mothers are allowed to accompany their children during the transitional period of enrollment. As expected by the proponents of such programs, Rauh and her colleagues (2000) reported that abrupt transitions to child care prolonged negative emotions and made adaptation more difficult, especially when children were enrolled as toddlers rather than infants. When mothers familiarized their children to child care in a more leisurely manner and accompanied their children in the center, by contrast, adjustment was easier. Similarly, Ahnert, Gunnar, et al. (2004) found that child-mother attachments remained secure or shifted from insecure to secure when mothers accompanied their children to child care for a longer period. In addition, securely attached toddlers had markedly lower cortisol levels than insecurely attached infants while the mothers accompanied them, suggesting that secure infant-mother relationships reduced the perceived stressfulness of the novel child care environment.

Effects on Child-Parent Relationships

In this section, we turn attention from the children's initial emotional responses to the effects of child care on the relationship between children and their parents.

Changes in Parenting

Perhaps in defensive response to widespread concerns about the riskiness of nonparental care, many researchers noted that employed and unemployed mothers behaved similarly with their children (Bornstein,

Maital, & Tal, 1997; Easterbrooks & Goldberg, 1985; Rubenstein & Howes, 1979; Rubenstein, Pedersen, & Yarrow, 1977; Stith & Davis, 1984), or they emphasized that employed mothers paid more attention, vocalized more, and expressed more positive emotions to their children than stay-at-home mothers did (Caruso, 1996; Schubert, Bradley-Johnson, & Nuttal, 1980; Schwartz, 1983). Such inconsistencies were at least partially attributable to situational variability (Crockenberg, & Litman, 1991; Zaslow, Pedersen, Suwalsky, & Rabinovich, 1989), underscoring the importance of assessing children in a variety of social situations. In addition, surprisingly few researchers studied the experiences of the same children at home and in child care centers; indeed, many researchers have implicitly failed to recognize that children in child care facilities are not only exposed daily to an additional set of experiences at child care, but also have experiences at home that differ from those experienced by peers who do not receive regular nonparental care.

Ahnert, Rickert, et al. (2000) detailed the weekday experiences of German toddlers who either attended or did not attend child care facilities. The children's social experiences differed depending on where they were observed, and the children in the two groups also had different experiences at home with their parents. At home, parents interacted more intensely with the child care children, as if attempting to make up for the time they were apart; during comparable portions of the day, they attended to, communicated with, and stimulated their children more than parents of home-only children. Similarly, Booth, Clarke-Stewart, Vandell, McCartney, and Owen (2002) reported that mothers of children in child care spent more time interacting with their children, even on weekends, than did mothers of home-only children. Burchinal, Bryant, Lee, and Ramey (1992) likewise found that mothers of children in child care were more involved with their 6- to 12-month-olds than were mothers of home-only children.

However, maternal sensitivity and levels of positive child engagement decline when children—especially infants and toddlers—spend many hours in child care facilities (NICHD Early Child Care Research Network, 2003a). This means that the quality of mother-child relationships also declines in such circumstances, especially when the child care is of poor quality (NICHD Early Child Care Research Network, 1999a; Sagi, Koren-Karie, Gini, Ziv, & Joels, 2002). For example, Ahnert, Rickert, et al. (2000) found that mothers of children in child care tended to respond hesitantly to their

children's distress signals in the evenings, even when the children indicated by intensified levels of whining that they wanted their mother's attention. Similar patterns of interaction were described by Nelson and Garduque (1991), who found that 2- to 4-year-olds behaved more negatively when interacting with their parents than with their care providers. Rubenstein and Howes (1979) likewise showed that more negative affect was displayed at home than in care settings. To foster secure child-parent relationships and promote children's emotional equilibrium, families thus need to titrate and adjust the children's experiences at home, especially when poor child care experiences further tax the children's relationship skills (Ahnert & Lamb, 2003; Lamb, 2005). Specifically, parents need to be especially attentive to children and their needs, responding sensitively to fusses and cries when they are together, thereby providing the emotion-regulating support that children typically do not obtain from care providers in group settings.

Measuring Child-Parent Relationships

Although changes in parental behavior typically accompany enrollment in child care, adverse effects on child-parent relationships are not inevitable, especially when parents and children have established harmonious relationships. Fears about adverse effects of early and extended nonparental child care have long been prominent, however.

Many of the early studies involved the Strange Situation procedure, which was designed to measure the quality of child-parent attachment by observing children's reactions to reunion with their parents following two 3-minute separations in an unfamiliar context (Ainsworth, Blehar, Waters, & Wall, 1978) and has become popular in part because it is one of few measures providing valid insight into children's early socioemotional development. Following the brief separations involved in the Strange Situation, most infants greet the returning parent warmly, either by approaching, asking to be picked up, or smiling and vocalizing. Children who behave in this fashion are deemed securely attached (Ainsworth et al., 1978). Other children are deemed insecure because they behave avoidantly (ignoring the adults' bids, failing to greet, and perhaps even withdrawing) or resistantly (ambivalently mingling bids for contact with angry rejection of contact offered to them).

In a widely cited early study, Blehar (1974) compared 2- and 3-year-old children receiving full-time child care with children of similar ages cared for exclusively at home. When the children were observed in the

Strange Situation, many of those in child care appeared insecurely attached to their mother. Because Blehar's findings seemed to confirm widespread fears that child care had negative effects on child-parent relationships, several investigators attempted—unsuccessfully—to replicate her findings (e.g., Portnoy & Simmons, 1978; Ragozin, 1980).

Is it appropriate to use the Strange Situation when evaluating children whose daily experiences of separation might have affected their tolerance for brief separations like those involved in the Strange Situation? Clarke-Stewart (1989) and Thompson (1988) in fact suggested that children enrolled in child care might appear insecure even when they were securely attached to their parents. In addition, Clarke-Stewart and her colleagues (1994) reported that child care children appeared more independent than home-only children when observed in unfamiliar test situations with their mother. Because independence from mother was correlated with several measures of social competence with unfamiliar adults, Clarke-Stewart et al. worried that the children's independence might be misinterpreted as insecurity, but later assessments (at 15 months) of 1,153 infants participating in a longitudinal study revealed that infants with extensive child care experiences were neither less distressed nor more independent in the Strange Situation than peers without nonparental care experiences (NICHD Early Child Care Research Network, 1997b). The validity of the Strange Situation remains an issue when children as old as those studied by Blehar are concerned, however, because the procedure was initially developed and validated for use with toddlers under 20 months of age (Ainsworth et al., 1978).

Variation in Child-Parent Relationships

Beginning in 1986, a series of reports in both the popular media and the professional literature again fanned fears that early initiated nonparental care might adversely affect child-parent attachment and related aspects of psychosocial development (e.g., Belsky, 1986). This conclusion was largely supported by studies in which the Strange Situation was used to assess socioemotional adjustment. Reviewing the results of four such studies, Belsky (1988) reported that the proportion of insecure (especially insecure/avoidant) attachments was higher (41%) among children receiving out-of-home care than among home-only children (26%). He thus concluded that extensive nonmaternal care in the 1st year of life made insecure child-mother attachments more likely.

Noting that Belsky's (1986; see also Belsky & Rovine, 1988) review was selective (he had deliberately focused only on children from more advantaged and stable backgrounds), Clarke-Stewart (1989) combined data from all known studies in which the Strange Situation had been used, regardless of socioeconomic status. In this rather heterogeneous sample, 36% of the infants in full-time care were classified as insecure compared with 29% of the infants whose mothers were employed part-time or were not employed. Acknowledging an "elevated risk" of insecure attachment among infants in child care, Clarke-Stewart emphasized the needs (a) to explore a variety of factors other than emotional insecurity that might explain these differences in child behavior and (b) to use a wider range of measures when evaluating adjustment to child care. Shortly thereafter, Lamb, Sternberg, and Prodromidis (1992) obtained raw data from several investigators, recoded the data, and reexamined the effects of child care on the security of infant-mother attachment. Access to raw data allowed Lamb et al. to assess the effects of such factors as extent of care and age of enrollment more fully than had hitherto been possible. Their reanalysis showed that children who began receiving nonmaternal care between 7 and 12 months were more likely to be insecurely attached (37%) than were those cared for exclusively by their mother (29%). Subsequent meta-analyses by Erel, Oberman, and Yirmiya (2000) of data obtained in 59 studies revealed no significant effect of child care on the security of child-mother attachment, however, and suggested that earlier enrollment was preferable. Interestingly, adverse effects were more commonly found in earlier studies, whereas positive effects or no differences were more common in later studies.

When children in the large NICHD Study of Early Child Care (1997b) were observed in the Strange Situation at 15 months, there were no differences in the proportion of secure attachments depending on whether or not these infants had experienced nonmaternal care. In the NICHD study, furthermore, the effects of child care on attachment at both 15 and 36 months were moderated by the mother's involvement and sensitive parenting. Greater maternal sensitivity was associated with increases in the probability that children would be classified as securely attached to their mother, and maternal sensitivity moderated estimated effects of the amount, quality, and instability of child care. Children whose mothers were less sensitive were more likely to be insecurely attached to them, especially when the children

spent long hours in care and the child care was of poor quality (NICHD Early Child Care Research Network, 1997b, 2001b). Such findings indicated that parenting continues to shape the quality of child-parent relationships even when children experience child care, and that sensitive parenting moderates the effects of child care on attachment security. In addition, the results of the NICHD study identified amount of early child care as a risk factor that made children more susceptible to the adverse effects of insensitive parenting, probably because these parents were unable to provide their children with the types of soothing, emotion-regulating attention in the evenings that allowed the children to return to child care the next day in states of emotional equilibrium (Ahnert & Lamb, 2003; Lamb, 2005). In Israel, however, the link between maternal sensitivity and attachment security is not evident when children attend poor-quality child care centers (Aviezer, Sagi-Schwartz, & Koren-Karie, 2003). Insecure infant-mother attachments appear more common when Israeli children attend centers providing care of poor quality (Sagi et al., 2002).

As indicated earlier, the observation of Strange Situation behavior at best provides a very narrow assessment of the effects of child care on child-parent relationships. Associations between Strange Situation behavior and measures of later performance tend to be impressive only when there is stability over time with respect to family circumstances and caretaking arrangements (Ahnert, 2004; Belsky & Fearon, 2002; Goldsmith & Alansky, 1987; Lamb, Thompson, Gardner, & Charnov, 1985). Thus, the hypothesized links between nonparental care, insecure/avoidant attachment, and subsequent behavior problems need to be evaluated more thoroughly. There is as yet no evidence that avoidant infants who have experienced nonparental care in fact behave any differently in future years than similar infants who behave securely in the Strange Situation (Grossmann, Grossmann, & Waters, in press; Lamb et al., 1985). In addition, it is obviously important to view out-of-home care in the context of other social and familial variables that affect child-parent relationships.

Because sensitive parenting continues to shape the quality of child-parent relationships when children attend child care facilities, it is important to note that sensitivity is itself conditioned by parental motivation and attitudes (see Bell & Richard, 2000). Harrison and Ungerer (2002), for example, reported that Australian mothers who returned to the workforce because they wanted to do so described many benefits for themselves, their families, and

their children, expressed less separation anxiety, and were less likely to have insecurely attached children than unemployed mothers were. Likewise, Stifter et al. (1993) found that mothers who returned to work early and reported more separation anxiety were more likely to behave intrusively and to have insecurely attached infants. Scher and Mayseless (2000) reported an association between the number of hours spent at work, separation anxiety, and insecure patterns of attachment. There is also some evidence that variables such as birth order (Barglow, Vaughn, & Molitor, 1987), temperament (Belsky, 1988; Melhuish, 1987), level of familial stress, differences in maternal personality (Belsky & Rovine, 1988), maternal role satisfaction (Hock, 1980), cultural differences in parenting values (Burchinal, Ramey, Reid, & Jaccard, 1995), and the availability of social support (Crockenberg, 1981) may mediate the effects of child care experiences on infant-mother attachment. As a result, it is important to identify, measure, and take these factors into account when interpreting the effects of child care on the quality of child-parent relationships, and to recognize that family factors remain the best predictors of children's development, even when they attend child care facilities (Lamb, 1998; NICHD Early Child Care Research Network, 1998b).

Relationships with Care Providers

Whatever happens to child-parent relationships when children begin attending out-of-home care facilities, enrollment also offers opportunities to form relationships with other adults. We consider the development of this relationship, next.

Concepts and Measures

Enrollment in child care allows children to form significant relationships with providers but does not lead care providers to displace mothers as primary attachment figures. After observing infants interacting with their mother and care providers in the laboratory, for example, early researchers reported that children overwhelmingly preferred to interact with and be near their mother and were often upset when left alone with care providers. Positive responses to care providers were more common in the presence of strangers, however (Cummings, 1980; Farran & Ramey, 1977; Fox, 1977).

In child care settings, children show a preference for stable over unstable care providers when their parents are absent. They also show more positive emotions and

explore more in the presence of regular care providers and those who have provided their care longer. For example, toddlers consistently seek comfort from stable and familiar care providers when distressed, interact with them preferentially when not distressed, and are more rapidly soothed by them than by unstable providers (Anderson et al., 1981; Barnas & Cummings, 1994; Rubenstein & Howes, 1979). Such differences may reflect in part some characteristics or skills of the providers because stable providers were often the head teachers and were highly involved with children. Barnas and Cummings thus speculated that the children had been able to form secure attachments to those care providers who had been reliable sources of care.

In more recent studies, many researchers have used Ainsworth et al.'s (1978) Strange Situation (SS) or Waters's (1995) Attachment Q-set (AQS) to examine the quality or security of the relationships between children and their care providers. Although scores on the two measures are highly correlated (Sagi et al., 1995), they capture different aspects of child-adult relationships. Specifically, the SS emphasizes the adequacy of adult responses to children's separation distress and children's feeling about the comfort and protection they receive, especially when distressed (Ainsworth et al., 1978; Lamb et al., 1985), whereas the AQS explores adult-child interactions in a variety of everyday situations, capturing child behaviors that include security, comfort, and attention seeking (Booth, Kelly, Spieker, & Zuckerman, 2003; Waters, 1995). In a recent meta-analysis, Ahnert, Pinquart, and Lamb (in press) found that the SS and AQS revealed equivalent proportions of secure (as opposed to insecure) child-care provider attachments, although secure relationships to care providers were less common than secure relationships to mothers or fathers. The security of children's attachments to their mother, father, and care providers were minimally but significantly intercorrelated, suggesting that children construct intertwined internal working models of significant relationships with adults. For the most part, however, the characteristics of interaction with particular individuals shape the quality of specific relationships. The security of child-care provider attachment is not simply determined by the security of child-parent attachment, as many attachment theorists once hypothesized.

Correlates and Antecedents

As with parents, the security of infant-care provider attachment is associated with the sensitivity, involvement,

and quality of the care provided by care providers, although considerable disagreement exists about the ways the qualities underlying secure child-care provider attachments should be conceptualized and assessed. Some researchers argue that, as with mother-child dyads, the security of child-care provider attachments depends on the sensitivity of the care providers' behavior with individual children. Consistent with this view, Galinsky et al. (1995) reported that infants behaved as though they were more securely attached to their providers in home-based settings after the care providers' participated in a training program designed to enhance their sensitivity.

Highly trained care providers can appear even more sensitive than mothers in one-on-one free-play situations (Goossens & van IJzendoorn, 1990), but dyadic sensitivity necessarily decreases in group settings because care providers have to divide their attention among multiple children (Goossens & Melhuish, 1996). This may explain why some researchers have found no significant associations between the security of child-care provider attachment and measures of the care providers' sensitivity in child care settings (e.g., Howes & Smith, 1995). Children in specific groups also tend to develop relationships with their shared care providers that are of similar quality (Sagi et al., 1985, 1995), and the security of child-care provider attachment remains the same even when care providers change (Howes, Galinsky, & Kontos, 1998). These findings suggest that the security of child-care provider attachments is shaped primarily by group-directed rather than individual-focused behavior, with relationships between care providers and children reflecting group dynamics rather than the dynamics of individual dyads (Ahnert & Lamb, 2000; Ahnert, Lamb, & Seltenheim, 2000).

Because some researchers have assessed the promptness and adequacy of care providers' responses to individual children, whereas others have used group-focused measures of responsiveness, Ahnert et al. (in press) were able to examine the differential impact of the two types of responsiveness on emerging child-care provider relationships. Meta-analyses revealed that children's relationships with care providers, especially in centers, were predominantly shaped by behavior toward the group as a whole. Only in small groups was the security of relationships with care providers predicted by measures of dyadic responsiveness similar to those that predict the security of children's attachments to their parents (De Wolff & van IJzendoorn, 1997).

Factors such as group size and adult-child ratio appear to moderate the associations between care providers' behavior and the security of child-care provider relationships. In group settings, sensitive care providers clearly need to monitor children's emotional needs, and in small groups (or those with high adult-child ratios) they may be able to respond to almost every social bid. They cannot do so in large groups, however, and characteristics other than group size may thus become important. For example, gender (which is normally seen as an individual characteristic) becomes a powerful group-structuring feature when many children are grouped together (Leaper, 1994, 2002; Maccoby, 1998). In such contexts, gender not only divides groups but changes the context and dynamics of the subgroups as well. Boys are more likely to be accepted if they are ranked high in dominance (e.g., Sebanc, Pierce, Cheatam, & Gunnar, 2003), whereas emotional patterns—such as happy-positive and angry-negative patterns—affect girls' popularity (Denham & Holt, 1993; Denham et al., 2001).

If care providers' activities in centers are primarily group-oriented, then group dynamics and interactions may be affected by group characteristics of this sort, as well as by the fact that care providers tend to be females whose professional attitudes might reflect (female) emphases on safety and relaxation more than (male) emphases on excitement and exploration. The meta-analyses conducted by Ahnert et al. (2005) in fact revealed that girls tended to develop secure relationships with care providers more often than boys did; similar gender-based differences are evident in other measures of the quality of child-care provider interactions (e.g., Leaper, 2002). Such findings suggest that care providers tend to provide care that fits their own gender-stereotyped attitudes and that, as a result, boys may have more difficulty forming close relationships with (female) teachers, establishing connections to the (female) world of education, and thus benefiting from later education. Antecedents of individual differences in care provider sensitivity have received little attention from researchers, although Hamre and Pianta (2004) found that care providers (especially in home-based settings) were less sensitive and more withdrawn when they were depressed.

Children's backgrounds, characteristics, and child care histories also affect the security of their attachments to care providers. For example, children with better-educated and more affluent families are more so-

cially responsive and may thus establish new social relationships more easily than less advantaged children (e.g., Belsky, Woodworth, & Crnic, 1996; Crockenberg & Litman, 1991), although this appears to be true only when the children are in home-based care arrangements (Elicker, Fortner-Wood, & Noppe, 1999); socioeconomic background appears to be less influential when children attend child care centers. Perhaps this is because care providers in center contexts are forced to focus on group integration rather than on the children's family backgrounds. Howes and Smith (1995) reported that secure child-care provider relationships were more common when children were younger, but other researchers have not found similar correlations between age and the security of child-care provider attachment (e.g., Cassibba, van IJzendoorn, & D'Odorico, 2000). Reasoning that this might be because age is often confounded with child care history, Ahnert et al. (in press) predicted and found that older children were less likely to form secure attachments to their care providers only when their child care histories had been discontinuous. This underscores the importance of stable care experiences, which allow child-care provider relationships time to develop and deepen.

Predictive Value

Relationships with care providers merit attention because they significantly affect children's development. The security of both infant-mother and infant-care provider attachment are correlated with the level of competence evident when children play with adults as well as the degree of engagement in play with peers (Howes & Hamilton, 1993; Howes, Matheson, & Hamilton, 1994). More impressive, Israeli infants who behaved securely with care providers in the Strange Situation were less ego-controlled and more empathic, dominant, purposive, achievement-oriented, and independent 4 years later than those whose relationships were insecure-resistant (Oppenheim, Sagi, & Lamb, 1988). School children's perceptions of their relationships with teachers are also predicted by the quality of their first attachment to care providers, underscoring the long-lasting impact of these early relationships (Howes, Hamilton, & Philipsen, 1998).

Relationships with Peers

Just as enrollment in child care provides opportunities to form relationships with adult care providers, so does it

increase opportunities for relationships with peers and other children.

Developmental Functions of Peer Relationships

The opportunity to interact with peers in child care settings may be especially valuable for children from small families who do not have siblings and thus would not otherwise interact with developmentally matched partners who, unlike adults and children, have similar levels of social understanding and behavior. Peer interactions permit communications from which children gain insight into other children's daily lives, share experiences, and learn from one another. These exchanges most often occur during pretend play (e.g., McCune, 1995), when children as young as 2 years can relate to the fictive play scenarios of their partners, agreeing on themes, roles, and rules and adjusting them as necessary in the course of play. Pretend play is more successful when peers or siblings rather than adults (even mothers) are involved (Brown, Donelan-McCall & Dunn, 1996). Peer interactions also provide a protected environment in which children can deal with emotions and explore intimate themes. For example, when children elaborate being-afraid-of-the-dark themes with their peers, the peers' emotional supportiveness determines whether the peers are trusted and whether the interactions continue (Hughes & Dunn, 1997).

Mutual interests characterize early friendships and distinguish them from other peer relationships. When Werebe and Baudonniere (1991) observed two young friends interacting in a laboratory playroom with another peer, for example, interactions between the friends were more specific, complex, and extended than interactions with the other child, even though the children interacted in a friendly manner with the unfamiliar peer. Peer interactions also provide opportunities to test social exchange strategies, explore social bids and dialogue structures, develop rules, and deal with compromises. Peer conflicts are especially important because they promote children's awareness of discrepancies between their intentions and those of their peers. Whereas conflicts with adults lead children to merely accept the adults' more competent solutions, conflicts among peers are more challenging developmentally because they force children to compromise if they want interactions to continue (Hartup & Moore, 1990). Peer interactions also play an important role in the formation of social identity, particularly with respect to gender. Peer groups tend to be structured by gender, and this may

foster the imitation of same-sex behaviors as well as gender identification (Maccoby, 1998).

Developmental Course of Peer Relations

Peers are not only attractive to growing children but also become sources of social, emotional, and cognitive stimulation and support, particularly when stable and enduring relationships develop. Patterns of reciprocal interaction are evident in child care facilities even among toddlers (e.g., Brownell & Carriger, 1990; Finkelstein, Dent, Gallacher, & Ramey, 1978; Rubenstein & Howes, 1976; Vandell & Wilson, 1987), although these early interactions typically involve simple rituals because infants and toddlers have difficulty coordinating their actions with peers. The everyday encounters with peers made possible by enrollment in child care may facilitate the acquisition of social skills, however.

As soon as children acquire the ability to reference and transform actions in ways that other children understand, they begin to imitate one another. Thereafter, imaginative play allows preschoolers to share meanings and learn from each other (e.g., Hartup & Moore, 1990; McCune, 1995; Mueller, 1989). Regular interactions with the same peers permit children to develop friendships characterized by specific patterns of interaction (Kenny & La Voie, 1984). Describing the early development of friendships among 2-year-olds over a 10-month period, Whaley and Rubenstein (1994) noted striking elements of intimacy (the dyad's tendency to separate itself from other peers), similarity (the tendency to imitate the other's behavior and to create routines based on them), loyalty (the tendency to defend one another against other peers), and support (the tendency to soothe each other when they were distressed). Based on such observations of children in child care facilities, Howes (1996) reported that the first friendships appear after age 2, mainly involve one or two same-sex peers, and are stable over periods of 1 to 2 years.

It seems likely that sensitive care providers might help young children to cope with and learn from unsuccessful interactions with peers, but little relevant research has been conducted. Interestingly, Lollis (1990) found no differences in the quality of early peer interactions when adults either intervened by offering cautious support (minimal intervention group) or by getting actively involved (interactive intervention group). When the adults left, however, peers in the interactive intervention group were able to maintain high levels of play longer. Rubin, Hastings, Chen, Stewart, and McNi-

chol (1998) found that controlling and intrusive adult behaviors were associated with aggressive interactions among peers.

Preconditions for Peer Relationships in Child Care

The development of relationships with peers is affected not only by specific developmental attainments, especially in the social-cognitive and social-emotional realms, but also by socialization practices within the family (e.g., NICHD Early Child Care Research Network, 2001a). Child-parent relationships are believed to have the greatest impact on peer relationships, such that children who experience warm parenting styles and harmonious families tend to be well adjusted socially, unaggressive, and popular (e.g., Ladd & Le Sieur, 1995). Moreover, maternal sensitivity predicts peer competence in a variety of settings, including child care facilities (NICHD Early Child Care Research Network, 2001a). Attachment theorists have further predicted that children who have secure relationships with their parents should be sociable and socially competent (e.g., Elicker, Englund, & Sroufe, 1992; Sroufe, 2000), but the empirical evidence is contradictory (e.g., NICHD Early Child Care Research Network, 1998a), suggesting that parent-child relationships are not the only family factors affecting the peer system. For example, children also benefit from relationships with siblings, from whom they learn (among other things) how to deal with disrupted interactions (J. Dunn, Creps, & Brown, 1996). Children with siblings may also have more appropriate expectations of peers and thus be better prepared to interact with peers in child care settings than children who have no siblings (Hoff-Ginsberg & Krueger, 1991; Perner, Ruffman, & Leekam, 1994).

Many of the skills that children use when interacting with parents are not directly transferable to interactions with peers (e.g., Mueller, 1989; Vandell & Wilson, 1987). It is thus important to understand the unique features of peer culture that shape group dynamics in child care settings. Clearly, to form enduring relationships with peers, children must not only understand their peers' intentions and feelings but also orient their own intentions and feelings accordingly (e.g., Brown et al., 1996). Observing preschoolers in child care, Denham and her colleagues (Denham & Holt, 1993; Denham et al., 2001) described contrasting patterns of emotional communication—happy-positive and angry-negative—that reliably differentiated groups of children. These patterns were so pervasive that they even differentiated

subgroups and affected the children's popularity. The ability to regulate emotions and adjust behavior to changing demands and circumstances also affects the quality of peer relationships (Fabes et al., 1999; Raver, Blackburn, Bancroft, & Torp, 1999; Thompson, 1993; Walden, Lemerise, & Smith, 1999).

Prosocial and Agonistic Interactions with Peers in Child Care

Empathetic and prosocial behaviors first appear between 12 and 18 months of age, when infants recognize their individuality, become aware of their feelings, and begin to realize that others have feelings as well (Eisenberg, Shea, Carlo, & Knight, 1991). In group care settings, 2-year-olds no longer respond contagiously to their peers' emotions, crying and wanting to be soothed when their peers cry. Instead, toddlers observe their peers' negative emotions carefully and attempt to respond appropriately (e.g., Bischof-Koehler, 1991). Their responses are typically prosocial (soothing, helping, giving or sharing) and gender-differentiated: Girls respond prosocially to peers more often than boys do.

The development of prosocial behaviors in group settings has been the focus of little systematic research, however. Hay and her colleagues (Hay, 1994; Hay, Castle, Davies, Demetriou, & Stimson, 1999) have shown that children adjust behaviorally to the demands of particular situations and persons and thus come to respond empathically in more clearly defined circumstances as they grow older. Other researchers have described increases in prosocial behaviors as a result of successful socialization (Eisenberg & Fabes, 1998; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992), yet others have reported no associations between child age and prosocial behavior (e.g., Farver & Branstetter, 1994), even though toddlers understand the concept of empathy and base friendships on it.

Peer relationships are frequently characterized by conflicts. In the early years (1 to 4 years), conflicts often emerge when children simultaneously want the same toys (e.g., Caplan, Vespo, Pedersen, & Hay, 1991; Hay, Castle, & Davies, 2000; O'Brien, Roy, Jacobs, Macaluso, & Peyton, 1999). Caplan et al. have shown that the frequency of possession conflicts does not vary depending on the number of toys available. Indeed, conflict occurred even when identical alternative toys were available! Hay and her colleagues further distinguished between reactive (child snatches the desired toy from a peer) possession conflicts, which involve defense of the

child's possessions and thus appear normal, as opposed to proactive (child attacks the peer in anticipation of the latter's desire for a toy) possession conflicts that reflect either misunderstanding of peers' intentions or social dominance strategies, and in both cases presage later aggressiveness (Calkins, Gill, & Williford, 1999).

Students of peer interaction in child care settings seldom encounter the types of intimidating or hurtful aggressiveness described by Coie and Dodge (1998) in school-age peer groups. Among preschoolers, however, researchers have identified temperaments that reflect poor inhibitory control and negative emotional expressions (such as anger) that could lead to "high approach-low avoidance" (Fox, 1994) behavior patterns. Such children appear actively involved in interactions with peers, although their social skills are inadequate. When they need to cope with conflicts and frustrations, for example, these children cannot fall back on positive interaction strategies and thus often fail to maintain constructive interactions with their peers (Rubin et al., 1998; Shaw, Keenan, & Vondra, 1994). Although such children may have difficulty being accepted by other children, they do appear to develop friendships.

The Impact of Child Care on Peer Relationships

Because many parents choose child care arrangements in the belief that peer interactions play an important role in social development, especially by fostering the development of empathy and the acquisition of social skills, it was surprising when some early reports suggested that infant child care was associated with increased aggressiveness toward peers (see review by Clarke-Stewart, 1988). However, most of these studies involved unrepresentative high-risk samples and did not control for family variables, or were conducted in facilities providing care of low quality (e.g., Haskins, 1985; Vandell & Corasaniti, 1990b). Other researchers reported no increases in aggression and assertiveness on the part of children who had experienced infant child care (e.g., Hegland & Rix, 1990).

Family experiences and children's personalities indeed affect levels of agonistic interactions with peers in child care settings. For example, Klimes-Dougan and Kistner (1990) reported that infants from disadvantaged families responded to signals of distress from their peers with anxiety, anger, and physical attacks, even when the peers had previously interacted with them prosocially. Watamura, Donzella, Alwin, and Gunnar (2003) found that shy and fearful children had special

difficulty interacting with more socially competent children. This made child care settings more stressful for them and could thus lead to social isolation and, perhaps, internalizing behavior problems if care providers did not intervene successfully.

According to Farver and Branstetter (1994), prosocial behaviors with peers are associated with positive expectations of peers' behaviors, friendship formation, and easy temperaments, suggesting that care providers may need to focus special attention on children with difficult behavioral dispositions or adverse family backgrounds. Unsatisfactory relationships with peers may develop when care providers fail to provide adequate and appropriate supervision. For example, Howes and Hamilton (1993) found significant correlations between peer aggression and staff turnover in a longitudinal study of children ages 1 to 4 years, and Kienbaum (2001) described positive associations between warm care provider behaviors and prosocial behaviors among kindergartners. In a longitudinal study, Howes, Hamilton, and Matheson (1994) followed 48 children who entered full-time child care (either center- or home-based) in the 1st year of life (the average age at enrollment was 5 months). The first data collection took place 1 year after enrollment and subsequent data gathering occurred every 6 months thereafter. The more secure the child-care provider relationship, the more complex and gregarious and the less aggressive was the play observed with peers at age 4, whereas dependence on care providers was associated with social withdrawal and hostile aggressive behaviors. These predictive associations parallel other reports that preschoolers who have secure relations with their teachers and care providers are more socially competent with peers (e.g., Howes, 1997; Mitchell-Copeland, Denham, & DeMulder, 1997; Oppenheim et al., 1988; Pianta & Nimetz, 1991). In addition, gendered cultures develop in the preschool years, influencing children's relationships with (overwhelmingly female) care providers in different ways (see "Relationships with Care Providers"). Care providers should thus be aware of these processes and strive to build secure relationships with both girls and boys in their care.

The quality of interactions with peers is also affected by group characteristics. Unstable and large groups may leave peers to negotiate conflicts in isolation, whereas stable small groups delineate domains of conflict clearly and allow care providers to intervene promptly

and effectively. J. J. Campbell, Lamb, and Hwang (2000) showed that such group characteristics significantly affected the quality of early peer interactions. Stimulating programs also help to minimize peer conflict at every age. For example, M. K. Rosenthal (1994) reported that children in home-based care developed more positive relationships with their peers when care providers organized group activities on a regular basis. In selected centers providing care of excellent quality, Rubenstein and Howes (1979) noted that conflicts with peers were infrequent, whereas home-reared counterparts and peers in other centers experienced conflict more frequently. These results underscore the benefits of regular positive encounters with peers in stable small groups and may explain why children appear more sociable and popular when they have been exposed to regular child care of high quality from infancy (Andersson, 1992; Field, 1991a; Howes, 1990).

The effects of many child care characteristics remain unclear or unknown, however. For example, whereas many American researchers advocate small groups, large groups with low adult-child ratios are preferred in some countries, because small groups are believed to impede positive group dynamics (Boocock, 1995). Other researchers have asked whether same-age or mixed-age groups best support peer interactions (e.g., Goldman, 1981; Rothstein-Fisch & Howes, 1988). Howes and her colleagues reported peer interactions of higher quality in mixed-age groups in which older children can serve as models for younger children (Howes & Farver, 1987), whereas children in same-age groups experienced more reciprocal interactions (Howes & Rubenstein, 1981). Nevertheless, when Bailey, Burchinal, and McWilliam (1993) compared the development of social competence in 2- to 4-year-olds from same-age and mixed-age groups longitudinally, they found no differences. Gender and cultures in preschool may promote different pathways for boys and girls, however. If peer acceptance is correlated with age in mixed-age groups (Lemerise, 1997), for example, and, as reported earlier, peer acceptance of boys but not of girls is correlated with dominance ranking (Seban et al., 2003), then younger boys might do better in same-age groups, whereas girls would function equally well in same- and mixed-age groups.

Clearly, we do not understand group dynamics in child care very well and have inadequately conceptualized the ways care providers can shape children's peer

relationships while effectively supervising groups of young children. In addition to continued research on care providers' behaviors and child-care provider attachments, research is needed on group dynamics and the "connectedness" of individuals in child care centers (Maccoby & Lewis, 2003).

Behavior Problems, Compliance, and Personal Maturity

Independent of the social relationships potentiated by child care, many researchers have examined the effect on children behavioral tendencies and adjustment.

Compliance with Parents and Care Providers

Researchers such as Belsky (1988, 1989) have portrayed insecure infant-mother attachments as a likely consequence of early and extensive nonmaternal care and have argued that as a result, noncompliance is likely to follow enrollment in child care (Ainsworth et al., 1978; Arend, Gove, & Sroufe, 1979; Londerville & Main, 1981). Consistent with this hypothesis, the results of several early studies suggested that nonmaternal child care was associated with noncompliance, both at home and in child care centers (Belsky & Eggebeen, 1991; Belsky, Woodworth, & Crnic, 1996; Crockenberg & Litman, 1991; Finkelstein, 1982; Rubenstein, Howes, & Boyle, 1981; Schwarz, Strickland, & Krolick, 1974; Thornburg, Pearl, Crompton, & Ispa, 1990; Vandell & Corasaniti, 1990a, 1990b).

In a study of 18-, 24-, 30-, and 36-month-olds assessed at home, in their child care centers, and in a standardized laboratory situation, however, Howes and Olenick (1986) reported that compliance with adult requests at home and in the laboratory did not vary depending on the quality of out-of-home care or even on whether the children had any regular out-of-home care experiences, although children without child care experiences were least likely to regulate their own behavior and emotions in the laboratory. In the laboratory, children from high-quality centers were more compliant and less resistant than children in low-quality centers. In exploratory regression analyses, the quality of center care was the most powerful predictor of compliance, but unfortunately, the different measures of compliance were not stable over situations, making it inappropriate to speak of compliance and noncompliance as traits. Simi-

lar findings were obtained in the Goteborg Child Care Study, in which compliance with mother's requests were assessed in home observations when the children were 28 and 40 months of age (Ketterlinus, Bookstein, Sampson, & Lamb, 1989; Sternberg et al., 1991). No reliable dimension of compliance was evident at 28 months, but individual differences in noncompliance at 40 months were predicted by the quality of both home and alternative care and by the amount of nonparental care received before age 2. Compliance was highly correlated with the degree of parent-child harmony, suggesting that compliance is best viewed as an aspect of cooperation with the parents rather than as a characteristic of the individual child. Subsequently, Prodromidis, Lamb, Sternberg, Hwang, and Broberg (1995) supplemented the observational measures of mother-child compliance with ratings made by teachers and parents through 80 months of age. Once again, no consistent or reliable dimension was evident at 28 months; indices of compliance with teachers and mothers loaded on the same factor but were not stable over time and were uncorrelated with any aspects of the children's child care histories. Noncompliant children received care of poorer quality at home and were more likely to have controlling parents regardless of their child care experiences.

Like Prodromidis et al. (1995) and Sternberg et al. (1991), Clarke-Stewart et al. (1994) reported that different indices of compliance did not form a single coherent dimension. In this study, middle-class 2- to 4-year-old children in child care, especially those in center care, were more compliant with unfamiliar experimenters than those in the exclusive care of their parents, especially when the children experienced intermediate amounts of high-quality care on a regular basis (10 to 30 hours per week). Observed levels of compliance with parents at home were also higher for children in child care, whereas measures of family characteristics and parental behavior had a greater impact on compliance than child care variables did. Similar results were obtained in the large multisite study undertaken by the NICHD Early Child Care Research Network (1998a, p. 1164): "Although 2-year-olds who spent more time in nonmaternal care were reported by their mothers to be less cooperative and by their caregivers to exhibit more behavior problems . . . by the time the children were 3 years of age, no significant effects of amount of child care experience could be detected." Measure of the quality of care had very little impact on measures of the

children's behavior in this study, whereas measures of the quality of home care and child-mother relationships were more strongly related to measures of the children's behavior. DeSchipper, Tavecchio, van IJzendoorn, and Linting (2003) reported that Dutch infants and toddlers were more noncompliant with care providers the more their child care schedules varied from day to day, although these effects were not statistically significant. Feldman and Klein (2003) reported that Israeli toddlers were similarly compliant with mothers, fathers, and care providers, that warm adult control was the most reliable correlate of child compliance, and that maternal sensitivity predicted compliance with care providers.

Taken together, these reports reveal a tendency for early enrollment in child care to be associated with noncompliance and less harmonious child-mother interactions at home. However, several contradictory findings and evidence that noncompliance does not constitute a coherent cross-situational trait imply that the association is context-specific and poorly understood. This signals the need for further efforts to understand the origins, reliability, and implications of these potentially important associations.

Behavior Problems

Research on the effects of child care on behavior problems other than compliance has also yielded results that at first glance appear inconsistent. On the one hand, Balleyguier (1988) reported that French infants in day care cried more, threw more tantrums, and were more oppositional at home during the 2nd year of life than were those who remained in the exclusive care of their parents. Similarly, in a large retrospective study, Bates et al. (1994) assessed associations between the extent of nonmaternal care in the 1st, 2nd to 4th, and 5th year of life and scores on multiple teacher- and mother-reported indices of adjustment after controlling for family background, gender, and other possible correlates. The extent of care in the most recent period was most influential, with children who were currently in child care appearing to be most poorly adjusted. In addition, infant care predicted less positive adjustment in kindergarten even after the effects of later care histories were taken into account. Interestingly, however, greater child care exposure was associated with teacher reports of fewer internalizing symptoms (e.g., somatic complaints, anxiety, depression). And in the multisite EPPE Project, enrollment in group care prior to the age of 2 was associated with increased behavior problems when these British

children were 3 and 5 years of age (Sylva et al., 2004). Analyzing data from the National Longitudinal Study of Youth (NLSY), furthermore, Baydar and Brooks-Gunn (1991) reported that White 4-year-olds who began receiving nonmaternal care in the 1st year were believed by their mother to have more behavior problems than those who began receiving nonmaternal care later, or not at all. By contrast, using the same data set but different statistical controls, Ketterlinus, Henderson, and Lamb (1992) reported that children who started child care in the 1st or 2nd year of life and were in day care for at least 2 years did not have more reported behavior problems than children who experienced no day care. Ephemeral effects of nonparental care on behavioral problems were also suggested by Borge and Melhuish (1995), who followed all the children in a rural Norwegian community from their 4th birthday through third grade. Behavior problems were no more common at either 4 or 8 years of age among those who had received nonmaternal care in their first 3 years. Children who experienced more center care between ages 4 and 7 had significantly fewer behavior problems at ages 7 and 10 years in the views of both mothers and teachers, even though there was little association between the behavior problems reported by mothers and teachers. Teachers, but not parents, reported that children who experienced more day care before 4 years of age behaved more poorly at age 10.

In a retrospective study of 6- to 12-year-olds in middle-class families, Burchinal et al. (1995) reported that infant day care had no effect on maternal reports of children's externalizing and internalizing behavior problems, although children with preschool experiences had higher levels of externalizing problems than did children with no preschool experiences, and preschool experiences predicted more positive ratings of social behavior in African American but not White children. High-quality child care, initiated at 12 months of age for preterm low-birthweight infants participating in an intensive intervention study, was even associated with a decline in the incidence of behavior problems reported by mothers when their children were 26 to 36 months old (Brooks-Gunn, Klebanov, Liaw, & Spiker, 1993; Infant Health and Development Program, 1990). And in annual assessments from kindergarten through sixth grade, children from impoverished families who entered child care in infancy did not have more externalizing behavior problems than children who did not receive infant day care (Egeland & Hiester, 1995).

Pierrehumbert (1994; Pierrehumbert & Milhaud, 1994) reported that Swiss children who behaved insecurely with their mother in the Strange Situation at 21 months were rated more aggressive by their mother at 5 years of age unless they had experienced more than average amounts of nonmaternal care in the first 5 years, in which case their levels of aggression were not elevated. In a later study of 89 Swiss families with 3-year-olds, however, Pierrehumbert et al. (2002) reported no association between behavior problems and either the amount or type of nonparental care experienced, although the care providers' values and attitudes were associated in the expected directions with measures of the children's behavior problems. Furthermore, Scarr et al. (1995) reported that length of time in center care had no effect and the observed quality of care had minimal effects on children's behavioral adjustment and manageability as reported by both parents and teachers. Family background (social class, parental stress, ethnicity) accounted for substantial portions of the variance in this large multisite study of infants, toddlers, and preschoolers, however. In addition, Jewsuwan, Luster, and Kostelnik (1993) reported that 3- and 4-year-old children who were rated by their parents as anxious had more difficulty adjusting to preschool, whereas children rated by their parents as sociable had a more positive reaction, especially to their peers. Similarly, DeSchipper, Tavecchio, Van IJzendoorn, and van Zeijl (2004) found that children who had easy temperaments adapted to parallel child care arrangements more readily and had fewer behavior problems than those with difficult temperaments. These results underscore the importance of considering individual differences among children when examining the effects of child care.

Against this confusing background, a recent report from the NICHD Early Child Care Research Network (2003a) attracted considerable attention because of the clear indication that the amount of nonmaternal care in the first 4.5 years of life predicted the level of externalizing behavior problems (including assertiveness, disobedience, and aggression) displayed at home or in kindergarten. The elevated risk of behavior problems on the part of children with extensive child care histories was evident in reports by mothers, care providers, and teachers, and the effects remained significant even when the effects of maternal sensitivity, family background, and the type, quality, and stability of child care were taken into account (see also NICHD Early Child Care Research Network, 1998a, 2002a).

Interestingly, much less attention has been paid to an article published in the same journal (Love et al., 2003) indicating that similar associations were not evident in three other large multisite studies. Love et al. attributed the differences to the fact that the NICHD researchers studied centers that tended to provide care of mediocre quality, whereas the centers he and his coauthors studied provided care of higher quality. Quality of care also proved to be important in another multisite study, this involving children from low-income families in three cities. Votruba-Drzal, Coley, and Chase-Lansdale (2004) reported that 2- to 4-year-old children had fewer externalizing and internalizing behavior problems the higher the quality of out-of-home care experienced, and for these children, increases in the amount of time spent in nonparental care facilities had a salutary effect, rather than the adverse effect reported by the NICHD Early Child Care Research Network (2003a). Boys, in particular, benefited from care of higher quality. In a similar multisite study of 4-year-olds, Loeb, Fuller, Kagan, and Carrol (2004) found that children in family day care settings had more behavior problems than children in other types of care, especially those who were cared for by individual relatives. In the NICHD Early Child Care Study (2004), however, high-quality child care did not appear to moderate the adverse effects of family risk factors, except that 3-year-olds from minority and single-parent families who received low-quality nonparental care were rated as less prosocial by their mother. Overall, the results of the NICHD Early Child Care Study confirmed that family background and relationship factors had a greater impact on the children's adjustment than either the extent or quality of nonparental child care, although the extent of care had a significant, negative, effect.

In sum, whether or not it is mediated through the quality of attachments to care providers, the quality of nonparental child care appears to modulate the effects of nonparental child care on many aspects of child behavior and adjustment, although family experiences appear to have the most important impact on child behavior. Thus, children who have experienced nonparental care from infancy tend to be more aggressive, more assertive, and less compliant with adults than peers who have not had these experiences, but the associations are weaker, if not nonexistent, when the quality of care is better. Effects on noncompliance with adults are not as clear, however, both because compliance and noncompliance have been studied less extensively

and because noncompliance appears to be situation- and relationship-specific rather than trait-like. Unfortunately, many of the studies focused on behavior problems have not assessed quality of care systematically, and the actual behavior problems at issue are a heterogeneous melange, including poor relationships with peers, aggression, and noncompliance.

Personal Maturity

The personal maturity of children in day care has not often been studied, although there is some evidence that nonparental care of high quality fosters personality development. In the Goteborg Child Care Study, mothers described the children's personalities at 28 and 40 months of age using Block and Block's (1980) California Child Q-set (CCQ). Their ratings were used to generate scores for the children's ego resilience, ego control, and field independence (Broberg et al., 1989; Lamb, Hwang, Bookstein, et al., 1988; Lamb, Hwang, Broberg, & Brookstein, 1988). Perceived personality maturity was quite stable over time and was best predicted by observational measures of the quality of care received at home and in the alternative care settings. The children viewed as most mature by mothers were those who had received care of higher quality from nonparental care providers as well as from their parents. There were no differences between children in the home-based care, family care, and center care groups on any of the personality measures at either age.

Most (87%) of the children in this study were reassessed immediately prior to enrollment in first grade (80 months of age) and toward the end of second grade (101 months of age). Once again, personal maturity was assessed using the CCQ, but a different pattern of results was now evident. Children who had been enrolled since toddlerhood in home-based child care settings appeared less mature than those in the other groups (Wessels, Lamb, Hwang, & Broberg, 1997). Over time, in addition, ego undercontrol decreased less, whereas ego resilience and field independence increased less in the children who had received home-based care than in those who had remained at home with their parents or attended child care centers.

No other researchers have explored type of care effects, and most have examined contemporaneous associations rather than longitudinal relations. Hestenes, Kontos, and Bryan (1993) showed that 3- to 5-year-olds expressed more positive affect when their child care arrangements were of higher quality. The appropriate-

ness of the adults' behavior, along with the extent to which they manifested high levels of engagement, was especially significant. Positive self-perceptions were also correlated with high-quality care, even after controlling for differences in social class, ethnicity, and family background, in a large-scale study of infants, toddlers, and preschoolers in child care centers (*Cost, Quality, and Child Outcomes in Child Care Centers*, 1995). Reynolds (1994) reported that preschool and elementary school intervention were associated with improved teacher ratings on various indices of mature adjustment to school in the fifth grade. And, as discussed earlier (see section on "Relationships with Care Providers"), children who had secure relationships with their care providers were more ego-resilient and more appropriately ego-controlled than those who had insecure relationships (Howes, Matheson, et al., 1994).

In sum, although the number of studies is quite small, the available evidence suggests that center care of high quality has positive effects on personal maturity, whereas children receiving care of lower quality tend to be less mature. Further exploration in large samples is called for, however, particularly in light of Wessels et al.'s (1997) findings that the effects of quality diminish over time.

Cognitive and Linguistic Competence

Many researchers have studied the effects of child care arrangements on children's cognitive and linguistic competence. Only over time have the findings revealed a clear pattern.

Early Findings

At first glance, research over the past 15 years on the effects of nonmaternal care on cognitive and linguistic competence appears to have yielded quite contradictory and inconsistent results. These apparent inconsistencies underscore the fact that the effects of child care must be viewed in the context of a complex constellation of phenomena, including family and parent characteristics as well as characteristics of the child care arrangements. When all of these factors are taken into account, a much clearer picture of child care and its impact emerges. In this subsection, we first review research on the effects of standard or community child care arrangements before turning to studies focused on child care programs specifically designed to enhance the development of

children whose circumstances place them at risk of later academic failure.

Some early researchers reported that child care had negative effects on cognitive development. In a retrospective study of third graders, for example, Vandell and Corasaniti (1990a, 1990b) reported that extensive care beginning in infancy was associated with poorer scores on standardized measures of cognitive development, and in a smaller study of Swiss infants, nonmaternal infant child care was associated with lower cognitive test performance at age 2 (Pierrehumbert, Ramstein, & Karmaniola, 1995). Using data from the NLSY ($N = 1,181$), Brooks-Gunn and her colleagues (e.g., Baydar & Brooks-Gunn, 1991; Brooks-Gunn, Han, & Waldfogel, 2002) reported that maternal employment during the 1st year of life was associated with poorer cognitive abilities in 3- and 4-year-olds, and Desai, Chase-Lansdale, and Michael (1989) reported poorer verbal abilities on the part of boys in the sample. The children received varying types of early nonmaternal care (often by relatives), and few of the children were enrolled in center-based care during the 1st year of life.

Other early researchers reported neither positive nor negative effects. Thornburg et al. (1990), for example, found that early child care (full or part time, initiated before or after infancy) did not affect the cognitive achievement scores of a large group of Missouri kindergartners. Likewise, Ackerman-Ross and Khanna (1989) reported no differences in receptive language, expressive language, and IQ between middle-class 3-year-olds who either remained home or received child care beginning in infancy. Burchinal et al. (1995) found only weak positive associations between preschool or center-based child care and either cognitive or linguistic performance scores Wechsler Intelligence Scales for Children-Revised and Problem Picture Vocabulary Test (WISC-R and PPVT scores) at 6 to 12 years of age in a sample of middle-class children.

By contrast, Clarke-Stewart (1987; Clarke-Stewart et al., 1994) reported that middle-class 2- to 4-year-old children in centers scored better on many measures of cognitive development than children who remained in the exclusive care of their parents, had in-home sitters, or were in home-based care, and that the effects were greater in centers of higher quality (see later discussion). Another prospective longitudinal study of children from educationally advantaged backgrounds revealed that boys, but not girls, who attended a 1-year preschool program performed better on a battery of

achievement measures administered in second and third grade (Larsen & Robinson, 1989). In Sweden, Broberg, Hwang, Lamb, and Bookstein (1990) assessed verbal intelligence when the children participating in the Goteborg Child Care Study were nearing the end of second grade (average age 101 months). The children's performance on standardized measures of cognitive ability was predicted by the number of months the children had spent in center-based care before 3.5 years of age. By contrast, children in home-based care performed more poorly than those in the center-based care and home-only comparison groups. In a retrospective study, Andersson (1989, 1992) similarly found that Swedish children who entered child care in infancy scored significantly better on standardized measures of cognitive ability and teacher ratings of academic achievement at both 8 and 13 years of age, even after controlling for differences in their family backgrounds. These results were largely consistent with those of studies from Norway (Hartmann, 1991), New Zealand (A. B. Smith, Inder, & Ratcliff, 1993), and Britain (Wadsworth, 1986).

Differential rates of illness may account for some of the inconsistencies evident in this literature. For example, Feagans, Kipp, and Blood (1994) showed that, when children in child care had chronic ear infections, they were much less likely to pay attention during book-reading sessions than children without ear infections. These children were also rated more distractible and inattentive by their mother. Unfortunately, researchers have paid little attention to the role that illness may play in mediating the effects of child care. Children in group care settings are obviously more susceptible to illness and infection than children who are exposed to fewer sources of possible infection, and this might work to children's disadvantage, especially in the first 2 years of life, when the immune system is still immature.

Reflecting the inconsistencies summarized here, a meta-analysis of 59 studies conducted by Erel et al. (2000) revealed no reliable differences in cognitive competence between children with and without histories of nonparental child care. If one focuses on studies conducted in Europe, where the quality of child care tends to be higher, positive effects on children's cognitive and linguistic outcomes have been reported more consistently, however (Boocock, 1995; Scarr, 1998). For example, Sylva et al. (2004) found that preschool experiences, especially in high-quality settings, enhanced the academic and cognitive performance of children in the large multisite EPPE study, with benefits evident during

the preschool years as well as when the children were 5 and 7 years old. As we note later, effects generally appear to differ depending on the backgrounds of the children involved as well, with children from disadvantaged backgrounds more likely to benefit than those from more advantaged backgrounds unless the care is of very high quality, in which case all children may benefit.

Children from Low-Income Families

As discussed in the section on enrichment programs, many researchers in the United States have shown that children from low-income families benefit from participation in programs, such as Head Start and Early Head Start, designed to enhance the school readiness and academic performance of children from disadvantaged family backgrounds (Spieker, Nelson, Petras, Jolley, & Barnard, 2003). However, these effects are often attenuated over time when not supplemented by continued enrichment.

Child care arrangements can mitigate the adverse effects of unstimulating or confusing family environments on cognitive and linguistic development even when special intervention programs are not involved. In a study focused on low-income mothers and their second graders, for example, Vandell and Ramanan (1992) reported that maternal employment in the first 3 years was associated with superior academic performance, especially when the mother remained employed for the remainder of the preschool years. Similarly, center care of the quality typically available in poor communities in the United States had positive effects on development over the first 3 to 4 years of life for children from low-income families (Loeb et al., 2004). Some preschool enrichment programs are not stimulating enough to enhance the competencies of children from advantaged backgrounds, however. For example, Caughy, DiPietro, and Strobino (1994) reported that enrollment in child care before age 1 was associated with better reading recognition scores for 5- and 6-year-old children from impoverished backgrounds but poorer scores for children from more advantaged backgrounds. Center-based care begun in the first 3 years was also associated with higher math performance scores in children from impoverished backgrounds and lower math scores for children from more stimulating homes. Children from more disadvantaged backgrounds also benefited more from preschool experiences than did peers from more advantaged backgrounds in the large EPPE study conducted in Great Britain (Sylva et al., 2004). Likewise, African American but not White children benefited from preschool in

a study of middle-class 6- to 12-year-olds conducted by Burchinal et al. (1995).

Overall, it seems that children from low-income families benefit when they attend stimulating child care centers. By contrast, recent evaluations of both Sure Start in the UK and Early Head Start in the USA found that early intervention had negative effects on children from the most disadvantaged backgrounds (Belsky et al., 2005; Early Head Start Research and Evaluation Project, 2002a). Children from more advantaged backgrounds do not consistently profit from child care in this way, presumably because they enjoy rich stimulating environments at home. Indeed, early and extensive child care can even have negative effects, especially on language development, when the benefits attributable to growing up in advantaged families are attenuated by child care (Burchinal, Peisner-Feinberg, Bryant, & Clifford, 2000). Children from all family backgrounds appear to benefit when child care is of high quality, however. Positive family factors (such as greater family income, more sensitive mothering, and less authoritarian child-rearing attitudes) are associated with indices of more positive child functioning and continue to affect children positively even when they spend much time in child care settings (NICHD Early Child Care Research Network, 1998b, 2001c). Indeed, family factors are more reliable predictors of children's cognitive competencies than the quality or type of nonparental child care (NICHD Early Child Care Research Network, 2002a).

Quality and Types of Child Care

Higher-quality care is positively associated with better cognitive and language development, whereas lower-quality care is associated with poorer outcomes. Such findings have been obtained in the Bermuda Study (McCartney, 1984; Phillips, McCartney, & Scarr, 1987), the Chicago Study (Clarke-Stewart, 1987), the Child Care and Family Study (Kontos et al., 1994), the Cost, Quality, and Child Outcomes Study (Peisner-Feinberg & Burchinal, 1997), the Goteborg Child Care Study (Broberg et al., 1990; Broberg, Wessels, Lamb, & Hwang, 1997), the NICHD Study of Early Child Care (NICHD Early Child Care Research Network, 1994, 1999b, 2003b, in press), the EPPE Study (Melhuish, Sylva et al., 2001; Sammons et al., 2002, 2003; Sylva et al., 2004), and in a large multisite study in Northern Ireland (Melhuish, Quinn et al., 2001; Melhuish et al., 2002a, 2002b), as well as in several smaller studies (Field, 1991a; Hartmann, 1995). Similar results have

been reported internationally regardless of how quality is measured or of the specific types of educational programs implemented (Boocock, 1995; Tietze & Cryer, 1999). The effects diminish over time, however, presumably because the beneficial effects of high-quality care are undercut by increasing exposure to less stimulating environments, both at home and at school.

With regard to the characteristics of cognitively stimulating environments, high-quality cognitive and linguistic stimulation is more likely when positive adult-child relationships (Meins, 1997; van IJzendoorn, Dijkstra, & Bus, 1995; Williams & Sternberg, 2002) and egalitarian peer interactions (see "Relationships with Peers") prevail. Not surprisingly, therefore, the NICHD Early Child Care Research Network's (2002a) structural equation model revealed that both care provider training and adult-child ratios affected cognitive competence via their impact on the quality of care (i.e., care providers' sensitivity to nondistress, detachment, stimulation of cognitive development, and intrusiveness; classroom characteristics of chaos, overcontrol, and emotional climate; see also Burchinal et al., 2000; Peisner-Feinberg et al., 2001). Likewise, home-based care providers who were better educated (more recent and higher levels of training) provided richer learning environments as well as warmer and more sensitive care. The associations were amplified when settings had groups of the recommended sizes (Clarke-Stewart et al., 2002).

We might expect that any effects of the type of care would vary depending on the differential opportunities for child-care provider relationships in center-based and home-based setting (see "Relationships with Care Providers"). Unfortunately, variations in the quality of care received and the fact that some children experience a variety of care settings either sequentially or simultaneously complicates research on these topics, but the results of the NICHD Early Child Care Research Network study (2000c) provide some insight into the relative merits of home-based and center-based care of equivalent quality. As in other studies (Broberg et al., 1997; Burchinal et al., 1995; Caughy et al., 1994; Clarke-Stewart et al., 1994; NICHD Early Child Care Research Network, 2002b, 2003b), center-based care appears to have some advantage over home-based care with respect to cognitive and language development, perhaps because children in centers are typically exposed to a richer language environment and have more opportunities to encounter developmentally stimulating events than children in less formal settings. Children in center-based care are also more likely than those in home-based care

to have peers who engage them in discussions and arguments that promote the effective use of language.

Researchers have also asked whether experiences in child care during specific developmental periods have distinctive effects. In the NICHD study (NICHD Early Child Care Research Network, 2000c) as well as in studies of maternal employment (Baydar & Brooks-Gunn, 1991; Brooks-Gunn et al., 2002), sensitive care and individual language stimulation during the first 2 years had a greater effect on subsequent cognitive and linguistic functioning than high-quality parenting in later years (Siegel, 1999). In addition, children whose mothers were not employed full time and children in home-based child care had better cognitive and language skills at age 3 than those who experienced other types of high-quality care. Perhaps as a result, the positive effects of home-based nonparental care on cognitive and linguistic development are evident at 24 and 36 but not 54 months, by which time peer (as opposed to adult) stimulation starts to become more important (NICHD Early Child Care Research Network, 2000c).

Enrichment Programs

The effects of child care on diverse aspects of development, but especially cognitive skills and academic performance, have also been elucidated by studying the effects of especially designed enrichment programs, particularly in the United States.

History of Head Start Programs

Numerous attempts have been made to evaluate the long- and short-term effects of compensatory enrichment programs for children from disadvantaged backgrounds. The amount of attention paid to this topic reflects in large part the tremendously optimistic fanfare that accompanied the rapid nationwide expansion of these programs in the mid-1960s as part of President Johnson's twin crusades, the Great Society and the War on Poverty (Steiner, 1976; Zigler & Muenchow, 1992; Zigler & Valentine, 1979). In this context, the establishment of Head Start in 1965 took and retains center stage in U.S. efforts to enhance the welfare of its children. Because of its tremendous costs and broad constituency, furthermore, the debates have been prolonged, although systematic efforts to study the effects of Head Start have been surprisingly inadequate.

In the late 1950s, social scientists began to marshal evidence suggesting that human abilities were more

pliable than previously recognized (e.g., Bloom, 1964; Hunt, 1961). In response to this, a small number of model preschool programs were developed and evaluated. The results obtained documented the value of compensatory education, although most researchers sought primarily to contrast the relative efficacy of different curricula and pedagogical approaches rather than the utility of compensatory preschool education per se (e.g., Bereiter & Engelmann, 1966; Caldwell & Richmond, 1968; Copple, Sigel, & Saunders, 1984; Gray & Klaus, 1965; Stanley, 1973). Before this programmatic research had advanced enough to permit the evaluation and fine-tuning of intensive model interventions, political pressures and the availability of funds led to the premature launching of Head Start on a nationwide scale. Originally intended as a summer-long pilot program for children from impoverished backgrounds, Head Start quickly became a year-round program attended by preschoolers in the year or two before they entered the school system. A half-million children were enrolled by the summer of 1965, and by 1998, some 800,000 children attended Head Start programs, mostly for a few hours per day, while some of the mothers attended parent education and skill development classes, often in the same building (Administration for Children & Families, 1999).

Head Start programs have always varied greatly, in large part because federal administrators have explicitly deferred to the grassroots clientele whose loyalty has allowed the program to prosper for 4 decades. Most programs emphasize the direct delivery of services to children, and this is viewed as most effective (S. L. Ramey & Ramey, 1992; Roberts, Casto, Wasik, & Ramey, 1991; Wasik, Ramey, Bryant, & Sparling, 1990). Similarly, parent participation is widely viewed as an important adjunct to successful early intervention programs, but its extent varies greatly from program to program (Comer, 1980; C. Powell & Grantham-McGregor, 1989; D. R. Powell, 1982; Seitz, 1990), and potentially valuable home-visiting components are provided by only a small number of Head Start programs (Roberts & Wasik, 1990, 1994).

Originally intended as a broadly focused compensatory and enrichment program, Head Start's political proponents quickly came to depict it as a program designed (in large part) to enhance children's school performance. Evaluations shortly after enrollment could not, of course, track either behavior or achievement at school, and so the fateful decision was made to measure

IQ, a construct with which psychologists and educators had extensive experience and that they were able to measure quickly and reliably (J. S. Kagan et al., 1969). Unfortunately, this decision and the initial results helped foster unrealistic and simplistic views of the problems posed by poverty, and of their susceptibility to intervention (Sigel, 1990).

Despite evidence that short-term increases in IQ could be attributed to enhanced motivation rather than intelligence (Zigler & Butterfield, 1968), initial reports pleased Head Start's political and academic progenitors: The IQ scores of children in Head Start programs increased over the time they were enrolled, and the IQ scores of children attending Head Start programs were significantly higher than those of comparable children who did not attend the programs. The euphoria quickly faded following publication of the Westinghouse Report in 1969 (Cicirelli, 1969), however. The results of this large multisite evaluation confirmed that children who had attended Head Start programs indeed had higher IQs, although these advantages quickly faded after the children left the programs and entered the regular public school system. The methodological sophistication of the Westinghouse Report was widely criticized at the time (D. T. Campbell & Erlebacher, 1970; Datta, 1976; Lazar, 1981; M. Smith & Bissell, 1970), but similar findings were reported by other researchers (e.g., McKey et al., 1985). Together, these reports fueled (a) criticisms that compensatory education was a wrong-headed failure that should be abandoned (Jensen, 1969; Spitz, 1986); (b) efforts to underscore that the major—nonintellectual—goals of Head Start (such as improved medical, mental health, and dental care) had not been evaluated (D. J. Cohen, Solnit, & Wohlford, 1979; Hale, Seitz, Zigler, 1990; National Head Start Association, 1990; North, 1979; Zigler, Piotrkowski, & Collins, 1994); (c) arguments that practitioners needed to build on the acknowledged short-term contributions of Head Start by complementing them with continuing enrichment following enrollment in public school (Doernberger & Zigler, 1993; S. L. Ramey & Ramey, 1992); (d) recommendations that interventions would be more effective if children were enrolled at much younger ages (S. L. Ramey & Ramey, 1992); and (e) awareness that poverty had multiple facets and impacts, such that amelioration of its effects would require complex, multifaceted, multidisciplinary, and extensive interventions (Sigel, 1990). The emergence in the 1990s of Early Head Start for children under 3 years of age represents one be-

lated response to some of these issues, as did the earlier introduction of Parent Child Centers.

Later Evaluations of Preschool Intervention Programs

The Consortium for Longitudinal Studies (1978, 1983; Darlington, Royce, Snipper, Murray, & Lazar, 1980; Lazar, Darlington, Murray, Royce, & Snipper, 1982) followed participants in 11 early intervention studies using a uniform set of measures. Their analyses confirmed that effects on IQ quickly faded following graduation from the programs, although the researchers were able to identify impressive group differences in other aspects of school performance, including retentions in grade and premature school leaving (see also Barnett, 1995; Karoly et al., 1998). Few of these longitudinal studies involve Head Start graduates, in part because assignment to Head Start and comparison groups is not random and in part because there is so much diversity among Head Start programs that consistent effects should perhaps not be expected. Notwithstanding such methodological shortcomings, other reports suggest better school performance on the part of Head Start graduates. For example, Hebbeler (1985), McKey et al. (1985), and Copple, Cline, and Smith (1987) reported that Head Start graduates were more likely than children from comparable backgrounds who did not attend Head Start to be promoted, perform adequately at school, and have adequate nutrition and health care. Because the quality of Head Start programs is so variable, it is possible that the effects of Head Start would appear greater and more enduring if focus was placed on the good programs and their graduates (Gamble & Zigler, 1989). Consistent with this hypothesis, Bryant, Burchinal, Lau, and Sparling (1994) reported that the quality of Head Start classrooms, assessed using Harms and Clifford's (1980) ECERS scales, was correlated with scores on standardized measures of achievement, school readiness, and intelligence at the end of the Head Start year, regardless of the quality of home care. Most of the classrooms were rated "adequate" in quality; none were deemed "developmentally appropriate." Such findings, of course, underscored the need for improvements in the overall quality of Head Start (see also Gamble & Zigler, 1989).

Currie and her colleagues (Currie, 2001; Currie & Thomas, 1995, 1999, 2000; Garces, Thomas, & Currie, 2002) have examined the long-term effects of Head Start not by following graduates and nongraduates over time, but by selecting subjects retrospectively from large, nonexperimental, longitudinal studies such as the

National Longitudinal Survey (NLS) and the Panel Study of Income Dynamics (PSID). In their first study, Currie and Thomas (1995) selected children in the NLS who had attended Head Start programs and compared them with siblings who had not been in Head Start, reasoning that the sibling comparisons would control for family background effects. Their analyses revealed the expected increases in test scores associated with Head Start attendance. Currie and Thomas were the first researchers able to compare outcomes for individuals from different racial backgrounds, and they found that the gains associated with Head Start attendance persisted into adolescence for the White children, who continued to experience less in-grade retention, whereas they faded out in the early elementary grades for African American children, probably because the African American children studied attended poorer-quality elementary schools—poorer even than the schools attended by African American children on average (Currie & Thomas, 2000). Similar findings regarding the greater benefits of early intervention for children at greatest risk have been reported by other researchers (Brooks-Gunn, 2003).

In a later study, Whites and African Americans born between 1965 and 1977 were interviewed in the 1995 wave of the PSID, when they ranged between 18 and 29 years of age. After controlling for background variables, Garces et al. (2002) found that Whites who attended Head Start were 20% more likely to complete high school and 28% more likely to attend college than siblings who did not, whereas Head Start attendance had no comparable effect on African Americans. On the other hand, African Americans who attended Head Start were 12% less likely to report being booked or charged with a criminal offense than siblings who did not attend Head Start, and in this case there was no comparable difference among Whites. Using an innovative analytic technique, general growth mixture modeling, Kreisman (2003) likewise showed that different groups of children who attended Head Start had different developmental trajectories, but she was unable to explore the characteristics (e.g., racial background) of children in the different groups.

Of the early intervention programs that have managed to follow their graduates over extended periods of time, most attention has been paid to the Perry Preschool Program in Ypsilanti, Michigan, which began in 1962 (Barnett, 1985, 1993a, 1993b; Berrueta-Clement, Schweinhart, Barnett, Epstein, & Weikart, 1984). One

hundred and twenty-eight African American children from low-income families were randomly assigned to control and intervention groups. Beginning when they were 3 to 4 years old, children in the intervention group received 2.5 hours of class instruction per day throughout a 30-week school year, 13 of them for 1 year and 45 of them for 2 years. In addition, mothers and children were visited at home weekly for about 90 minutes. The children and their official records were reevaluated annually through 11 years of age as well as at 14, 15, 19, and 28 years of age using a battery of measures primarily focused on achievement, ability, and school performance (Schweinhart, Barnes, & Weikart, 1993). These data revealed that children in the program had higher achievement scores at ages 9 and 14, were more likely to graduate from high school, were more likely to be employed and not to have been arrested by age 19, earned more, were less likely to have a history of frequent arrests by age 28, and were less likely to go on welfare than those in the comparison group.

Much of the popular attention paid to this program reflects the decision to estimate in dollar terms the costs and benefits of enrollment in the preschool program (Barnett, 1993a, 1993b). The most widely publicized figures suggest that an average investment of \$12,356 per child who participated in the program resulted in benefits through age 28 of \$70,876. These benefits reflected the additional costs of completed education and higher wages and the lower costs of incarceration and welfare. Benefits are projected to continue as well, presumably justifying an initial investment that was substantially greater than the average cost of typical preschool programs or Head Start programs.

The results of the Perry Preschool Project underscore the potential value of an extended preschool intervention of high quality, but do not reflect the likely effects of large established programs like Head Start, which serve a somewhat different clientele over a briefer period of time with much less rigorous control over quality (Zigler & Styfco, 1994). Greater attention to quality might improve the average effectiveness of early intervention programs like Head Start. Likewise, extension of the programs by enrolling children at younger ages, providing full-day services, and/or continuing to provide enriching services after school enrollment typically enhance the effects of preschool on the intellectual performance of children from impoverished backgrounds (see also Clark & Kirk, 2000; Cryan, Sheehan, Wiechel, & Bandy-Hedden, 1992; Elicker & Mathur, 1997; Fusaro, 1997; Gullo, 2000;

Sheehan, Cryan, Wiechel, & Bandy, 1991; Vecchiotti, 2003), although the large EPPE study showed no differences between the effects of full-day and part-day programs in the United Kingdom (Sylva et al., 2004).

European Intervention Programs

In most European countries, preschool programs (often akin to American kindergarten) are mandatory in the year or years before school officially begins; as a result, the effects of preschool programs on school preparedness have not been studied extensively. Nevertheless, considerable public debate about the structure, components, and goals of these preschool programs is now taking place throughout Europe. Some educators want emphasis placed on cognitive competencies rather than socialization and exploration, and the debate has only become more intense in response to evidence of major cross-cultural variation in the basic reading and mathematics competencies of eighth graders in the 39 industrialized countries studied (OECD, 2002). This has raised questions not only about the quality of the different school systems but also about how preschool programs should prepare children for school. Sure Start programs in the UK have modest but positive effects on most children and mothers, although effects on the most disadvantaged children were negative (Belsky et al., 2005).

Earlier Intervention

C. T. Ramey and his colleagues (C. T. Ramey, 1992; C. T. Ramey & Smith, 1977) have continued to study a small cohort of children who entered the Abecedarian intervention project in North Carolina as infants in the late 1960s. All of the children came from impoverished African American backgrounds. When they were 3 months old, half of the children were enrolled in a full-time, full-year, center-based intervention program designed to prepare them for school, and this program continued until kindergarten. Upon enrollment in kindergarten, half of the children in each group began an intervention program that continued through the first 3 years of elementary school.

In every assessment between 6 and 54 months, a greater proportion of the children in the intervention group had an IQ in the normal range (Martin, Ramey, & Ramey, 1990), and at the time of entry into kindergarten, the children in the experimental group had IQ scores 8.5 points higher than those of children in the comparison group, although the difference narrowed to 5 IQ points by second grade (C. T. Ramey & Campbell,

1984, 1987, 1991, 1992). At the beginning of kindergarten, the children in the enrichment group also performed better on measures of narrative skills than children in the control group, but these differences were no longer evident by the spring (Feagans & Farran, 1994), and other children in their classrooms performed better on measures of paraphrasing than did children from either the enrichment or comparison groups. Children in the intervention group also performed better on tests of conservation at ages 5, 6, and 7; their school performance and academic achievement were better; they were less likely to repeat grades; and they were less likely to have special education needs when they received the preschool intervention as well (F. A. Campbell et al., 1995; F. A. Campbell & Ramey, 1990; Hovacek, Ramey, Campbell, Hoffman, & Fletcher, 1987). Later assessments showed that children in the intervention group completed more years of school than those who did not (F. A. Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001; F. A. Campbell, Ramey, Pungello, Sparkling, & Miller-Johnson, 2002). Somewhat surprisingly, the elementary school enrichment component had little impact (F. A. Campbell & Ramey, 1994, 1995).

Wasik et al. (1990) later showed that the Abecedarian intervention was even more influential when it was supplemented by a home-based family education program, which became Project CARE. At every assessment through 54 months of age, children receiving both center- and family-focused intervention in Project CARE performed better than those receiving only center-based intervention. According to C. T. Ramey, Ramey, Hardin, and Blair (1995), however, intensive home visits by themselves had no effect on the children's performance or on their families, even though home visiting has proven effective in other studies (Seitz, 1990).

Burchinal, Lee, and Ramey (1989) compared the developmental trajectories of Black children from impoverished backgrounds who (a) entered the intensive intervention programs at 2 to 3 months of age, (b) were enrolled in community child care at an average of 20 months, or (c) had minimal or no child care experiences. Semiannual assessments between 6 and 54 months using the Bayley Mental Development Index (MDI), the Stanford-Binet, and the McCarthy scales revealed that the children in the intervention group consistently performed the best, followed by those in community care settings, followed by those who had minimal child care experiences. This suggests that

community child care can have beneficial effects on the cognitive performance of children from impoverished unstimulating homes, although the lack of random assignment to the two nonexperimental comparison groups compromises the assessment of causality. The same is true of the New York City Infant Day Care Study (Golden et al., 1978), in which disadvantaged children whose parents chose to enroll them in day care centers had higher IQ scores at 18 and 36 months than children whose parents chose to keep them primarily at home.

Sparling et al. (1991) later developed an intensive intervention program modeled after the Abecedarian program for a large-scale randomized control study of low-birthweight premature babies, the Infant Health and Development Program (1990). Mothers and infants in this study were randomly assigned to either program (intervention) or control groups. The program involved weekly home visits for 3 years after hospital discharge, high-quality educationally oriented day care from 12 to 36 months of age, and parent group meetings on a bi-monthly basis. Enrollment in this program led to significant improvements in the IQs of infants at age 36 months (Brooks-Gunn et al., 1993; C. T. Ramey et al., 1995). The effects on the heavier babies was greater than on the lighter babies, but was statistically significant in either case at the time of the 3-year follow-up (C. T. Ramey et al., 1995), although by 5 years of age, significant effects were evident only among those who were heavier at birth (Brooks-Gunn et al., 1994). Intervention had substantially more powerful effects on the infants of mothers with the lowest education, and had no effect on the infants of mothers who were college graduates (C. T. Ramey et al., 1995). Subsequent analyses showed that the magnitude of the effects on IQ varied depending on the extent to which the families participated and took advantage of the services offered to them (Blair, Ramey, & Hardin, 1995; C. T. Ramey et al., 1992). This is consistent with other evidence suggesting that more intensive programs have a greater impact on child development than less intensive programs do (S. L. Ramey & Ramey, 1992). Furthermore, the results of the Infant Health and Development Program, the Abecedarian Program, and Project CARE all underscore the importance of providing care and stimulation directly to children in out-of-home contexts.

Responding to calls that intervention for children at psychosocial risk should begin as early as possible, the U.S. Administration for Children, Youth, and Families (ACYF) developed Early Head Start in 1994 and funded

the first 143 programs in 1995. By 2002, 664 programs nationwide were serving 55,000 children. As with Head Start, programs vary widely depending on local needs and resources, with some programs providing home-based, some center-based, and some both home- and center-based services to infants, toddlers, and their parents from pregnancy through the 3rd year of life (Early Head Start Research and Evaluation Project, 2002b). To assess the implementation and effectiveness of Early Head Start,ACYF also commissioned a random assignment study of families who were and were not offered services through local programs. The Early Head Start Research and Evaluation Project (2001, 2002a) found that Early Head Start services had a significant impact on the supportiveness and positiveness of the mothers' and fathers' behavior as well as on the cognitive performance, language development, and social-emotional behavior of the children at ages 2 and 3. Effects tended to be stronger when families were enrolled in programs that had implemented a wider range of services, especially when they provided both home- and center-based services. African American children tended to benefit the most and White children the least, and children from the most disadvantaged programs were adversely affected. Although children receiving Early Head Start services performed much better than peers in the control groups, it is noteworthy that they continued to score far below national norms, whereas children in the more intensive and extensive Abecedarian Project performed at around national norms.

Supplementary Enrichment for Graduates of Preschool Programs

Unfortunately, public school enrichment programs (such as Program Follow Through) designed to attenuate the IQ decline that typically occurs when children leave enrichment programs (Doernberger & Zigler, 1993; Kennedy, 1993) have never been well funded, and thus implementation has been limited despite a small but persuasive body of evidence showing that programs of this sort can indeed be beneficial. Abelson, Zigler, and DeBlasi (1974) and Seitz, Apfel, Rosenbaum, and Zigler (1983) showed that one cohort of children who went from Head Start to Follow Through programs in New Haven, Connecticut, maintained higher scores on measures of IQ, school achievement, and social-emotional development than children who attended traditional school programs through grade 9. A comparable demonstration program involving comprehensive preschool and

school-age intervention, complemented by parental involvement during the preschool and early elementary years, was conducted in Chicago, although, as in New Haven, children were not assigned randomly to the two groups. Fuerst and Fuerst (1993) and Reynolds (1992a, 1992b, 1994, 1998, 2000; Reynolds, Temple, Robertson, & Mann, 2001; Temple, Reynolds, & Miedel, 2000) reported that, after controlling for family background, graduates had better reading and mathematics achievement scores, were significantly less likely to be retained in grade, were less likely to be referred for special education, were less likely to engage in criminal activities, and were more likely to graduate from high school than children who received traditional schooling. Reynolds (1994) further found that participation in the elementary school component of the program had beneficial effects independent of the preschool component. Interestingly, there was very little difference between the effects of 1- and 2-year enrollment periods, suggesting that it might be more effective to expand the number of children served rather than to extend the length of time each was enrolled (Reynolds, 1995). Taylor and Machida (1994) reported that parental participation in school activities was associated with learning skills and more strongly associated with classroom behavior after several months in Head Start. Maintenance of parental involvement also played an important role in ensuring the long-term continuity of effects on the children's performance in the Chicago Child-Parent Centers (CPC; Reynolds, 1992b), although site-level factors, such as location, curriculum, parental participation rates, family stability, and the proportion of children who came from low-income families, had much less impact on the children's outcomes than preschool participation (Clements, Reynolds, & Hickey, 2004).

Summary

The onset of nonparental child care stresses children, especially those who enter child care after becoming attached to their mother. Secure child-mother relationships do not appear to help children cope with these stresses as much as attachment theorists originally believed, and thus familiarization programs and supportive child-care provider relationships are needed to help children adjust to the onset of child care.

Parental sensitivity remains a key determinant of children's adjustment even after the onset of child care, and the life changes that accompany the onset of mater-

nal employment and child care often affect the quality of parental behavior. Families need to find ways to compensate for the time they spend apart and to respond sensitively to children's needs to minimize or avoid adverse effects on attachment security. Supportive and secure child-care provider relationships can also play an important role in promoting children's well-being. Care providers are not mother substitutes, however. Whereas dyadic interactions are central to parent-child relationships, the quality of care providers' behavior in relation to groups of children is crucial. Both child-care provider interactions and group dynamics define the climate that powerfully affects children's adjustment, for good and for ill.

For children without siblings, child care may provide unique opportunities for socialization with and by peers on a regular basis. However, the development and significance of relationships with peers are affected not solely by enrollment in child care but also by social-cognitive and social-emotional characteristics that are significantly shaped by socialization in the family. In addition, child care practices can foster good and hinder poor interaction skills, which in turn affect later behavioral adjustment and personality maturation. Extensive experience of mediocre or poor-quality care is associated with increased behavior problems.

Longitudinal studies are disappointingly rare, but all show that the positive cognitive effects of high-quality intervention are attenuated over time unless maintained by continuing care or education of high quality. Of course, success at school demands cognitive and linguistic competencies that are affected by experiences both at home and in child care facilities. High-quality child care can thus counteract the adverse effects of poorer experiences with parents. High-quality child care is not as helpful for children from more advantaged backgrounds, however. Instead, care of poorer quality has effects that vary depending on its quality relative to the quality of care and stimulation that children would receive at home. As a result, the performance of some children from supportive and stimulating families may be affected adversely by out-of-home care experiences.

Unfortunately, few attempts have been made to evaluate the relative effectiveness of different curricula or pedagogical approaches, so we cannot identify which features of successful programs are particularly valuable for which children. Likewise, the literature permits us to offer only the most general conclusions about the beneficial effects of high-quality care rather than em-

pirically supported conclusions about the value of particular programs and approaches. Research on particular programs and approaches will be particularly helpful in the face of growing evidence that the effects of quality are considerably less powerful than expected. It is also surprising that such little evidence exists concerning the effects of Head Start, particularly considering the enormous cumulative and annual public costs of the program.

AFTERSCHOOL CARE

The need for nonparental care does not end when children enter the elementary education system at around 6 years of age (enrollment ages vary across cultures and communities), particularly as parental employment rates continue to rise in association with children's ages, and have always been higher for parents with school-age rather than preschool-age children or infants (see "Changing Patterns of Care in the United States and Europe: Parenting and Alloparenting"). In the United States, an estimated 78% of the mothers with school-age children were employed outside the home by 1997, compared with 40% in 1970 and 75% in 1995 (H. Hayghe, personal communication, October 17, 1995; Hofferth & Phillips, 1987; U.S. Bureau of Labor Statistics, 1987, 1998). The typical school day extends for only 6 hours, and in many European countries, some children go home for lunch at the end of or in the middle of the school day. These practices were institutionalized at a time when mothers were expected to be working in and around the home, able to care for their children when they were not in school. Obviously, these conditions no longer exist in most industrialized countries. Instead of returning from (or going to) school from a home supervised by their mother, many children attend formal afterschool programs, are supervised informally by neighbors, relatives, or babysitters, or are left unsupervised. By 1999, 49% of the 6- to 11-year-olds in the United States whose primary caregivers were employed received some kind of regular afterschool care, including care by relatives (25%), before- and afterschool programs (15%), or home-based child care (7%; Sonenstein et al., 2002). Before- and afterschool nonmaternal care arrangements are more common when mothers are single or work longer hours (NICHD Early Child Care Research Network, 2004), and two somewhat unconnected bodies of literature have emerged, one concerned with the

characteristics of children who are unsupervised, and one with the effects of formal afterschool programs. These literatures are reviewed separately here.

Self-Care

According to the 1999 National Survey of America's Families (NSAF), 3.3 million school-age children (15% of the 6- to 12-year-olds in the United States) stay at home, unsupervised by an adult, on a regular basis (Vandivere, Tout, Zaslow, Calkins, & Capizzano, 2003). Closer analysis of the NSAF data shows that self-care becomes more common as children grow older: 7% of 6- to 9-year-olds but 26% of 9- to 12-year-olds and 47% of 14-year-olds were left regularly to care for themselves in 1999 (K. Smith, 2002; Vandivere et al., 2003), and the average amounts of time spent unsupervised also increase as children grow older (Vandivere et al., 2003). Contrary to popular belief, unsupervised children are not more likely to be found in impoverished, minority communities. In fact, Vandivere et al. reported that low-income and less-educated parents were less likely to leave their children unsupervised after school than were parents with higher incomes or higher levels of education. Similarly, Vandell and Ramanan (1991), using data from the NLSY, reported that children were more likely to be supervised after school when family income and social support levels were lower. Self-care is also more common when mothers work full time or parents are divorced/separated (K. Smith & Casper, 1999; Steinberg, 1986; Vandivere et al., 2003). Hispanic children are much less likely than non-Hispanic children to be left unsupervised (Vandivere et al., 2003).

Since the 1970s, great concern has been expressed about the safety and welfare of unsupervised young children (Bronfenbrenner, 1976; Genser & Baden, 1980), whose circumstances fit the legal definition of child neglect in most states. Perhaps because this legal characterization makes parents unwilling to admit the care status of their children, there has been much less research on the psychosocial and behavioral adjustment of young children than on the status of children in middle school, with surprisingly little attention paid to their differing developmental needs. Whereas a case can be made that eighth graders benefit from learning to be responsible and independent during periods of unsupervised self-care, for example, the same argument should not be made with respect to first graders living in urban communities.

Much of the concern about "latchkey" children was prompted by Woods (1972), who studied African American fifth graders in the inner city and found that the latchkey girls scored more poorly on measures of cognitive/academic, social, and personality adjustment than did peers in the care of adults. In particular, unsupervised girls had poorer achievement test scores and poorer relationships with their peers at school. On the basis of open-ended interviews with children in self-care arrangements, furthermore, Long and Long (1983, 1994) concluded that latchkey children were at risk for a wide variety of social, academic, and emotional problems. Richardson et al. (1989) later reported that eighth graders in the Los Angeles and San Diego metropolitan areas were more likely to abuse illicit substances when they spent more time in self-care. Similarly, adolescents who were regularly unsupervised after school were more likely to smoke cigarettes, consume alcohol, and use drugs (Mott, Crowe, Richardson, & Flay, 1999; Mulhall, Stone, & Stone, 1996). Vandell and Posner (1999) reported that third graders who cared for themselves regularly had more behavior problems in both third and fifth grade, whereas self-care by fifth graders was not associated with behavior problems. Pettit, Laird, Bates, and Dodge (1997) reported that sixth graders were less socially competent and performed more poorly in academic contexts when they had spent more time in self-care as first and third graders. These associations remained even after controlling for differences in earlier child adjustment and family social class. As in Vandell and Posner's study, the amount of self-care in fifth grade was not associated with problematic behavior in sixth grade. Colwell, Pettit, Meece, Bates, and Dodge (2001) also reported that self-care beginning in the first grade was associated with behavior problems in the sixth grade. Socioeconomic status affects these associations; children in less-advantaged families are more likely to be characterized by significant correlations between self-care and either behavior problems or poorer academic performance (Marshall et al., 1997; Vandell & Posner, 1999).

By contrast, Galambos and Garbarino (1983) reported no differences in achievement, classroom orientation, adjustment to school, and fearfulness on the part of fifth and seventh graders who were either adult-supervised or cared for themselves after school in a rural community; neither did Rodman, Pratto, and Nelson (1985), who studied fourth and seventh graders matched on age, gender, family composition, and socioeconomic status. There were no differences in locus

of control, behavioral adjustment, and self-esteem. Similarly, Vandell and Corasaniti (1988) reported that White suburban middle-class third graders in self-care after school did not differ from children in the care of their mother on any dimensions. In fact, the latchkey children appeared to function better at school and in the peer group than peers who went to formal afterschool programs. The mother's marital status did not moderate any of these differences or nondifferences.

Vandell and Ramanan (1991) later studied third to fifth graders whose mother was a participant in the NLSY; the children were thus disproportionately likely to be born to adolescent, poor, minority parents, but only 28 of the 390 children were unsupervised after school, which limits the strength of the conclusions that can be drawn from the study. There were no differences between latchkey and mother- or other-care children in the total number of behavior problems, although those who were unsupervised after school were rated as more headstrong and hyperactive than those in other- (but not mother-) care after school. Children in other-care after school had fewer behavior problems and higher PPVT scores than children cared for by their mother after school. All of these differences disappeared following statistical controls for family income and emotional support, however, presumably because mother-care was the arrangement most likely to be chosen by the poorer, less emotionally supported families. Likewise, analyses of nationally representative data gathered in the 1999 NSAF showed no differences in behavior problems in 6- to 12-year-olds depending on whether or not they regularly cared for themselves (Vandivere et al., 2003).

As Steinberg (1986, 1988) pointed out, researchers need to distinguish among several groups of children who are all unsupervised by their parents after school: some stay home alone; some go to a friend's house, where they may be but typically are not supervised by the friend's parent; some "hang out" in the mall or some other public place. These differences may be associated with important differences in the psychosocial status of the children concerned, argued Steinberg, particularly if they lead to differences in exposure to antisocial peer pressure. As predicted, suburban fifth, sixth, eighth, and ninth graders appeared more susceptible to antisocial peer pressure (as indexed by the children's responses to hypothetical vignettes on a measure developed by Berndt, 1979) when they tended to hang out in public places, and those who went to a friend's house were more susceptible than those who stayed home alone (Steinberg, 1986). Children who stayed

home alone did not in fact differ from those who were under adult supervision. Steinberg also reported group differences in the children's reports of their parents, with the parents of boys in self-care being more permissive than those of boys in adult care of some sort, and the permissiveness of girls' parents being correlated with the degree to which they were unsupervised (adult care, self-care at home, at friend's house, hanging out). Parental permissiveness was itself associated with the susceptibility to peer pressure, whereas authoritative parental practices (Baumrind, 1968) were associated with greater resistance to peer pressure.

Comparable results were obtained by Galambos and Maggs (1991) in a longitudinal study of sixth graders living with both of their parents in suburban Canadian communities. Children who were not at home after school were more involved with peers, and unsupervised girls were more likely to have deviant peers, poor self-images, and be at risk of problem behavior, although the risks were reduced by less permissive and more accepting parental behavior. As earlier reported by Steinberg (1986) and Rodman et al. (1985), children who stayed at home unsupervised did not differ from those who were under adult supervision.

Formal Afterschool Programs

Just as self-care may have varied effects depending on the children's characteristics and circumstances, afterschool care likely has diverse effects on children's adjustment, but unfortunately these issues have not been well explored. School-age child care (SACC) programs serving several million children in the United States operate in diverse locations, and the types and quality of care vary widely. In one study of 30 SACC programs, R. Rosenthal and Vandell (1996) reported that children and parents evaluated the programs more positively when they were smaller, staff-child ratios were lower, the staff was more emotionally supportive, the variety of possible activities was greater, and negative staff-child interactions were less common. Pierce, Hamm, and Vandell (1999) similarly found that lower child-adult ratios were associated with more positive staff-child interactions and more time spent in constructive activities. These variations in quality are obviously important: High-quality programs are associated with more positive academic and social outcomes, whereas programs have negative or ambiguous effects when the quality is poorer (Vandell & Pierce, 1999, 2001; Vandell, Shuman, & Posner, 1999).

Focusing on 6-year-olds in a variety of programs, Pierce et al. (1999) found that children, especially boys, in programs characterized by positive interactions with the staff had fewer behavior problems, better academic grades, and better social skills than children in settings characterized by negative staff-child and peer relationships even after controlling for family background characteristics. Subsequent assessment of these children and programs revealed that the majority of programs provided care of mediocre or barely adequate quality (Vandell & Pierce, 2001) and that the higher the quality of afterschool care received by those children through fourth grade, the better their academic performance and the less they reported feeling lonely. In addition, girls, but not boys, had better work habits and social skills when they had attended higher-quality programs. Better peer relations in the SACC programs were associated with less depression.

In an earlier study of third graders in Milwaukee in which single-parent, African American, low-income families were oversampled, Posner and Vandell (1994) sought to describe the components and effects of formal afterschool programs. Formal care was more likely when mothers were better educated and family incomes were lower; Whites were more likely to leave their children unsupervised, and African Americans were more likely to count on informal afterschool care arrangements. After controlling statistically for these factors, Posner and Vandell found that children attending formal afterschool programs received better grades for mathematics, reading, and conduct than did peers in the mother-care and other-care groups. The former also had better work habits and better peer relations than those in the other-care group. These results are perhaps attributable to the fact that, in comparison with the other children, children in the formal settings spent more time in academic and enrichment activities with both adults and peers, but less time watching television or playing with siblings. Unlike Vandell and Ramanan (1991), Posner and Vandell found that children in the other-care group performed more poorly than those in mother-care with respect to reading grades, work habits, and behavior problems, perhaps because these arrangements seemed quite inconsistent and variable from day to day. The more time these children spent in unstructured outdoor activities, the poorer their grades, work habits, and emotional adjustment. When reassessed as fourth and fifth graders, children who were performing better and were better behaved as third graders engaged in

more constructive afterschool activities as fifth graders (Posner & Vandell, 1999). In addition, African American children who engaged in more nonsport activities over the study years were better adjusted in fifth grade. White children had poorer grades and more behavior problems when they spent more time in unstructured activities. Finally, in the multisite NICHD Study of Early Child Care (2004), kindergartners and first graders had higher standardized test scores when they participated in extracurricular activities after school, but all other types of before- or afterschool arrangements were unrelated to measures of the children's functioning after controlling for background factors.

Summary

Overall, the data suggest that the lack of direct supervision in afterschool hours has effects on children that vary depending on their age, what they are doing, and the extent to which they are monitored by their parents. Direct adult supervision appears to remain an important determinant of children's adjustment at least through midadolescence, although researchers have paid inadequate attention to developmental differences and have failed to study the psychosocial adjustment of the youngest children left unsupervised. Self-care is associated with poorer outcomes among 8- to 9-year-olds (American third graders) but is not consistently associated with poor outcomes among older preadolescents. Among adolescents, there are few consistent effects when children are at home alone and are (loosely) monitored by their parents, but those who are not monitored and especially those who hang out with peers unsupervised are most likely to get into trouble, have behavior problems, and perform poorly at school. It is not clear whether the widespread availability of cell or mobile phones may affect the level of supervision or give parents a false sense of security regarding their children's whereabouts and activities.

In light of demographic data suggesting that some kindergartners are left alone regularly, it is noteworthy that the research literature has focused on children in third grade or higher, with most studies concerned with young adolescents. From the fifth grade, children who are regularly at home after school behave and perform similarly whether or not an adult is present, but the distance from adult supervision explains differences in the outcomes of unsupervised children who do not go home after school. Parental disciplinary practices appear to

modulate these differences in predictable ways. Unfortunately, all of these findings are compromised by the absence of longitudinal data and the strong possibility that differences among children (in their preferences to be and do things with their peers, for example) may precede rather than be consequences of the differing types of supervision.

Third and fourth graders seem to do better academically and behaviorally when they are in formal after-school programs, although this may not be true of children from more affluent families. Participation in formal programs by such children appears to promote more constructive uses of time as the children mature, though there has yet to be much research on children older than 10 or 11 years. Interestingly, however, recreational programs for disadvantaged teenagers and teenagers considered at risk for antisocial behavior have tended not to have the expected positive effects on adolescents (McCord, 1990).

CONCLUSION

After nearly 3 decades of intensive research on nonparental child care, considerable progress has been made, although we still have much to learn about the mechanisms by which out-of-home care affects children's development. In large part, our continuing ignorance about developmental processes reflects the extent to which researchers were preoccupied too long with the wrong questions—first asking “Is day care bad for children?” instead of “How does child care affect children's development?”—and later remained focused on the effects of child care and the effects of child care quality instead of recognizing that child care has myriad incarnations and must always be viewed in the context of children's intrinsic characteristics, developmental trajectories, and other experiences. We should not be surprised that children's experiences away from home are formatively significant, although simplistic assessments of these experiences and limited opportunities for truly experimental research have impeded progress. In addition, there is vast (and often poorly specified) variability within and among studies with respect to the actual care arrangements studied, the amount and quality of care received, the age at which it began, the number and type of changes in the patterns of care, and the ways outcomes were assessed. Even when the same outcomes are assessed, variations in the ages of assessment and en-

rollment, means of quantification, and the composition and selection of comparison groups often preclude anything more than tentative conclusions about specific care arrangements.

Clumsy investigative strategies notwithstanding, we can actually answer a few of the simpler questions with some confidence. We now know, for example, that child care experiences *need not* have harmful effects on children's development and on their family relationships, although they *can* do so. Most children's relationships with their parents do not differ systematically depending on whether or not they receive regular nonparental care. Most children in out-of-home facilities remain attached to their parents and still prefer their parents over teachers and care providers. Meaningful relationships are often established with peers and care providers, however, and these can affect children's later social behavior and personality maturity. In addition, exposure to peers may offer some children (e.g., those who are singletons or have shy temperament) opportunities they could not experience at home, thereby launching them on different developmental trajectories.

Early exposure to nonparental care of poorer quality also fosters excessive assertiveness, aggression, and behavior problems in some children for reasons that are not yet well understood. Insecure parent-child attachments do not modulate these effects, as once believed, because nonparental care experiences are not reliably associated with insecure infant-mother attachment, but poor relationships with care providers do appear to mediate the effects of nonparental care on children's aggressiveness. Children in higher-quality facilities who enjoy good relationships with stable providers are not more aggressive than peers who have experienced care only from their parents.

The onset of regular nonparental care for infants and toddlers has complex psychobiological and behavioral effects on their functioning both at home and in child care centers. As a result, maladaptive behavior on the part of children who spend many hours in child care may reflect not the direct effects of nonparental care, but the inability of parents to buffer the enhanced levels of stress occasioned by the time spent in child care. Successful adaptation demands careful equilibration of the contrasting limitations and benefits of the two environments, with parental care characterized by stress reduction and emotional regulation, whereas care providers emphasize cognitive stimulation and behavioral regulation. Home remains the center of children's lives even

when children spend considerable amounts of time in child care, and thus parents who fail to recognize and respond to their children's need for emotion regulation when they are reunited after long hours in stress-inducing child care arrangements are at least partly responsible for the dysregulation that becomes manifest in misbehavior.

Assertions that nonparental care does not consistently or inevitably have either positive or adverse effects on children's development must be further qualified on a number of grounds. Some of the most important stem from the fact that, with few exceptions, quasi-experimental studies have not been possible. Because the children and families studied are not assigned randomly to nonparental and exclusive parental care groups, preexisting group differences—particularly those that led to the enrollment of some but not other children in nonparental care settings in the first place—may continue to explain at least some of the between-group variance discerned. Statistical controls for some of the known group differences and potentially influential factors (such as social class) reduce but do not completely eliminate the problem, limited as they are to imperfect measures of factors that are operationalized as linear and independent sources of influence. Still, it is comforting to note that researchers are continuing to refine their understanding of these factors.

In addition, although researchers have more recently done a much better job of sampling the range of settings experienced by most children, settings providing care of the poorest quality are disproportionately excluded from studies. The most intensive studies still tend to overrepresent middle-class White North Americans in placements of better-than-average quality, whereas the larger multisite studies and surveys include more diverse and ethnically representative groups. For a variety of reasons, the large multisite studies (but not the NICHD study) are least likely to include microanalytic components, however, so sampling limitations are an especially important consideration when behavioral observations are at issue.

Over time, researchers' focus has clearly shifted from between-group to within-group (correlational) strategies. Most researchers embracing such strategies have attempted to assess the predictive importance of the quality of care, and there is a clear consensus that the quality of care, broadly defined and measured, modulates the effects of nonparental child care on child development. Interestingly, improvements in quality appear to

have significant positive effects even at the highest end of the range sampled, suggesting that there is no threshold beyond which quality of care no longer matters. The magnitude of the effect is considerably smaller than expected, however, although the fact that researchers must estimate the importance of quality in the context of complex correlational models that also include a range of other potential influences makes it doubtful that we will ever really know how important quality is in an absolute sense. The recent and widespread focus on the quality of care has also led researchers to neglect many of the other factors that affect children's development. Developmentalists now know that all aspects of behavioral development are multiply and redundantly determined; as a result, the absolute magnitude of each individual influence is likely to be quite small when all important factors are taken into account simultaneously. It would thus be a mistake to conclude, for example, that quality of care is not really important because its coefficients are small; by this logic, almost any factor could be deemed insignificant. A realistic appreciation of how complex developmental processes really are should instead foster a shift from the simplistic search for magic bullets to the patient but tedious evaluation of complex models of development. By the same token, however, researchers have a responsibility not to misrepresent either the costs or the benefits of variations in the quality of care, particularly in the face of political pressures to do so. For similar reasons, it is important to determine why early intervention programs with generally positive effects sometimes affect the most disadvantaged children negatively.

Nonparental care of superior quality is clearly beneficial to children and preferable to care of poor quality; parents and regulators need to evaluate the relative costs and benefits of incremental improvements in quality, however. Researchers, meanwhile, need to shift their attention to more detailed considerations of quality so as to define, more clearly than has been possible with the current generation of measures, what characteristics of care providers and out-of-home care settings have the greatest impact on specific aspects of development. Nonparental care needs to be designed to serve the needs of children and, in particular, to recognize that children of different ages and backgrounds have different needs and experience stress for different reasons. Thus, the global indices of quality that have served a first generation of researchers and regulators so well must now yield center stage to a generation of more refined measures and concepts that allow practitioners to

determine whether and how specific practices have unique effects on children's learning and development.

Type of care may also have varying effects depending on the age at which children enter nonparental care settings, with the planned curricula of child care centers become increasingly advantageous as children get older. It also appears likely that different children will be affected differently by various child care experiences, although we remain ignorant about most of the factors that modulate these differential effects. Child temperament, parental attitudes and values, preenrollment differences in sociability, curiosity, and cognitive functioning, gender, and birth order may all be influential, but reliable evidence is scanty.

In all, we have learned a great deal about the effects of out-of-home care and, in so doing, we have learned that these effects are a good deal more complex than was once thought. The challenge for the next decade is to determine how different experiences inside and outside the home are associated with specific outcomes for children in defined contexts and cultures.

| REFERENCES | 1022 |

Do research findings in child development influence relevant practice and is practice influential in planning research? I contend that at least for child development or child psychology the answer is often “no,” although this situation has changed dramatically in recent years. Research as the term is used in child psychology refers to results gathered in scientifically based studies. Practice is the use of research findings in service settings. Despite change, research findings are likely to be underused in practical settings like school classrooms, child guidance clinics, or policy settings. In fact, there is an oft-held view that research studies are not “user friendly” from the perspective of the classroom teacher, the clinician, or the policymaker. The underuse of research in practice stems from diversity in researchers’ and practitioners’ conceptual frameworks, problems that are addressed, and worldviews, or Root Metaphors (Pepper, 1942).

The field of human development embraces a variety of conceptual frameworks. In the last few decades, this diversity has included those who are trained and conduct research as Piagetians, neo-Piagetians, Vygotskians, Wernerians, Freudians, and Behaviorists. There are also, of course, the mini-theorists, who espouse their own philosophies or “schools,” who have devel-

oped groups of followers. Some have even labeled themselves as specialists in particular areas of development, such as cognitive science, neural development, behavior modification, and social cognition with a social psychological twist. There are also investigators who are problem-centered in their focus (e.g., the children’s concept of mind, language development, or development of self), who build on a range of theoretical perspectives. Disagreements arise within these groups because of differences of interpretation. The theoretical perspective and/or problem-centered focus of research that is undertaken provides the basis of a group or an organization that shares a common language—a language with its own working definitions of concepts. Similar types of variations can be observed in practice settings, also. Some practitioners apply theory to practice, and others make up their own theories of practice.

Not only is there diversity in the assumptions and theoretical and/or conceptual foci of study, but researchers and practitioners also diverge in their professional functions. Child psychology researchers have tended to perceive of themselves as engaged in basic theory-driven research in contrast to applied researchers who work with more concrete concerns. The basic researcher, as scientist, is trained to seek scientific generalization with experimental research, and may have little interest in developing technologies or practical suggestions (Polanyi, 1958).

On the other hand, there is a growing interest in blending science with application. There are researchers who

Thanks to K. Ann Renninger for helpful and constructive suggestions that have helped make this chapter more focused and to the point. Thanks also to Vanessa Gorman and Marsha Satterthwaite for editorial suggestions.

as science practitioners apply their research to what they see as relevant and appropriate real life situations. Other researchers conduct research in real-life contexts, adjusting or weighting variables in order to make comparisons and assess change. Yet, another group of researchers are practitioners who use research to inform their work with children in child guidance clinics, hospitals, schools, and juvenile courts. These researchers are clinicians who share responsibility for helping children (and often their families) cope with the worlds in which they live. These researchers can also be consumers who use the products of research when they become accessible and are appropriate for the work in which they are engaged.

Thus, although the researchers of child development undertake work based on the “research literature,” there is no reason to believe that all studies work within the same view of what is a science of child psychology, and this has an impact on the way in which research impacts practice. Debates on this issue abound, not only as to the definition, but also as to the appropriateness of the model of science currently in use. This was clearly reflected in articles by Bevan and Kessel (1994):

psychology’s methods and methodology must be far less rigid and our discipline’s view of what is scientifically acceptable must be far more pragmatic than has been the case for many decades. (Bevan & Kessel, 1994, p. 507)

They argued that psychology needs to be sensitive to human experience. Their position contrasted with that of Kimble (1994) who wrote:

If psychology is to be a science, it must play by the scientific rules, of which the most important is that it must be about observables. It must be a science of stimuli and responses, because the only public facts available are the things that organisms do (responses) and the situations in which they do them (stimuli). (p. 510)

The difference between these two views of science is profound. They suggest that the field is fractured and that the information available to the practitioner who is not trained in the field needs to be considered. How does research look to the practitioner? What does the practitioner need?

HOW DOES RESEARCH LOOK TO THE PRACTITIONER?

The field of child psychology with its diversity of interests and theoretical orientations has created a mixed and blurry image for itself. A substantial amount of scientific

laboratory research has been conducted and developmental methods are increasingly being used to approach problems in practice—a recognition that developmental approaches have much to offer in terms of mitigating social and individual dysfunction and much to contribute to the health and well-being of society. Whether child psychology is a basic or an applied science is no longer a useful question. Research is increasingly focused on real-life problems. A more important issue has become whether the application of scientific methods to real-life problems can serve practice and realistically be science.

Does the scientific study of complex social problems preclude careful science? Does the use of rigid scientific procedures narrow the problems for study and lead to the study of trivial questions? An effort to delineate some of the sources of the problem, including a discussion of the expected impact of scientific research findings on social change and social transformations is likely to increase understanding of the utility and application of research to practice. In spite of the claims made by psychologists as to their actual and potential contributions to the social welfare (Wiggins, 1994), there are those who are dismayed by psychology’s failure to address important human questions (e.g., Bevan & Kessel, 1994). There are also child developmental psychologists who argued that setting up a special field of applied developmental psychology might result in an eschewing of basic research (Morrison, Lord, & Keating, 1984).

The effort to apply science to practice is complicated. It is influenced by issues of time, context, and agenda. It is also influenced by how research is understood: its purposes and practices, and its complexities. Criticisms of researchers by practitioners are based in part on promises made and promises unfulfilled. The promise that research can be of social value needs to be tempered by its consumer’s awareness that there is an inevitable time lag between the time a project has begun and its acceptance and use in the field. The medical research on poliomyelitis and diphtheria are good examples from the past. Research on AIDS, cancer, and many other diseases reveals the same time lag—the time between the onset of research and its completion is highly unpredictable. A further complication is that there are so many factors in the life of a child that are reasonable sources of influence that it is difficult to evaluate the role and influence of each. While, disseminating current knowledge base can be slow and difficult, it is also the case that service providers and policymakers have their own agendas. These agendas have to be recognized, understood, and reconciled by both parties.

The researcher may view practitioners as being concrete, atheoretical, and pragmatic. The practitioner may view the researcher as engaged in using rigid and meaningless approaches to study trivial questions, driven by sometimes esoteric and unworldly theory. Research reports can be couched in probability terms that are useless for the day-to-day work of some practitioners. Practitioners sometimes accuse scientists of engaging with a fanatic and uncritical devotion to science. Therefore, why should a busy practitioner waste time reading such meaningless material? Not to be outdone by this type of criticism, the researcher is often disdainful of the practitioner's lack of understanding of science and the significance of data, even if it has been derived from careful methodology.

Interestingly, because of diversity of conceptual frameworks and roles, there is no definitive center that gives the field of child psychology a coherent view of childhood.

Images [of childhood] are basic assumptions or conceptions about children and the factors that influence their ontogeny. Images thus include beliefs regarding the existence of innate tendencies or dispositions, the susceptibility to external influences, the limits of human modifiability, the special importance of early experience, and the role of the individual. (Hwang, Lamb, & Sigel, 1996, p. 3)

The diversity of how childhood is described is a complication for researchers and practitioners alike—there is a sense in which both researchers and practitioners have a shared agenda to understand childhood, but the difference of lens affects the usefulness of the research. In a review of two major journals, for example, different images of childhood were found to stem from different perceptions of variables important to study (Sigel & Kim, 1996). We compared the topics studied, the methods used, and the samples described over 5 years. Of importance for this discussion is the finding that there were only rarely suggestions about “how” to use information from this research in the articles.

ON THE PROXIMAL AND DISTAL RELEVANCE OF RESEARCH, OR WHAT THE PRACTITIONER NEEDS

Child psychology includes a wide-range of problems of study; it contains many voices and languages. It draws on different methods, and yet each has its claims to science. I suggest that we reconsider Pepper's *Root*

Metaphor (1942), as a frame for understanding these differences. According to Pepper, the root metaphor a person selects (consciously or not) is his or her worldview.

In terms of researchers and practitioners, and the application of research to practice, the degree to which parties share the same, or approximately the same, root metaphor, the greater their mutual understanding and consequent communication. For example, if the researcher and the practitioner have a contextual perspective, they should communicate more effectively than when one views the world from a mechanistic root metaphor and the other a contextualist. It does not matter with which root metaphor a person works. If the researcher and the practitioner do not share the same metaphor, their communication will be compromised. For example, beliefs may not change despite evidence to the contrary (Sigel & McGillicuddy-De Lisi, 2002). Recognizing difference is of particular value in reaching consensus. Dialogue is enriched when there is an acknowledged awareness of operating belief systems that are derivatives of the root metaphors. A person's root metaphor can only be influenced by what he or she knows and understands.

Findings from research can only be used if the practitioner understands how to use them in the course of practice. I call this the *proximity index*, defined as the distance between the readiness for findings to be used and the understanding of the meaning and the comprehensibility of the research report. For example, if a teacher reads about the virtues of an inquiry discovery approach, but has always taught with a didactic approach, he or she needs to assess the implications of shifting pedagogical approaches without mastering procedures. If the approach is not mastered, or, as in the case of a research approach, the underlying assumptions are not understood, then any research results are likely to be compatible with the objectives of education, but incompatible with the goals of the instructor. If on the other hand, there is compatibility between the research and the atmosphere in the class, the new findings may aid the teacher in elaborating the approaches in the classroom. In terms of a proximity index, this could be labeled a Level 1 application. Each subsequent score on this type of hypothetical index requires additional judgments. At Level 2, the practitioners judge the findings of the study to be closer in terms of specific techniques used, but they may be uncertain about the level of their comparability. This requires that the practitioner assumes the role of evaluator or interpreter of the

research. As one approaches Level 5 in this continuum, the research may increasingly feel removed from classroom practice. The idea of weighting degrees of comparability involves consideration of how similar the children in the study were to those in his or her classroom, whether what was accomplished is a goal for his or her classroom, and whether the demonstrated effect seems applicable. In effect, the practitioner needs to reflect on a number of extrapolations, before deciding to apply it to his or her own practice (Morgan, Gliner, & Harmon, 2003).

Moreover, applicability does not need to be action-based. The practitioner can use the research to rethink the way he or she does his or her work, and to reflect about other areas to explore. For example, if one focused on the effects of culture, then there is reason to expect that the instructor will change his or her understanding of some of the events in his her classroom or clinic. By definition, even if different terms are used, this focus also includes consideration of reliability and validity. The question is no longer one of basic or applied science. Rather, the question becomes one of the practical use of any scientifically acquired knowledge: what function research serves, what the products of such efforts are, and how and when research can be used.

Several years ago, I participated in an intervention program in a middle-class elementary school system. The program was derived from Piagetian theory. One of the stipulations in their type of curriculum required the teachers to ask questions, to engage in dialogue, and to get the children to interact with each other, and with the teacher. The study was undertaken to observe teachers' question-asking techniques and follow-through, how they engaged the group, and whether or not they allowed the children to discover and share ideas. Observers went into the classroom with permission of the teacher, set up a rigorous observation schedule, and observed teachers' verbalizations every six seconds during a 30-minute extended play period. The results showed that the teachers asked many questions, but the questions were didactic and directive, such as: What is the name of this? What is the color of that? There was very little, if any, follow through. Instead, considerable attention was paid to the precise way in which the children spoke their answers. After the program was evaluated it was found that the children were no different in responsiveness and verbalization from children enrolled in traditional programs in that same school system, and that the teachers' questions never created a dialogue or a discussion. When these re-

sults were reported to the school committee, there was an immediate objection to the fact that the observers were new, unknown to the teachers, segmented in their approach, and so on. Rather than discussing the implications of the findings, the committee rejected them out of hand because they were not what were expected.

Resolution of this conflict took intense discussion and explanation. The committee eventually accepted the observation of the researcher as valid once audiotapes of the classroom were shared. It was not the quality of science that resolved the issue but the development of interpersonal trust and willingness of everyone to re-examine the research process. Clarifying the goals for the research together with the opportunity to think about these goals with data led the school committee and the leaders to alter their intervention efforts over time.

In order to enhance the proximity of research for the practitioner, a number of issues need to be addressed: (a) Who poses the research question? (b) How are data collected and analyzed? (c) How are data disseminated? The conflicts between general findings and any specifications for application and the practical problems that are involved in integrating research findings into practice need to be explored.

Who Poses the Research Questions and How Is Research Conducted?

The posing of the research question is one of the most difficult intellectual challenges. The structuring of the research question is part of the scientist's way of working. Each participant in any collaborative effort will frame the question of interest from his or her own frame of reference. The scientist will put it into the genre of science with the precision necessary for subsequently setting up a study whereas a practitioner may phrase the question within an action based practical framework that is consistent with his or her setting. The process of identifying *the* research question is difficult and will require considerable discussion.

The typical situation is one in which the researcher and the practitioner come from different settings, however, the researcher and the practitioner can be the same person (e.g., Blechman, 1990, where the therapist is also the researcher) and/or of the same root metaphor.

In the situation where the practitioner wishes to study a particular question (e.g., evaluation of a curriculum or a mode of psychotherapy) and to do so requires a working relationship with a researcher, their partner-

ship requires equal status so that the study meets the interests of both parties. As Scholnick (2002) points out, partnerships can support change, and yield products that differ qualitatively from what any one person can accomplish independently. The effectiveness of the partnership will depend on how the relationship is structured, the personalities of the principals, clarification of theoretical views, and shared goals.

Most so-called partnerships are not truly equal when one researcher takes charge because of his or her expertise. I hope that this asymmetry is accepted and justified, but it is also the case that researchers may treat the practitioners insensitively and arrogantly. This type of interaction is most frequent when the practitioner is coerced by the administration, job situation, and so on to participate in an experimental research project. For research to inform practice, it needs to be undertaken on the basis of an authentic question.

How Are Data Collected and Analyzed?

Studies usually focus on a limited number of variables. They can be limited by the size of the population and also the research question. Thus, the probability is great that practitioners may think that constricted experimental environments decontextualize children. From this perspective, the child essentially becomes a partitioned object of study as defined by the variables of interest to the investigator. For example, most studies that investigate children's conservation of quantity or number rarely ask whether these children were studying these subjects in school. Is it not possible that the child's academic experience confounds the findings? The child in the experiment is treated as a participant unrelated to any other source of influence, and randomization of children is considered to address potential sources of error. In fact, phenomena are studied by partitioning not only the child, but also the problem. It is as though studies of cognition or motivation are insulated from other psychological systems. Yet, it is the case that the whole child is the person responding to whatever is being asked of him or her. This is a particular concern for the practitioner, especially as he or she thinks about applying research to practice.

Moreover, data obtained are often aggregated so that group variability is reported, not how particular individuals vary. Yet, the practitioner needs to know how a particular child might function given the use of those particular findings, or how a particular strategy will af-

fect a particular child. If this is the case, what are the limits as to how the teacher, therapist, or clinician can work with this child in a particular setting? The researcher is testing hypotheses to seek support for a theory and can as a result generalize about how a particular phenomena functions. The practitioner, on the other hand, is typically more interested in individual differences in a particular classroom, with a particular child or group of children, at a particular point in time.

The researcher works from a nomothetic model, eschewing idiographic or impassive analyses. The reason for this is probably due to his or her interest in generalizability. Unfortunately, the distal quality of the nomothetic model limits its contribution to practice. From a practitioner's perspective, idiographic reports are more meaningful because they present an integrated view of the person, more akin to profile analyses or case histories. Coupled with ideographic methods, nomothetic approaches assume power to inform both theory and practice.

How Are Data Disseminated?

Research results are usually presented in quantitative terms; the assumption is that the number tells an objective story whose meaning every reader shares. However, the fact is that the numbers are derived from the investigator's perspective. He or she chooses the methods by which to collect the data and the means of quantification. Since every quantitative method has its limits and biases, the reported numbers are subject to interpretation. The decision as to how to evaluate the numbers goes back to the initial organization and classification of the data, in addition to the data themselves.

How and when research information is disseminated depends on the target audience and the person who is disseminating the information. The audiences targeted to receive reports of research are typically the scientific community (including students in training to become researchers and practitioners), practitioners, and the lay public. Usually this task involves different discourses. More to the point are the traditional, and hence conventional, methods of reporting research.

Typically, research findings are written and published in books and journals that are primarily accessible to the researcher. Its accessibility is only limited by its comprehensibility and that depends on the familiarization with the particular discourse of the author. For scientists, the discourse is familiar. For the practitioners, especially

those unfamiliar with the scientific jargon and style of writing, the research findings and their interpretation are elusive and hence neither accessible nor useful. While the researchers should be intimately acquainted with the setting to which they claim their research applies, so too the practitioner should assume some responsibility for becoming informed about how to read and interpret this material in order to form a rational basis for evaluating the quality and the appropriateness of what he or she finds. Research reviews, if carefully structured to clarify concepts and ground examples in practice may be useful to practitioners; the lay public may need still another form of communication.

On a more informal level, disseminating research findings can be done in the course of researchers consulting with service providers. How this is done will depend on the relationship of the researcher to the service partners. Often practitioners would like information that they can use immediately. However, carrying out any research project takes time. The gap between discovery and implementation is not only due to the length of time required to do the research, but also to the commitment of scientists and practitioners to their own construction of knowledge: what counts as a research question, what is expected as findings, and how well the research process, including its limits and possibilities, is understood and explained.

CONCLUSIONS

The field of child psychology is in ferment. In the past, we accepted this since we believed the field to be a young science—it just needed to grow and mature. Scientific knowledge was, we believed, cumulative and linear in its development. After 100 years, we can no longer claim youth. Fermentation reflects effervescence, a bubbling change that alters the character of substance. To carry on the analogy, the process is not linear and, in addition, it is in the current vernacular “chaotic,” becoming transformed into a new whole. In a sense, those of us in child psychology are sharing the same crisis that our idealized physics colleagues are facing—the new scientific revolution, *the science of chaos* (Gleick, 1987). Does that not sound like an oxymoron? We have been encouraged to think in terms of stability, equilibrium, and homeostasis. Our science is grounded in the precepts of prediction. To predict means to be able to control, to define, to be precise,

and to identify the ingredients of the whole. Yet, in order to work in and with practice requires moving away from linear models and comfort with complexity and change.

What kinds of mechanisms can be devised so that empirical research can be brought to the fore to provide answers to questions dealing with *how* and *why* children develop as they do? What are the mechanisms that aid in keeping the trajectory of development optimal? What contributions can be made to prevent dysfunctional development? What are the requirements to optimal development? Should not developmental research offer useful and meaningful explanations for the course of development and where needed provide approaches for the prevention and amelioration of conditions that may hinder the optimization of the developmental trajectory?

Efforts to apply research to practice require acknowledging the inherent tensions of trying to validate theory and research in practical settings. They require stretching and/or adapting the root metaphors in which we have been trained so that collaborations between researchers and practitioners are the basis of research and of any application of research to practice.

background, 831–832
degree of persuasion achieved, 833
exchanges between parents and offspring, 833, 834
National Science Foundation (NSF) and FTC, 834–836
parent-child supermarket aisle interaction over breakfast cereal, 835
recognition and understanding of commercials, 833
reforms and subsequent research, 836–838
research topics, 832–834
responses to advertising by cognitive stage, 837
allocation of time and attention, 818–824
developmental changes, 821
preferences, 820
television viewing, school or work, and sleep, by age, 819
time, 818–819
content/themes of televisual media, 821–823
applications, 823–824
children's programming, 822
educational programming, 822
entertainment, 821–822
sexual intimacy, 823
violence, 822–823
emerging issues, 847–854
impact/consequences, 852–854
creativity, 826–827
displacement, 830–831
fantasy play and daydreaming, 825–826
favorable outcomes, 825
interference, 830
mental ability, 826
mixed outcomes, 825–827

- path model diagram, 829
- school performance, 824–831
- selective media use, 829
- specific hypotheses, 825–827
- tastes and preferences, 831
- television's contribution, 830–831
- viewing and achievement, 827–831
- visual skills, 825
- vocabulary, 825
- new delivery systems, 850–852
- overview/introduction, 817–818, 854–855
- ratings and codes, 847–850
- statistics:
 - media availability in homes of young people, 851
 - media exposure by gender and age, 852
- use of television and other film-related media, 818–821
 - gratifications, three major, 820–821
 - typology of users, 823–824
 - what's special, 819–820
- violent entertainment, 822–823, 838–847
 - aggregating the evidence, 841–844
 - cultivation theory, 844–845
 - desensitization, 844
 - effect sizes for early factors, 840
 - fear hypothesis, 844
 - other violence-related hypotheses, 844–845
 - surgeon general's inquiry, 838–841, 845–847
 - timeline, 839
 - V-chip, 845–847
- Memory:
 - autobiographic; developmental differences, and mechanisms of suggestibility, 802–810
 - children's memory for traumatic events, 802–810
 - scaffolding strategy, 34
- Mental retardation, 453–490
 - behavioral phenotypes, 457–463
 - Down Syndrome, 458–459
 - Prader-Willi Syndrome, 459–460
 - Williams Syndrome, 460–461
 - behavior analysis, 487–488
 - case examples:
 - Down Syndrome, 458–459
 - Prader-Willi Syndrome, 459–460
 - Williams Syndrome, 461
 - changing ecology of mental retardation, 468–469
 - child factors, 472–473
 - classification approaches:
 - degree-of-impairment, 456–457
 - etiologial, 457
 - two-group/cause, 457
 - concepts and issues, 461–463
 - contextualist views of development, 466–477
 - developmental implications, 463–466
 - developmental psychopathology perspectives/approaches, 488–489
 - diagnosis, 455–456
 - families and:
 - parental reactions, 467–468
 - parent and family factors, 473–474
 - parent and family reactions, 472–474
 - parent-child interactions, 469–471
 - parent-family support groups, 488
 - perceptions, 471–472
 - history of field, 468
 - interventions, 483–488
 - examples, 485–488
 - generic and specialized issues, 484
 - for maladaptive behavior-psychopathology, 486–488
 - reading instruction for children with Down syndrome, 485–486
 - noncategorical philosophies, 484
 - overview/introduction, 453–455, 488–490
 - professions associated with different syndromes, 485
 - research issues, 477–483
 - schools, neighborhoods, and larger ecologies, 474–475

 - contextual integration, 605
 - intervention development/expansion, 604–605
 - leadership team/administrator training, 604
 - ongoing consultation/support, 603–604
 - program evaluation, 604–605
 - training-to-begin stage, 603
 - developmental arenas in program implementation, 597–609
 - developmental snapshots, 610–616
 - emotionally disturbed students, 608
 - integration, 609–610, 614–616
 - intelligence skills, 594
 - levels of use and concern, 598
 - overview/introduction, 592–595, 598, 616
 - personal experience (one consultant's developmental journey), 606
 - program implementation, 597–601
 - factors impacting initiation into the implementation process, 600–601
 - factors impacting movement toward regular use, 601
 - factors important during institutionalization, 601
 - resistant clinical constituents, 612–614
 - school-based interventions, complex, longitudinal nature of, 595–597
 - schools/child, 605–609
 - early elementary, 605–607
 - middle elementary, 607
 - middle school and beyond, 607–608
 - special populations, 608–609
 - social-emotional learning intervention, 601–602
 - structure of social decision making approach, 611
- Social interactions, scaffolding strategy, 34
- Socialization-interaction, 467
- Social network, and parenting, 908–909
- Social organization, learning environments and, 302, 304–305, 316
- Social sciences learning environments, 301
- Social/sociomathematical norms, 133–137
- Socioeconomic status (SES):
 - category of economic deprivation, 703–704
 - child maltreatment and, 511
 - parenting and, 909–910
 - reading and, 52, 55
- Song of Fear, 642
- Spatial thinking, 197–243
 - conceptualizing, 199–204
 - definitions, 200
 - diversity of development and, 205–209
 - culture, 207
 - explaining differences, 208–209
 - gender, 207–208
 - group differences, 207–209
 - individual differences, 205–207
 - geography and, 213–222
 - across the life span, 202–204
 - maps, 215–238
 - components of map understanding and map education, 223
 - definitions and principles, 216–220
 - developmental pathway to understanding, 223–232
 - duality principle, 216–217
 - education, illustrative materials and activities for, 233–238
 - embedded model of understanding external spatial representation, 224
 - functions, 220–221
 - map-space-self relation, 224
 - north, teaching, 235–236
 - overview/introduction, 197–199, 238–243
 - purpose principle, 219–220
 - qualities of the map user, 232–233
 - representational understanding, 225–227
 - spatialization principle, 217–219
 - spatial understanding, 227–232
 - as tools within/beyond geography, 216
 - viewing angle, 228–229
 - viewing azimuth, 229–232
 - viewing distance, 227–228
 - performance differences as deficits; case for intervention, 209–213
 - pervasiveness of, 199–200
 - questions/conclusions, 238–243
 - applied developmental psychologists, 239–241
 - educators, 241–242
 - evolving questions in evolving environments, 242–243
 - scholars of the development of spatial cognition, 239
 - universality of development and, 204–205
- Special education, learning disabilities and, 424–425
- Speech and language pathology, perspective on learning disabilities, 427
- Stanford Achievement Test, 405–406
- Strange Situation, 517, 663–664
- Stress-inoculation programs, 626

1072 Subject Index

- TCI model, 610, 614–615
Teachers, learning environment features, 129–130, 302, 316, 322–325
Technology:
 learning environments and, 131–132, 302, 316–317, 320–322, 330
 war trauma intervention and, 647
Television viewing. *See* Media and popular culture
Temporary Assistance for Needy Families (TANF), 742
Terror attacks, 621–622, 633–634
Texas Primary Reading Inventory (TPRI), 52, 63
The Children's Institute (TCI), 610
Theories, development of, 167–173. *See also* Scientific thinking and learning
Theory of mind (TOM), 511–512
ThinkerTools, 300
Three mountains task, 202
Tools of the Mind, 6–7, 10, 17, 29–38
 adversity experiences, 32
 assessment perspectives on, 34–35
 background, 30
 Buddy Reading, 33
 case example, 29–38
 coherence and integrity, 36–37
 contributions to secure relationships, 33
 expectations for evidence and accountability, 37
 Freeze Game, 32–33
 implementation challenges, 35–38
 play and play planning, 30–32
 professional development, 36
 quality issues in early care and education, 36
 research gaps, 37–38
 scaling, 35
Traits, character and, 251–253
Transmission model of teaching/learning, 261
Trauma. *See* War trauma
Traumatic events, children's memory for, 802–810
Traumatic grief or bereavement, 624
Triple word form theory (learning disabilities), 427

UCLA Trauma Psychiatry Program, 644
UDSSI triad model, 114
University-based Behavior Genetics Clinic, UCLA, 486–487
UWLDC treatment research, 433, 435

Vanderbilt Kennedy Center Behavioral Analysis Clinic, 487
VCUG paradigm (voiding cystourethrogram), 803–804
Violent entertainment, 822–823, 838–847
 aggregating the evidence, 841–844
 cultivation theory, 844–845
 desensitization, 844
 effect sizes for early factors, 840
 fear hypothesis, 844
 other violence-related hypotheses, 844–845
 surgeon general's inquiry, 838–841, 845–847
 timeline, 839
 V-chip, 845–847
Virginia Phonological Awareness Literacy Screening (PALS), 52, 63
Virtues, character and, 253–255
 bag of virtues and foundations, 255–257
 character and virtue ethics, 257–258
Voices of Love and Freedom (VLF), 397

War trauma, 619–648
 community as context of healing, 627–640
 helping the helpers, 638–640
 mental health professional roles, 629
 open questions, 645–648
 organizational measures based on a generic frame of reference:
 case of evacuation from an attacked zone, 631–633
 overview/introduction, 619–620, 645–648
 resilience and coping, 626–627, 636–640
 silence/denial about previous traumatic experiences, 624–625
therapy/intervention(s):
 art activities, 635
 board games, 634–635
 community-based, 631–636
 continuity principle, 641
 drug treatment, 642
 expressive activity, 634–636
 fear-focused intervention, 640
 generic principles, 629
 indicated individual and small-group symptom-focused interventions for PTSD, 640–645
 in vitro flooding, 642–644
 nature-assisted projects/support programs, 636
 play, 634, 635, 641
 prewar generic anticipatory interventions, 630–631
 psychosocial group programs, 644
 puppets, 634
 school as focal point for generic intervention, 638
 school-based intervention following a terrorist attack incident, 633–634
 self-guided, self-control exposure therapy, 643
 self-hypnosis for relaxation, 642
 solution-focused orientation, 639
 Song of Fear, panicking room, 642
 stress-inoculation programs, 626
threats, and impact on children, 620–627
 basic infrastructures, 621
 chemical, biological, or radiological weapons, 621–622
 deployment of loved ones, 624
 mass terror attacks, 621
 parents' posttraumatic stress, 624
 separation from family, 624
 war-related coping mechanisms, interference with postwar adjustment, 625
 war-related psychological responses, and intervention challenges, 622–626
Web-Based Integrated Science Environment (WISE), 300, 305, 306, 310–312, 321
Wechsler Individual Achievement Test (WIAT-II), 440
Wechsler Intelligence Scale for Children (WISC-III), 435
Welfare and employment transitions, welfare reform policy, and the well-being of poor children, 741–759
 experimental tests of welfare/employment policies (two synthesis projects), 742–752
 adolescent children, 747–749
 age of child as moderator of effects across and within studies, 749
 differential patterns of involvement, 749–750
 estimating causal influence of income, 751–752
 mediating effects/processes, 745–746, 748–749
 moderators of effects, 746–747
 pattern of effects, 744–745, 748
 preschoolers and elementary school-age children, 743–747
 nonexperimental studies of mothers' transitions off welfare and increased work involvement in relation to child well-being, 751–759
 changes in family material resources, 754–755
 child care, 759
 child outcomes, 755–757

- effects on child functioning of mothers' transitions
 - after 1996 welfare reform legislation (PRWORA), 753–759
- effects on child functioning of receiving and transitioning off Aid to Families with Dependent Children, 752–753
- job quality and the working poor, 757–758
- macroeconomic trends, 753–754
- work intensity, 758–759
- Where Are We? (WAW?)* curriculum, 236–238
- Williams Syndrome. *See* Mental retardation
- Wisconsin Fast Plants, 182
- Woodcock-Johnson (WJ-III), 440
- Word problem solving, 116–120
- World Health Organization's Global Burden of Disease (GBD) study, 526
